$$\frac{\Delta E_3}{I_3} = \frac{\Delta E_6}{I_6} = \left[R_K + \sqrt{3}\omega 10^{-9}\,\mathrm{logh}\left(\frac{S_{3,1}\,S_{6,1}}{S_{2,1}\,S_{5,1}}\right)\right] + j\omega 10^{-9}\left(0\cdot 5 + 2\,\mathrm{logh}\,\frac{(S_{2,1}\,S_{3,1}\,S_{5,1}\,S_{6,1})^{\frac{1}{4}}}{bS_{4,1}}\right) \quad . \quad (14h)$$

The remaining thirty impedance equations may be written down in a similar way.

(iii) *Characteristics of different current permutations* (*without transposition*).

It is usual to transpose long and important power lines primarily to reduce inductive interference with communication circuits. On double circuit lines this involves the use of special and expensive transposition towers, and if transposition could be avoided, say, on short lines where also the power and communication circuits are widely separated, a considerable saving would result. It is desirable, therefore, to examine the impedance equation for a non-transposed double circuit line from the standpoint of the power supply engineer, the most important aspects of the problem being:—

(1) The obtaining of equal phase impedances in the two circuits. (This ensures that when operated in parallel the load is equally divided between them.)

(2) Reduction in phase impedance so as to decrease the impedance voltage-drop in the line.

Considering item (1), investigation shows that out of all the twelve possible arrangements (see Figs. 3 (*a*) to 3 (*l*)) here are only two, viz. Figs. 3 (*d*) and 3 (*g*), in which the six impedance equations are not all different. For these two arrangements the impedances of conductors carrying currents of the same time phase (those in the same horizontal plane) in the two circuits are equal, and thus either of these methods may be adopted for parallel operation. It may be noted that in all arrangements without transposition there is transformer action between conductors differing in time phase, and Figs. 3 (*d*) and 3 (*g*) are no exceptions.

Respecting power transference between conductors *of the same circuit* (which it is desirable to keep as low as possible from a practical standpoint), there is nothing to choose between Fig. 3 (*d*) and Fig. 3 (*g*), because the three terms in the apparent resistances due to this effect have the same numerical values in both cases and differ only in sign.

Consider now the question of power transference between the two circuits, each considered as a unit. The power transferred to or from circuit A by circuit B

= I^2 [Sum of three apparent phase resistances per cm — Sum of three a.c. resistances per cm of isolated phase conductor] watts/cm

where I = R.M.S. phase current (in amperes).

In the case of Figs. 3 (*d*) or 3 (*g*), this is equal to

$$\left[\sqrt{3}\omega 10^{-9} I^2\,\mathrm{logh}\left(\frac{S_{3,1}\,S_{4,1}\,S_{1,2}\,S_{6,2}\,S_{2,3}\,S_{5,3}}{S_{2,1}\,S_{5,1}\,S_{3,2}\,S_{4,2}\,S_{1,3}\,S_{6,3}}\right)\right] \text{watt/cm} \quad . \; . \; . \; . \; . \; . \; . \quad (14j)$$

$$= \text{zero.}$$

Thus for these arrangements there is no transference of power between the two circuits.

Respecting item (2) above, investigation shows that the effect of mutal inductance of the second circuit may increase or decrease the apparent phase reactance compared with that of a single circuit at similar spacings, and we have therefore to deduce what phase sequence of currents gives the lowest reactances.

In all the twelve possible impedance equations applying to any one conductor position, there are only *three* different reactance values, i.e. there are only *nine* different reactance values in all the thirty-six impedance equations. This is evident if we consider the rule given below equation (14*a*) for writing down the apparent reactance of any conductor. The denominator of the logarithmic term in the apparent reactance involves the dimension from the conductor position considered to the other of the same time phase, which is necessarily in the opposite circuit in one of three possible positions. Thus for any given conductor position in circuit A there are only three possible dimensions to conductors in circuit B, and, therefore only three possible reactance values, which, by using the rule already given, can be written down directly. As an example, we give the values for conductor Position 1 in Figs. 3 (*a*) to 3 (*l*) as follows:—

$$\text{Figs. 3 }(a),\ 3\ (d),\ 3\ (g)\text{ and }3\ (j) = j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{2,1}\,S_{3,1}\,S_{4,1}\,S_{5,1})^{\frac{1}{2}}}{bS_{6,1}}\right)\ \text{ohm/cm.}$$

$$\text{Figs. 3 }(b),\ 3\ (e),\ 3\ (h)\text{ and }3\ (k) = j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{2,1}\,S_{3,1}\,S_{4,1}\,S_{6,1})^{\frac{1}{2}}}{bS_{5,1}}\right)\ \text{ohm/cm}$$

$$\text{Figs. 3 }(c),\ 3\ (f),\ 3\ (i)\text{ and }3\ (l) = j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{2,1}\,S_{3,1}\,S_{5,1}\,S_{6,1})^{\frac{1}{2}}}{bS_{4,1}}\right)\ \text{ohm/cm}$$

We next observe that while the numerator of the logarithmic term involves the square root of any dimension, the denominator involves the dimension itself, so it is probable that the lowest reactance value will occur when the biggest of the three possible dimensions (i.e. $S_{1,4}$ for conductor Position 1) appears in the denominator, and this is actually the case. By applying the same method to conductor Positions 2 and 3, we find that the lowest reactances occur when the top conductor of either circuit carries current of the same time phase as the bottom of the other, i.e. as in Figs. 3 (*c*) or 3 (*l*),* which are, therefore, the most favourable arrangements from this standpoint.

It may be noted that for the above figures there is a transference of power between the circuits given by

$$\left[\sqrt{3}\omega 10^{-9}I^2\ \text{logh}\left(\frac{S_{3,1}\,S_{6,1}\,S_{1,2}\,S_{4,2}\,S_{2,3}\,S_{5,3}}{S_{2,1}\,S_{5,1}\,S_{3,2}\,S_{6,2}\,S_{1,3}\,S_{4,3}}\right)\right]\ \text{watts/cm} = \left[\sqrt{3}\omega 10^{-9}I^2\ \text{logh}\left(\frac{S_{6,1}\,S_{4,2}\,S_{5,3}}{S_{5,1}\,S_{6,2}\,S_{4,3}}\right)\right]\ \text{watts/cm} \quad (14k)$$

(iv) *Effects of transposition.*

(*a*) *Circuits transposed at same frequency.*—Regular transposition equalizes the impedances of all three phases of each circuit over an integral multiple of three transpositions, provided the two circuits are transposed in such directions as to maintain the same relative positions of conductors carrying currents of the same time phase.

As in the untransposed case, for ten of the twelve possible current permutations the impedances of one half are the same as for the other half, with the values for the two circuits interchanged in any instance. The corresponding arrangements of current sequence for the transposed case are the same as already given for the untransposed case, and give ten different impedance equations. For the remaining two cases the four impedances are all equal, as we shall see later, so that the total number of impedance equations is eleven.

Calculation of impedance of Circuits B, Fig. 3 (*c*) *and A, Fig.* 3 (*l*).

Taking as a typical case the arrangement of Fig. 3 (*c*) over an integral multiple of three transpositions, the impedance per unit length of any phase of the right-hand circuit will be equal to one-third of the sum of the separate impedances of conductor positions 4, 5 and 6; that is,

$$= \left[\left\{R_K + \sqrt{3}\omega 10^{-9}\ \text{logh}\left(\frac{S_{5,1}\,S_{6,2}\,S_{4\,3}}{S_{5,3}\,S_{6,1}\,S_{4,2}}\right)^{\frac{1}{3}}\right\} + j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{1,2}\,S_{1,3}\,S_{2,3})^{\frac{1}{3}}}{b}\,\frac{(S_{5,1}\,S_{6,1}\,S_{4,2}\,S_{6,2}\,S_{4,3}\,S_{5,3})^{\frac{1}{3}}}{(S_{4,1}\,S_{5,2}\,S_{6,3})^{\frac{1}{3}}}\right)\right]\ \text{ohm/cm to neutral} \quad . \quad (15a)$$

Similarly,

Impedance of Circuits A, Fig. 3 (*c*) *and B, Fig.* 3 (*l*).

$$= \left[\left\{R_K + \sqrt{3}\omega 10^{-9}\ \text{logh}\left(\frac{S_{2,4}\,S_{3,5}\,S_{1,6}}{S_{3,4}\,S_{1,5}\,S_{2,6}}\right)^{\frac{1}{3}}\right\} + j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{1,2}\,S_{1,3}\,S_{2,3})^{\frac{1}{3}}}{b}\,\frac{(S_{5,1}\,S_{6,1}\,S_{4,2}\,S_{6,2}\,S_{4,3}\,S_{5,3})^{\frac{1}{3}}}{(S_{4,1}\,S_{5,2}\,S_{6,3})^{\frac{1}{3}}}\right)\right]\ \text{ohm/cm to neutral} \quad . \quad (15b)$$

In view of the practical importance of transposed circuits, it is useful for reference to enumerate all the remaining possible impedance equations as follows:—

Circuits A, Fig. 3 (*a*) *and B, Fig.* 3 (*j*).

$$\text{Impedance} = \left[\left\{R_K + \sqrt{3}\omega 10^{-9}\ \text{logh}\left(\frac{S_{5,1}\,S_{6,2}\,S_{4,3}}{S_{4,1}\,S_{5,2}\,S_{6,3}}\right)^{\frac{1}{3}}\right\} + j\omega 10^{-9}\left(0\cdot 5 + 2\ \text{logh}\,\frac{(S_{1,2}\,S_{1,3}\,S_{2,3})^{\frac{1}{3}}}{b} \times \frac{(S_{4,1}\,S_{5,1}\,S_{5,2}\,S_{6,2}\,S_{4,3}\,S_{6,3})^{\frac{1}{3}}}{(S_{6,1}\,S_{5,3}\,S_{4,2})^{\frac{1}{3}}}\right)\right]\ \text{ohm/cm to neutral} \quad . \quad (15c)$$

---

* The six reactance values of Fig. 3 (*c*) are the same as those of Fig. 3 (*l*), and the terms in the apparent resistances due to power transference are numerically equal but of opposite sign for corresponding conductor positions.

Circuits B, Fig. 3 (*a*) *and A, Fig.* 3 (*j*).

Same as equation (15*c*) except that sign of second term in apparent resistance is reversed.

Circuits A, Fig. 3 (*b*) *and B, Fig.* 3 (*k*).

$$\text{Impedance} = \left[\left\{R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh}\left(\frac{S_{4,1}\,S_{5,2}\,S_{6,3}}{S_{6,1}\,S_{4,2}\,S_{5,3}}\right)^{\frac{1}{3}}\right\} + j\omega 10^{-9}\left(0\cdot 5 + 2\operatorname{logh}\frac{(S_{1,2}\,S_{2,3}\,S_{1,3})^{\frac{1}{3}}}{b} \times \frac{(S_{4,1}\,S_{6,1}\,S_{4,2}\,S_{5,2}\,S_{5,3}\,S_{6,3})^{\frac{1}{6}}}{(S_{5,1}\,S_{6,2}\,S_{4,3})^{\frac{1}{3}}}\right)\right] \text{ ohm/cm to neutral} \quad . \quad (15d)$$

Circuits B, Fig. 3 (*b*) *and A, Fig.* 3 (*k*).

Same as equation (15*d*) except that sign of second term in apparent resistance is reversed.

Circuits A and B for both Figs. 3 (*d*) *and* 3 (*g*).

$$\text{Impedance} = \left[R_K + j\omega 10^{-9}\left\{0\cdot 5 + 2\operatorname{logh}\frac{(S_{1,2}\,S_{1,3}\,S_{2,3})^{\frac{1}{3}}}{b}\left(\frac{S_{4,1}\,S_{5,1}\,S_{4,2}}{S_{6,1}\,S_{5,2}\,S_{4,3}}\right)^{\frac{1}{3}}\right\}\right] \text{ ohm/cm to neutral} \quad . \quad (15e)$$

Circuits A, Fig. 3 (*e*) *and B, Fig.* 3 (*f*).

$$\text{Impedance} = \left[\left\{R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh}\left(\frac{S_{6,1}\,S_{5,2}\,S_{4,3}}{S_{4,1}\,S_{6,2}\,S_{5,3}}\right)^{\frac{1}{3}}\right\} + j\omega 10^{-9}\left\{0\cdot 5 + 2\operatorname{logh}\frac{(S_{1,2}\,S_{2,3}\,S_{1,3})^{\frac{1}{3}}}{b}\left(\frac{S_{6,1}\,S_{5,2}\,S_{4,3}}{S_{6,3}\,S_{5,1}\,S_{4,2}}\right)^{\frac{1}{3}}\right\}\right] \text{ ohm/cm to neutral} \quad . \quad (15f)$$

Circuits B, Fig. 3 (*e*) *and A, Fig.* 3 (*f*).

Apparent resistance same as equation (15*f*) with sign of second term reversed.

$$\text{Apparent reactance} = j\omega 10^{-9}\left[0\cdot 5 + 2\operatorname{logh}\frac{(S_{1,2}\,S_{2,3}\,S_{1,3})^{\frac{1}{3}}}{b}\left(\frac{S_{6,1}\,S_{5,2}\,S_{4,3}}{S_{4,1}\,S_{6,2}\,S_{5,3}}\right)^{\frac{1}{3}}\right] \text{ ohm/cm to neutral} \quad . \quad (15g)$$

Circuits A, Fig. 3 (*h*) *and B, Fig.* 3 (*i*).

Apparent resistance same as equation (15*g*). and apparent reactance same as equation (15*f*).

Circuits B, Fig. 3 (*h*) *and A, Fig.* 3 (*i*).

Apparent resistance as in equation (15*f*), and apparent reactance as in equation (15*g*).

There are thus eleven possible impedance equations, the total number of different reactances and resistances involved in all the equations being six and nine respectively for all arrangements of both circuits. From the standpoint of impedance (when transposed), we may classify Figs. 3 (*a*) to 3 (*l*) into three groups:—

Group 1, comprising Figs. 3 (*a*), 3 (*b*), 3 (*c*), 3 (*j*), 3 (*k*), 3 (*l*).
Group 2, comprising Figs. 3 (*d*), 3 (*g*).
Group 3, comprising Figs. 3 (*e*), 3 (*h*), 3 (*f*), 3 (*i*).

Group 1.

The characteristics of this group are that the apparent reactances of both circuits (in any figure) are the same, while the terms in their apparent resistances due to power transference are numerically equal but of opposite sign.

This group includes Figs. 3 (*c*) and 3 (*l*), which have the lowest reactances of any of the arrangements (less than that of a single circuit at similar spacings). In all cases there is a power transference between the two circuits, but it is least for Figs. 3 (*c*) and 3 (*l*).

Group 2.

In this group there is no power transference between the circuits, i.e. the apparent resistances are equal to the a.c. resistance of an isolated conductor. The reactances of both circuits are equal (and for the "grid" lines about 2 per cent higher than that of a single circuit at similar spacings).

Group 3.

In this group the apparent reactances of the two circuits are different, while the terms in their apparent resistances due to power transference are numerically equal and of opposite sign. There is a power transference between the circuits.*

From a practical aspect the amount of power transferred between the circuits is negligible, the greatest value on the "grid" lines being only 2·5 kW per mile (for Figs. 3 (*e*) and 3 (*j*)), and the smallest values (except for Figs. 3 (*d*) and 3 (*g*), in which no power is transferred) 0·28 kW per mile (for Figs. 3 (*c*) and 3 (*l*)). Thus the most useful practical arrangements are the same as those for non-transposed circuits, viz. Figs. 3 (*c*) and 3 (*l*), which have the lowest impedance, and Figs. 3 (*d*) and 3 (*g*), in which the circuits have equal impedances.

(*b*) *Circuits transposed at different frequencies.*—There is only one case of practical importance, namely, when the second circuit is transposed at one-third the frequency of the first. Under such conditions it is obvious † from symmetry that over an integral multiple of three transpositions of the circuit B all mutual inductance effects balance out, and the resistance and reactance of all six phases are the same as for a single circuit (see equation (10*a*)) at similar spacing and with the same phase sequence (provided the two circuits are symmetrical about the centre line of the pole).

In practice it will not always be possible to arrange that the distance between the sending and receiving ends of the line is an integral multiple of three transpositions of the circuit having the lesser frequency of transposition (i.e. circuit B). Under such conditions the unbalanced portion of the line may be reduced to a length not exceeding two transpositions of circuit A by transposing the two circuits at the same frequency over the odd portion of the line. The unbalance then remaining would be negligible in practice.

(E) MODIFICATIONS ON LONG LINES.

In the foregoing theory the impedance voltage-drop along a conductor has been taken as numerically equal to the absolute value of the current multiplied by the absolute value of the impedance. Actually the impedance voltage-drop is the absolute value of the vector difference between the sending- and receiving-end voltages. On short lines up to, say, fifty miles, the above assumption leads to an error of a few per cent, but on long lines the effects of the charging current must be taken into account.

For long lines electrically balanced either by regular transposition or equilateral triangular spacing of the conductors, the method of obtaining the impedance-drop is given in text-books on the subject, and need not be repeated here. The solution is as follows:—

Let E_s = sending-end voltage to neutral (volts).
E_r = receiving-end voltage to neutral (volts).
I_r = receiving-end current to neutral (amperes).
$Z = R_{KM} + jx$ = vector impedance per unit length of line (ohm/mile).
$Y = g + jc$ = vector admittance per unit length of line (mho/mile).

Then the impedance voltage-drop over a length l_1 miles,

$$E_s - E_r = E_r(\cosh\sqrt{(YZ)}l_1 - 1) + I_r\sqrt{\frac{Z}{Y}}\sinh\sqrt{(YZ)}l_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (18)$$

---

* The power transferred to circuit A from circuit B in a typical case such as Fig. 3 (*e*):—

$$= \left[\sqrt{3}\omega 10^{-9}\, 2\,\text{logh}\left(\frac{S_{6,1}S_{5,2}S_{4,3}}{S_{4,1}S_{6,2}S_{5,3}}\right)\right]I^2 \text{ watt/cm} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (16)$$

where I = absolute value of current in amps.

† This may be proved if desired as follows: Taking the arrangement in Fig. 3 (*l*), let the frequency of transposition of circuit A be three times that of B. Then keeping the right-hand circuit as in the diagram, let the left-hand circuit be transposed a complete turn of the lay. Over this length the impedance of any phase of circuit A will be given by

$$\frac{\Delta E_1}{I_1} = \left[R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\left(\frac{S_{5,1}S_{5,2}S_{5,3}}{S_{6,1}S_{6,2}S_{6,3}}\right)^{\frac{1}{3}} + j\omega 10^{-9}\left\{0\cdot 5 + 2\,\text{logh}\frac{(S_{2,1}S_{3,1}S_{2,3})^{\frac{1}{3}}}{b}\frac{(S_{5,1}S_{5,2}S_{5,3}S_{6,1}S_{6,2}S_{6,3})^{\frac{1}{3}}}{(S_{4,1}S_{4,2}S_{4,3})^{\frac{1}{3}}}\right\}\right] \text{ ohm/cm to neutral} \qquad (17a)$$

Over this length the left-hand circuit is transposed three times.

Now let the right-hand circuit be transposed one-third of a turn and maintained fixed while the left-hand circuit is transposed three times. Over this length the impedance is equal to

$$\frac{\Delta E_1}{I_1} = \left[R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\left(\frac{S_{6,1}S_{6,2}S_{6,3}}{S_{4,1}S_{4,2}S_{4,3}}\right)^{\frac{1}{3}} + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\frac{(S_{2,1}S_{3,1}S_{2,3})^{\frac{1}{3}}}{b}\frac{(S_{4,1}S_{4,2}S_{4,3}S_{6,1}S_{6,2}S_{6,3})^{\frac{1}{3}}}{(S_{5,1}S_{5,2}S_{5,3})^{\frac{1}{3}}}\right)\right] \text{ ohm/cm to neutral} \qquad (17b)$$

Repeat the last-named operation, and over this length we have

$$\frac{\Delta E_1}{I_1} = \left[R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\left(\frac{S_{4,1}S_{4,2}S_{4,3}}{S_{5,1}S_{5,2}S_{5,3}}\right)^{\frac{1}{3}} + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\frac{(S_{2,1}S_{3,1}S_{2,3})^{\frac{1}{3}}}{b}\frac{(S_{4,1}S_{4,2}S_{4,3}S_{5,1}S_{5,2}S_{5,3})^{\frac{1}{3}}}{(S_{6,1}S_{6,2}S_{6,3})^{\frac{1}{3}}}\right)\right] \text{ ohm/cm to neutral} \qquad (17c)$$

The impedance per length over an integral multiple of nine transpositions of the left-hand circuit is obtained by taking ⅓ of the sum of (17*a*), (17*b*) and (17*c*). This gives

$$\frac{\Delta E_1}{I_1} = \left[R_K + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\frac{(S_{2,1}S_{3,1}S_{2,3})^{\frac{1}{3}}}{b}\right)\right] \text{ ohm/cm to neutral} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (17d)$$

which is the same (cf. equation (10*a*)) as that of a single circuit. Similar remarks apply to circuit B, since if the mutual effect of B on A is nil, the reverse is also true.

This gives $E_s - E_r$ as a complex quantity, the absolute value of which is the numerical impedance voltage-drop. The impedance Z to be used in equation (18) is the value calculated by the methods given in sections (*c*) and (*d*) of this Appendix. For long lines not transposed (i.e. not electrically balanced) the impedance and admittance per unit length vary all along the line. Although it is theoretically possible to obtain a solution for this case, the result when obtained would be of great complexity and has no practical application, as all long lines must be transposed to avoid interference with other circuits. For this reason no attempt has been made to calculate this case.

(F) POWER LOSSES.

(i) *Introduction.*

On a short line the power losses are equal to the product of the square of the absolute value of the current and the line resistance. This method assumes that the capacity current may be neglected and also that leakage and corona losses are negligible. On a long line, the capacity current cannot be neglected, as it causes the absolute value of the current, upon which the heating depends, to vary all along the line. It is usual in such cases to evaluate the power losses as the difference between the sending- and receiving-end powers. If the leakage and corona loss are negligible or can be separately evaluated, this is an exact method, but it has the disadvantage that the losses are evaluated as the difference between two much greater quantities, so that the accuracy is not very great. For this reason we have deduced an expression for the power losses by integrating the I^2R losses all along the line, by which the losses may be directly evaluated. The method applies only when the line is electrically balanced either by regular transposition or equilateral spacing. This is the only case of practical interest.

(ii) *Losses on a long line.*

Take the voltage at the receiving-end E_r as the reference vector. Let the receiving-end current $I_r = (\mathfrak{J}_1 - j\mathfrak{J}_2)$. Then it is shown in text-books that at a distance l_1 miles from receiving end, the vector current

$$I_{l_1} = (\mathfrak{J}_1 - j\mathfrak{J}_2)\cosh\sqrt{(YZ)}l_1 + E_r\sqrt{\frac{Y}{Z}}\sinh\sqrt{(YZ)}l_1 \quad . \; . \; . \; . \; . \; . \; . \; . \qquad (19a)$$

Put

$$\sqrt{(YZ)} = \alpha + j\beta \quad \text{and} \quad \sqrt{\frac{Y}{Z}} = \gamma + j\delta$$

Thus

$$\begin{aligned} I_{l_1} &= (\mathfrak{J}_1 - j\mathfrak{J}_2)(\cosh \alpha l_1 \cos \beta l_1 + j \sinh \alpha l_1 \sin \beta l_1) + E_r(\gamma + j\delta)(\sinh \alpha l_1 \cos \beta l_1 + j \cosh \alpha l_1 \sin \beta l_1 \\ &= \Big[\mathfrak{J}_1 \cosh \alpha l_1 \cos \beta l_1 + \mathfrak{J}_2 \sinh \alpha l_1 \sin \beta l_1 + E_r(\gamma \sinh \alpha l_1 \cos \beta l_1 - \delta \cosh \alpha l_1 \sin \beta l_1) \\ &\qquad + j\big\{\mathfrak{J}_1 \sinh \alpha l_1 \sin \beta l_1 - \mathfrak{J}_2 \cosh \alpha l_1 \cos \beta l_1 + E_r(\delta \sinh \alpha l_1 \cos \beta l_1 + \gamma \cosh \alpha l_1 \sin \beta l_1)\big\}\Big] \quad . \; . \qquad (19b) \end{aligned}$$

The absolute (numerical) value of the current at a distance l_1 from the receiving end is given by the absolute value of equation (19*b*). This is as follows:—

$$\begin{aligned} |I_{l_1}|^2 &= (\mathfrak{J}_1^2 + \mathfrak{J}_2^2)(\cosh^2 \alpha l_1 \cos^2 \beta l_1 + \sinh^2 \alpha l_1 \sin^2 \beta l_1 + E_r^2(\gamma^2 + \delta^2)(\sinh^2 \alpha l_1 \cos^2 \beta l_1 + \cosh^2 \alpha l_1 \sin^2 \beta l_1) \\ &\quad + 2\mathfrak{J}_1 E_r(\gamma \sinh \alpha l_1 \cosh \alpha l_1 - \delta \sin \beta l_1 \cos \beta l_1) - 2\mathfrak{J}_2 E_r(\gamma \sin \beta l_1 \cos \beta l_1 + \delta \sinh \alpha l_1 \cosh \alpha l_1) \qquad (20) \end{aligned}$$

The power loss on a small length dl_1 of the line over which the current is sensibly constant

$$= |I_{l_1}|^2 R_K dl_1$$

and the total loss over a length l_1

$$= \int_0^{l_1} |I|^2 R_K dl_1$$

By integrating the right-hand side of equation (20) between the limits "0" and "l_1" we obtain

$$\begin{aligned} \int_0^{l_1} |I|^2 R_K dl_1 = \frac{R_K}{2}\Bigg[&(\mathfrak{J}_1^2 + \mathfrak{J}_2^2)\left(\frac{\sinh 2\alpha l_1}{2\alpha} + \frac{\sin 2\beta l_1}{2\beta}\right) + E_r^2(\gamma^2 + \delta^2)\left(\frac{\sinh 2\alpha l_1}{2\alpha} - \frac{\sin 2\beta l_1}{2\beta}\right) \\ &+ 2\mathfrak{J}_1 E_r\left\{\frac{\gamma}{2\alpha}(\cosh 2\alpha l_1 - 1) + \frac{\delta}{2\beta}(\cos 2\beta l_1 - 1)\right\} \\ &- 2\mathfrak{J}_2 E_r\left\{\frac{\delta}{2\alpha}(\cosh 2\alpha l_1 - 1) - \frac{\gamma}{2\beta}(\cos 2\beta l_1 - 1)\right\}\Bigg] \quad . \; . \; . \; . \; . \; . \; . \; . \qquad (21) \end{aligned}$$

This is the required expression for the power losses in a line of length "l_1," and it will be noted that the losses depend on the power factor at the receiving end. At unity power factor $\mathfrak{J}_2 = 0$ and the last term disappears. In its present form the expression applies when the power factor is lagging, because it was assumed in the beginning that $I_r = \mathfrak{J}_1 - j\mathfrak{J}_2$. For a leading power factor the sign of $\mathfrak{J}_2$ must be reversed and the last term made positive, thus increasing the losses.*

(G) EFFECTS DUE TO STRANDING.

It is well known that the self-inductance of a stranded conductor (of non-magnetic material) is less than that of a solid conductor having the same cross-sectional area, owing to the greater diameter. The amount of this reduction varies with the number of strands, and decreases as the number of strands increases, since when the number of strands is indefinitely large the inductance is the same as for a single conductor of the same total cross-section. The self-inductance of a stranded conductor is, however, less than for a single conductor of diameter equal to the maximum diameter of the stranded conductor. It is usual to work with this maximum diameter rather than with the diameter of the conductor of equivalent area. Accordingly, when the effect of stranding is taken into account in a single formula, the term due to internal self-inductance increases with number of strands in order to take into account the fact that the maximum diameter approaches the diameter of the equivalent conductor as the number of strands is increased. The problem has been solved by Dwight, who has shown that in the formula

$$L = \left(0 \cdot 5 + 2 \operatorname{logh} \frac{l}{b}\right) 10^{-9} \text{ henry/cm}$$

(b = overall radius, l = distance of return circuit), the effect of stranding may be taken into account by replacing the first term (0·5) by the following:—

For Single conductor, constant term = 0·5
61-strand ,, ,, = 0·517
37-strand ,, ,, = 0·528
19-strand ,, ,, = 0·555
7-strand ,, ,, = 0·642
3-strand ,, ,, = 0·777

When the spacing between the conductors is small (of the order of two or three feet), taking account of stranding alters the reactance by an amount in the region of one or two per cent, and this refinement may be justifiable. At the large spacings (12 to 25 feet and upwards) used on high-voltage lines, however, the alteration is less than 1 per cent (becoming decreasingly important as the spacing increases) and the effect may be neglected, bearing in mind the practical variations in the conductor spacings, the unknown effect of the steel towers, etc. For these reasons, no account is taken of stranding in the working formulæ given (Appendix IV).

For cables of non-magnetic material, the effect of spiralling of strands in giving an axial magnetic field may be neglected.

(H) CONDUCTORS WITH STEEL CORES.†

Effect on inductance.

The spiralling of the strands of a conductor tends to increase the self-inductance by producing a solenoid effect. In non-magnetic conductors this effect is quite negligible. In aluminium conductors with steel cores there arises a second effect due to the core, which operates in the reverse direction to the solenoid effects. The current carried by the steel core is smaller than would be carried if the conductor were homogeneous, thus reducing the linkages. When there is only one layer of aluminium over the steel core, the solenoid effect is found to preponderate, and the net result is an increase of inductance over that of a non-magnetic conductor of similar stranding and overall diameter, the amount of increase at 3-feet spacing varying up to about 17 per cent with the current carried, being greater at higher current densities.

With two or more layers of aluminium round the core, the solenoid effect more or less cancels out, since the spiralling is in opposite directions for alternate layers. In this instance, the effect of the low-current density in the core becomes apparent, and the net result is a slight decrease in the inductance of the order of 5 per cent at 3-feet spacing compared with that of a non-magnetic conductor of the same stranding and overall diameter. This inductance is, moreover, constant, and independent of the current flowing.

For long-distance transmission the conductors used will almost invariably have two or more layers of aluminium over the steel, and under such conditions it is sufficiently accurate to take the inductance of a steel-cored conductor as being equal to that of a homogeneous non-magnetic conductor of the same stranding and overall diameter. The error introduced thereby is unimportant at practical spacings of conductors, but for single-layer conductors, however, this method is too inaccurate.

---

* When two or more power circuits are in close proximity, equation (21) is only strictly true when the conditions are such that the effect of mutual inductance between them is balanced out. As already mentioned, this is not always the case when both circuits are transposed at the same frequency, but depends on the phase sequence of the conductor currents. For the "grid" lines the effect is, however, very small and may be neglected. It is to be noted that the above limitation applies also when the power losses are estimated from the difference between the sending- and receiving-end powers, as it is inherent in the ordinary hyperbolic theory of long lines upon which the method usually employed and the authors' method (see equation (21)) are both based.

† This information is based on the experiments of Prof. W. Work, of Pittsburg, on standard sizes of American conductors. See Bib. Ref. No. 1, Chapter II and Tables.

Effect on resistance.[*]

The addition of a steel core reduces the resistance of a conductor, as the core carries part of the current. The reduction is, however, only about 1 or 2 per cent. A much more important effect is that due to the spiralling of the aluminium wires, which produces an axial field along the conductor, giving rise to hysteresis and eddy-current losses in the steel. These losses vary both with frequency and current density, and depend also on the number of layers of aluminium over the steel. When only one layer of aluminium wire is used, the losses are greatest; with two layers spiralled in opposite directions the net effect is negligible, as the axial field is substantially eliminated. With three layers, the losses lie between those for a single layer and those for a double layer, due to the unbalanced effect of the outer layer.

For a conductor with a single layer of aluminium the increase in a.c. resistance with increasing current density may be as much as 25 per cent at practical current densities, while for a three-layer conductor the maximum increase is about 20 per cent.

APPENDIX III.—THE IMPEDANCE OF A LINE WITH EARTH RETURN.

(A) INTRODUCTION.

In Appendix II the problem of the impedance of three-phase overhead systems was dealt with. It has been assumed throughout this report that in normal operation the phase currents are balanced, i.e. the vector sum is zero, as will be the case in the systems with which the authors are particularly concerned. Under exceptional circumstances the currents may become unbalanced, and in the present Appendix it is proposed to deal with the most important case of this kind, namely, when there is a short-circuit to earth on one phase.

The solution of this problem involves a knowledge of the effective resistance and inductance of an earth return. This problem has been considered by many investigators, and a number of different solutions are available which, however, usually give similar numerical results for earth impedance. Since a consideration of each of these in detail would be too lengthy, the authors have decided to give one in detail, that due to Rüdenberg,[†] which they have themselves tested experimentally and found to be reasonably accurate. The methods in the others will be briefly indicated and a table of formulæ will be given.

(B) IMPEDANCE OF A SIMPLE LINE AND EARTH RETURN.

According to Rüdenberg, it is assumed that the line conductor can be taken as located along the axis of a semi-cylindrical trench of which the radius is the height of the conductor above earth. It is also assumed that the current flow is uniformly parallel to the line, that is, the crowding of lines of current flow due to finite earth plates is neglected.

Let ρ = distance of any point from the line, measured normal to the axis.
B = magnetic induction, the lines of which are presumed to be circles with the line as axis.
E = electric force assumed parallel to the line.
t = time co-ordinate.
i = current density at any point in the earth in absolute units.

Then, if the law of electromagnetic induction

$$\int B dl = 4\pi \int_S i dS$$

is applied to a toroid bonded by the cylinders ρ and $\rho + d\rho$, we have the standard equation

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}(\rho B) = 2\pi i \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22a)$$

But from the law of electric induction

$$\int E dl = \frac{\partial}{\partial t}\int_S B dS$$

If this is applied to a circuit formed by two filaments parallel to the axis and distant ρ and $\rho + d\rho$ from it we have

$$\frac{\partial E}{\partial \rho} = \frac{\partial B}{\partial t} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (22b)$$

But if u = specific resistance of the earth in absolute units

$$E = ui$$

whence

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial i}{\partial\rho}\right) = \frac{2\pi}{u}\frac{\partial i}{\partial t} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

---

[*] Skin-effect is negligible for commercial conductor sizes and frequencies.

[†] Bib. Ref. No. 24.

It is now assumed that the current density i is sinusoidal with the same frequency as the current in the line so that (23) becomes

$$\frac{1}{\rho}\frac{d}{d\rho}\left(\rho\frac{di}{d\rho}\right) = \frac{2\pi j\omega i}{u} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (24)$$

This is Bessel's equation, and since i must be zero when ρ is very large, i is proportional to a Bessel's function of second kind and zero order. Again, the integral of the current from $\rho = h$ to $\rho = \infty$ is equal to the current in the line (I), since the latter entirely returns by the earth. Thus

$$i = \frac{\sqrt{jK}H_0(\sqrt{jK}\rho)Ie^{j\omega t}}{\pi h H_1(\sqrt{jK}h)} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (25)$$

where H_0 and H_1 are Hankel functions of the zero and first orders, that is, Kelvin's functions $ker_0 + jkei_0$ and $ker_1 + jkei_1$, and

$$K = 2\pi\sqrt{f/u},$$
$$Ie^{j\omega t} = \text{total current, and}$$
$$f = \text{frequency.}$$

For $\rho = h$ immediately under the line,

$$\begin{aligned} E &= ui \\ &= \frac{u\sqrt{jK}H_0(\sqrt{jK}h)Ie^{j\omega t}}{\pi h H_1(\sqrt{jK}h)} \\ &= \omega Ie^{j\omega t}\left[\frac{\pi}{2} + j2\,\mathrm{logh}\left(\frac{2}{\gamma Kh}\right)\right] \end{aligned} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (26)$$

since Kh is generally very small. γ = Bessel's constant = 1·781 . . .

The potential drop in the earth is El, where l is the length of the line. Thus the effective resistance R and inductance L of the earth in absolute units for a length of line l are given by

$$\left.\begin{aligned} R &= \frac{\pi\omega l}{2} = \pi^2 fl \\ L &= 2l\,\mathrm{logh}\left(\frac{2}{\gamma Kh}\right) \end{aligned}\right\} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (27)$$

In actual practice the crowding of the lines of current flow at the earth plates must be taken into account by an added resistance and inductance R' and L'.

The self-inductance of the aerial lines of force of the line is given by

$$l(A_1 + 2\,\mathrm{logh}\,h/b) \text{ absolute units} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (28)$$

where A_1 is a constant depending on the stranding of the line conductor, b is the outside radius of the conductor in cm. The effect of the field of the wire in the earth is shown by Rüdenberg to die away rapidly at fairly short distances from the line.

Thus the total inductance of line and earth return is

$$L' + l\left(A_1 + 2\,\mathrm{logh}\,\frac{2}{\gamma Kb}\right) \text{ C.G.S. units} \quad . \; . \; . \; . \; . \; . \; . \; . \; (29)$$

and the total resistance

$$R' + \pi^2 fl + R_{Ka}l \text{ C.G.S. units} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; (30)$$

all the quantities being measured in electromagnetic C.G.S. units, and where R_{Ka} = resistance of the conductor per unit length in absolute units.

Rüdenberg's formulæ were recommended by the Comité Consultatif International des Communications Téléphoniques à Grande Distance,* but recently Pollaczek's formulæ have been preferred. Other formulæ, however, have been given, the most important of which are discussed below.

Breisig † uses the method of the energy of the magnetic field in order to deduce self-inductance and mutual inductance coefficients of an earth return. He considers the conductor as surrounded on all sides by the earth, but the conductor is taken as of finite length. The inductance so calculated should be too low on account of the overestimate of the attenuation of the aerial field by the assumption of earth on all sides.

Pollaczek ‡ makes somewhat the same assumptions as Rüdenberg, but takes the earth as a semi-infinite solid and the wire parallel to the surface and applies boundary conditions. He assumes that the electric force and current flow are parallel to the wire and uniform, and that the height of the line is small compared with other quantities. He obtains a Bessel's differential equation, as Rüdenberg, but develops some of the formulæ by means of series and integrals.

* Bib. Ref. No. 29.

† *Ibid.*, No. 22.

‡ *Ibid.*, No. 27.

Mayr * deals only with mutual inductance of earth currents, not self-inductance. He assumes that the earth is a conducting stratum 300–500 metres in thickness, with a perfect dielectric of unit permeability and specific inductive capacity above and below.

Carson † obtains a solution by means of periodic functions and Fourier integrals. With Rüdenberg and Pollaczek he assumes that the electric force is parallel to the line conductor and that the earth is a semi-infinite solid with finite conductivity. He determines the unknown functions by means of the condition that at the surface of the earth both the magnetic fields due to the line and due to the earth currents are continuous. His treatment differs from Pollaczek's only in the form of functions used.

When the impedance of an earth return is considered there is little difference between the formulæ of Rüdenberg, Pollaczek and Carson in practice. When the current distribution at wider separations is required, as in inductive interference, the formulæ of Pollaczek and Carson seem superior. It is hoped to treat this latter aspect in a future report.

A simple, practical method for estimating the effect of earth currents is to assume that the earth return current is located in an equivalent conductor below the surface of the earth. With a perfectly conducting earth this depth would be equal to the height of the line, but owing to the high resistivity it is actually much lower. For 50 cycles per second a depth of 500 or 600 metres has been suggested for earth of average resistivity. The depth of the image conductor decreases with increase of frequency and increase of earth conductivity.

Formulæ for impedance of line and earth return.

The resistance of the conductor and earth plates and the effect of stranding are neglected in the formulæ given below, proposed by the following authorities:—

RÜDENBERG—

Inductance (henrys/cm).

$$\left[1 + 2\,\text{logh}\left(\frac{2}{\gamma K b}\right)\right]10^{-9}$$

Resistance (ohms/cm).

$$\pi^2 f 10^{-9}$$

POLLACZEK—

Inductance (henrys/cm).

$$\left[1 + 2\,\text{logh}\left(\frac{2}{\gamma K_1 b}\right) + \frac{4\sqrt{2K_1 h}}{3}\right]10^{-9} \text{ if } K_1 h < 1$$

$$\left[2\,\text{logh}\left(\frac{2h}{b}\right) + \frac{\sqrt{2}}{K_1 h} - \frac{1}{2\sqrt{2K_1^3 h^3}}\right]10^{-9} \text{ if } K_1 h > 1{\cdot}25$$

Resistance (ohms/cm).

$$10^{-9}\omega\left[\pi/2 - \frac{4\sqrt{2K_1 h}}{3} + 4K_1^2 h^2(5/4 - \text{logh}\,\gamma K_1 h)\right] \text{ if } K_1 h < 1/4$$

$$10^{-9}\omega\sqrt{2}\left[\frac{1}{K_1 h} - \frac{1}{\sqrt{2K_1^2 h^2}} + \frac{1}{4K_1^3 h^3}\right] \text{ if } K_1 h > 1{\cdot}25$$

BREISIG—

Inductance (henrys/cm).

$$2\left[\text{logh}\left(\frac{\pi}{Kb}\right) - 1\right]10^{-9}$$

Resistance (ohms/cm).

$$\pi^2 f 10^{-9}$$

CARSON—

The total impedance of the earth return is given by

$$Z_0 + 4\omega(P + jQ)10^{-9} \text{ ohms/cm}$$

where Z_0 = impedance with perfectly conducting earth, i.e. with image conductor for earth return.

---

* Bib. Ref. No. 23.

† *Ibid.*, No. 25.

The impedance due to finite conductivity then gives:—

$$\textit{Inductance} = 4Q10^{-9} \text{ henrys/cm}$$
$$= -\,0\cdot 0386 + \tfrac{1}{2}\operatorname{logh}\left(\frac{1}{x}\right) + \frac{x}{3\sqrt{2}}10^{-9} \text{ henrys/cm}$$
$$\textit{Resistance} = 4\omega P$$
$$= 4\omega\left[\frac{\pi}{8} + \frac{x}{3\sqrt{2}} + \frac{x^2}{16}\left(0\cdot 6728 + \operatorname{logh}\frac{2}{x}\right)\right]10^{-9} \text{ ohm/cm}$$

where $x = 2hK < 1/4$

When $x > 1/4$ the formulæ are rather more complicated, being in the form of series, which, however, converge rapidly.

The following symbols are used in the above formulæ:—

$$K = 2\pi\sqrt{\frac{f}{u}}$$
$$K_1 = 2\pi\sqrt{\frac{2f}{u}}$$

f = frequency
s = specific resistance of earth in C.G.S. units
b = radius of line conductor (cm)
h = height of line conductor (cm)
$\gamma = 1\cdot 781 \ldots$ = Bessel's constant
$\omega = 2\pi f$

(C) Short-Circuit with other Conductors Present.

The previous calculations refer only to a single-phase current with a return path through the earth. In recent practice and on the proposed "grid" system the towers are joined together with a continuous earth wire, the conductivity of which is comparable with that of the phase wires (actually about one-half the phase wires). A considerable portion of the return current travels along the earth wire in parallel with the earth. For the purposes of calculation it is assumed that the earth wire is insulated from the earth except at the two ends of the section of line considered. In practice the earth wire is bonded at every tower, but there is not much exchange of current between earth and earth wire at intermediate towers, owing to the fact that when the earth current has spread out from the fault the earth plate at the tower generally acts as a high-resistance bond. The authors' experiments on the "grid" lines show that usually the "multiple" earths affect the current in the earth wire only at the ends of the section under short-circuit, and the average current is increased only by a small amount. With short lines the effect may be large. The matter is discussed more fully later.

Let Δe_1 = potential-drop per cm along Phase 1 assumed earthed at distance l cm from the earthed neutral of the generator.
Let J_1 = short-circuit current in Phase 1.

Then

$$\Delta e_1 = \left[R_{Ka} + j\omega\left\{A_1 + 2\operatorname{logh}\left(\frac{h_1}{b}\right)\right\}\right]J_1 + 2j\omega I_2\operatorname{logh}\left(\frac{h_2}{S_{2,1}}\right) + 2j\omega I_3\operatorname{logh}\left(\frac{h_3}{S_{3,1}}\right) - 2j\omega I_4\operatorname{logh}\left(\frac{h_4}{S_{4,1}}\right) \quad (31)$$

In this expression all quantities are in absolute c.g.s. units.

Where I_2 and I_3 are the currents in Phases 2 and 3.
I_4 and I_5 are the currents in earth conductor and earth respectively.
h_1, h_2, h_3, h_4 are the heights above earth (cm) of conductors 1, 2, 3 and earth wire respectively.
$S_{2,1}, S_{3,1}, S_{4,1}$ are the distances (cm) of Phases 2, 3 and earth wire respectively from Phase 1.
A_1 = a constant to take account of internal self-inductance of Phase conductor 1.

Let Δe = potential-drop per cm in the earth.

Then

$$\Delta e = \left[\frac{R'}{l} + R + j\omega\left(\frac{L'}{l} + L\right)\right]I_5$$
$$= \left[\frac{R'}{l} + R_4 + j\omega\left(A_4 + 2\operatorname{logh}\frac{h_4}{r_4}\right)\right]I_4 - J_1 2j\omega\operatorname{logh}\frac{h_1}{S_{1,4}} - 2j\omega I_2\operatorname{logh}\left(\frac{h_2}{S_{2,4}}\right) - I_3 2j\omega\operatorname{logh}\left(\frac{h_3}{S_{3,4}}\right) \quad . \quad . \quad (32)$$

In the above equations

$$J_1 = I_4 + I_5$$

(I_2 and I_3 being neglected in comparison with J_1, I_4 and I_5), and

R_4 = resistance of earth conductor per cm in absolute ohms.
R_4' = contact resistance in earth wire connections in absolute ohms.
A_4 = a constant to take account of internal self-inductance of earth wire.*
R = resistance of earth per cm length in absolute units.
L = inductance of earth per cm length in absolute units.
R' = resistance of earth plate and fault connection in absolute units.
L' = inductance in henrys of earth plate and fault connection in absolute units.
$S_{1,4}$, $S_{2,4}$, $S_{3,4}$ = distances in cm of phase conductors from earth wire.
I_5 = total current in earth.
r_4 = outside radius of earth wire in cm.

The convention adopted is that the positive direction of currents in the phases is in the direction of J_1, while the positive direction for I_4 and I_5 is opposite to J_1.

The potential V applied to the fault is given by

$$\frac{V}{l} = \Delta e_1 + \Delta e \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$

If the specific resistance of the earth is known and also the frequency, then R and L can be found from equation (27). The values of R', R_4', and L' must be estimated or assumed. When these quantities are known, and also I_2 and I_3, the values of

$$\frac{I_5}{J_1} \text{ and } \frac{I_4}{J_1}$$

can be calculated from equation (32). If these values are substituted in (31), Δe_1 is obtained as a factor times J_1, and Δe may also be obtained in similar form. Thus the total impedance V/J_1 can be found. In deriving the above equations the effect of I_2, I_3 and I_4 on the earth current has been neglected. Calculation shows that this is justifiable owing to the large attenuation of their magnetic fields in the earth. Further, the effect of the earth currents on the self-inductance of the earth wire has been neglected. This matter is difficult of approach since theories are least rigorous near the conductors, but the assumption is to some extent justified from Rüdenberg's point of view, though not from the position adopted by Pollaczek and Carson. Experimental evidence on currents in earth wires is difficult to obtain, but the authors' tests indicate that the above theory would, if anything, underestimate the earth wire current, whereas a mutual inductance effect due to the earth current would be expected to decrease the earth wire current. The matter would repay further study, but the authors are of opinion from experimental and theoretical considerations that, bearing in mind the magnitude of the earth wire current, serious errors are not involved.

Simpler expressions are obtained if the effect of the current in the insulated phases and stray resistances, etc., are neglected. On large interconnected systems the former assumption will be valid. The correction for the latter depends on particular cases and the resistance of the fault connection and earth plate may vary from a fraction of an ohm to several ohms. Under the above conditions, the above equations reduce to

$$\left.\begin{aligned} \Delta e_1 &= \left[R_{Ka} + j\omega\left(A_1 + 2\,\text{logh}\,\frac{h_1}{b}\right)\right] J_1 - 2I_4 j\omega\,\text{logh}\,\frac{h_4}{S_{1,4}} \\ \Delta e &= (R + j\omega L)I_5 \\ &= \left[R_4 + j\omega\left(A_4 + 2\,\text{logh}\,\frac{h_4}{r_4}\right)\right] I_4 - 2J_1\omega j\,\text{logh}\,\frac{h_1}{S_{4,1}} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (34)$$

To simplify, let

$$\begin{aligned} \lambda &= (R + j\omega L)10^{-9} \\ &= \left[\pi^2 f + j\omega\left(2\,\text{logh}\,\frac{2}{\gamma K h_1}\right)\right] 10^{-9} \text{ ohm/cm} \end{aligned}$$

$$\lambda_4 = \left[R_4 + j\omega\left(A_4 + 2\,\text{logh}\,\frac{h_4}{r_4}\right)\right] 10^{-9} \text{ ohm/cm}$$

$$\lambda_1 = \left[R_{Ka} + j\omega\left(A_1 + 2\,\text{logh}\,\frac{h_1}{b}\right)\right] 10^{-9} \text{ ohm/cm}$$

---

* The effect of stranding is unimportant at practical conductor spacings and is neglected in the working formulæ. This also applies to symbol A_1.

$$\left.\begin{aligned} L_1 &= 2j\omega 10^{-9} \operatorname{logh} \frac{h_1}{S_{4,1}} \text{ ohm/cm} \\ L_4 &= 2j\omega 10^{-9} \operatorname{logh} \frac{h_4}{S_{4,1}} \text{ ohm/cm} \end{aligned}\right\}$$ where $S_{4,1}$ means the axial distance from phase 1 to earth wire, see Fig. 7

Then equation (34) becomes

$$\Delta e_1 = \lambda_1 J_1 - L_4 I_4 \quad \ldots \ldots \quad (35a)$$

$$\Delta e = \lambda I_5 = \lambda_4 I_4 - L_1 J_1 \quad \ldots \ldots \quad (35b)$$

In these expressions Δe_1 and Δe are in volts/cm; J_1, I_4, I_5 are in amperes.

Also we have

$$J_1 = I_4 + I_5 \quad \ldots \ldots \quad (35c)$$

from which

$$\frac{I_4}{J_1} = \frac{\lambda + L_1}{\lambda + \lambda_4}$$

and

$$\frac{I_5}{J_1} = \frac{\lambda_4 - L_1}{\lambda + \lambda_4}$$

The impedance per cm is given by

$$\frac{V}{lJ_1} = \frac{\Delta e_1 + \Delta e}{J_1} = \lambda_1 J_1 + L_4 I_4 + \lambda I_5 = \lambda_1 - L_4 \frac{(\lambda + L_1)}{\lambda + \lambda_4} + \frac{\lambda(\lambda_4 - L_1)}{\lambda + \lambda_4}$$

$$= \left[\lambda_1 + \frac{\lambda(\lambda_4 - L_4) - L_1(\lambda + L_4)}{(\lambda + \lambda_4)}\right] \text{ ohm/cm} \quad \ldots \quad (35d)$$

The following figures may be of interest as indicating the measure of agreement to be obtained in practice. Some short-circuit tests were carried out by the authors upon a steel tower line * about 16 metres high and bearing a three-phase overhead system in vertical flat spacing with a normal voltage of 33 kV. The line was about 10 kilometres long. A steel earth wire, of low conductivity compared with the phase wires but of steel having a rather higher conductivity than usual, connected all the towers, an earth plate being provided at every other tower. Tests were made with a fault on one phase:—

(1) With a phase wire bonded at every fourth tower to simulate a multiple earthed earth wire.
(2) With a phase wire bonded only at each end of the line.
(3) With the steel earth wire alone.

Theoretical values were obtained assuming no local fault resistance or other stray effects. The earth resistance was taken as 1 000 ohms/cm cube from measurements on interference with telephone lines. The frequency was 50 cycles.

The measured values for the impedance and power factor for the three cases were:—

	(1)	(2)	(3)
Impedance	0·702 ohm/km	0·695 ohm/km	0·795 ohm/km
Power factor	51·8 per cent	53·5 per cent	49·9 per cent

The calculated values for cases (2) and (3), treated as above, were:—

	(2)	(3)
Impedance	0·683 ohm/km	0·760 ohm/km
Power factor	48·4 per cent	45·8 per cent

It is seen that " multiple " earths did not have a very great effect upon the impedance with a high conductivity earth wire ((1) and (2)). The general agreement is fairly close considering the uncertain nature of several of the dimensions and quantities involved, and a large part of the discrepancy can be explained by the neglect of earth plate and local fault resistance. For example, if a stray resistance (at fault or earth plate) of 0·2 ohm were taken as included in the measurement, the test values would have been modified to the following for comparison with theory:—

	(1)	(2)	(3)
Impedance	0·679 ohm/km	0·675 ohm/km	0·774 ohm/km
Power factor	50·2 per cent	51·9 per cent	48·5 per cent

---

* The Runcorn-Ellesmere Port Line of the Mersey Power Co., Ltd.

The conductivity of the earth does not have a very great effect upon the impedance, within fairly wide limits. To illustrate this, some figures are taken from some calculated for the proposed grid system for England and Scotland. The cases taken are for double and single circuit towers with a short-circuit on the lowest phase.

Resistivity of earth, ohms/cm cube	Impedance, ohm/km	Power factor, per cent	Tower
20 000	0·666	34·6	Single circuit
500	0·609	34·9	
20 000	0·676	33·4	Double circuit
500	0·616	33·9	

Dimensions are given in the worked examples, see later.

(D) THE EFFECT OF MULTIPLE EARTHS ON THE EARTH WIRE.

In practice the earth wire is connected to earth at every tower, so that the earth conductor and earth in parallel form a repeated network except at the ends of the section. Here the effective scheme of connections depends upon how exactly the fault occurs. The simplest assumption and one fulfilled in tests by the authors is that the fault takes place to the tower, so that the earth wire is directly connected to the current-carrying phase at the fault, and to the return conductor or pole or neutral of generator at the other end of the section. The earth current must, however, spread out before attaining uniform flow, and this interposes an " earth plate resistance " at each end in the path of the earth current proper. The effect of this is to produce a non-uniform potential distribution in the earth, with the result that there is an exchange of current between earth wire and earth, the earth wire current being large at the end of the line and decreasing to a constant value as the centre of the section is approached. If the earth plate resistance is large the increase of earth wire current at the ends will be correspondingly large, while if the earth plate resistance is very small the current in the earth wire will be constant, and it will behave as if there were no intermediate earths; for in this case the potential-drop is uniform both in the earth and earth wire, and there can be no exchange of current between them. If, on the other hand, there is an initial resistance in the connection between the earth wire and fault which is much higher than the earth plate resistance, then the earth wire current will increase from the ends to the centre of the line; formulæ for this case are not given in the present report but can be derived in the same manner as for the case considered.

Assume that the fault is to a tower so that the earth wire is directly connected to the fault phase, and also that the earth wire is connected to the other pole of the supply. Let the earth plate resistance at the fault and at the return pole be R', and let R_i' be the resistance of the intermediate earth plates, supposed uniform along the line. In the average case $R' = R_i'$, but since the effect depends largely upon the value R' it is desirable for illustration of the theory not to make this simplification. The problem can be solved as a repeated network, but this method leads to complicated formulæ if a finite number of towers is considered. Much simpler expressions are obtained if the earths at each tower are treated as a uniformly distributed " leakage " G, where

$$G = \frac{1}{R_i' l_0} \quad \text{and} \quad l_0 = \text{distance in cm between consecutive towers.}$$

It may be shown that *

$$\frac{I_4}{J_1} = \frac{R'(\lambda_4 - L_4)a_1 \cosh a_1 x}{(\lambda + \lambda_4)\left[(\lambda + \lambda_4)\sinh a_1 \frac{l}{2} + R' a_1 \cosh a_1 \frac{l}{2}\right]} + \frac{L_4 + \lambda}{\lambda + \lambda_4} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (36a)$$

where I_4 = current in earth wire.
J_1 = total current in short-circuited phase.
λ_4 = self-impedance of earth wire as above.
λ = self-impedance of earth per cm as above.
L_4 = mutual impedance between fault phase and earth wire.
$a_1 = G(\lambda + \lambda_4)$.
x = distance in cm from centre of fault section.
l = length of line between ends of short-circuited section. See Fig. 7.

---

[*] As mentioned later, the net effect of the "multiple" earths on the average percentage of short-circuit current passing through the earth wire and on the impedance of line and earth return is only a few per cent for the grid system, except on very short lines, say, about 1 mile long, and is therefore unimportant from a practical aspect, and has been neglected in the "working formulæ." For this reason the derivation of equations (36a) to (36f) (which is lengthy) is not given in detail herein, but will be published later in a paper dealing with the methods of test, etc., employed and the induced voltages, etc., observed in telephone circuits, in the authors' tests.

In the majority of cases $\alpha_1\frac{l}{2}$ is large, so that

$$\cosh \alpha_1\frac{l}{2} = \sinh \alpha_1\frac{l}{2}$$

Thus

$$\frac{I_4}{J_1} = \frac{(\lambda_4 - L_4)}{(\lambda + \lambda_4)\left[1 + (\lambda + \lambda_4)/\alpha_1 R'\right]}\,\frac{\cosh \alpha_1 x}{\cosh \alpha_1\frac{l}{2}} + \frac{L_4 + \lambda}{\lambda + \lambda_4} \quad \ldots\ldots \tag{36b}$$

As R' increases the fraction of total current in the earth wire approaches a limiting maximum value given by

$$\frac{I_4}{J_1} = \frac{\lambda_4 - L_4}{\lambda + \lambda_4}\,\frac{\cosh \alpha_1 x}{\cosh \alpha_1\frac{l}{2}} + \frac{L_4 + \lambda}{\lambda + \lambda_4} \quad \ldots\ldots \tag{36c}$$

Again, as R' decreases or as x decreases, I_4 tends to the value for an insulated earth wire as already treated, namely

$$\frac{I_4}{J_1} = \frac{L_4 + \lambda}{\lambda + \lambda_4} \quad \ldots\ldots \tag{36d}$$

Actually the first term is not usually of importance until x is nearly equal to $l/2$, owing to the rapid variation of $\cosh \alpha_1 x$. Fig. 9 shows a curve calculated for some tests on the Bedford–Little Barford Grid Line. Tests were made of earth resistivity by surface methods and also of earth plate resistance and tower resistances. The last were negligible, being of the order of 0·01 ohm at 50 cycles. The earth resistivity was taken as 2 000 ohms per cm cube, the intermediate earth plates as 2·5 ohms, and the terminal earth plates as 1·25 ohms; i.e.

$$u = 2 \times 10^{12}$$
$$R' = 1{\cdot}25 \text{ ohms}$$
$$R'_i = 2{\cdot}5 \text{ ohms}$$

All these values were averages from the tests made. The dimensions, etc., of the towers were similar to those given in Fig. 2 for single circuit " grid " lines. The line was transposed one complete turn of the " lay " in the length tested so that the effect of different heights of the phase wires was averaged. From Fig. 9 it is clear that most of the variation in current occurs in the kilometre adjacent to the end of the line. The value of I_4/J_1 observed at the end of the line was approximately 74 per cent as a mean for several observations, thus giving satisfactory agreement with the theoretical value of 72 per cent. The phase displacement between the total current and the earth wire current was small, the theoretical value being 3° 29′ in a positive direction, that is towards the voltage vector. The average of a number of observations at different short-circuit currents was 3° 20′, which is a remarkably close agreement.

The effect of the intermediate earths and consequent increase of earth wire current at the ends of the line was to increase the average value of the earth wire current from about 31 per cent of the total for the " insulated " case, i.e. without intermediate earths, at the centre of the line, to 34 per cent, an amount which may be ignored in practice.

The earth wire current at the end of the line is given by

$$\frac{I_4}{J_1} = \frac{\lambda_4 - L_4}{(\lambda + \lambda_4)\left[1 + (\lambda + \lambda_4)/\alpha_1 R'\right]} + \frac{L_4 + \lambda}{\lambda + \lambda_4} \quad \ldots\ldots \tag{36e}$$

and in the limiting case when R' is very large, $I_4 = J_1$ which is otherwise obvious. It is also clear that if $l/2$ is small $\cosh \alpha_1 x$ does not become negligible in comparison with $\cosh \alpha_1\frac{l}{2}$ even when $x = 0$, and the earth wire current will be greater than in the absence of intermediate earths, at all parts of the line. The initial current is, however, independent of the length of the line as is also, except for short lines, the current in the middle of the line.

The overall impedance of the line and earth return is given by

$$Z = \lambda_1 + \frac{\lambda\lambda_4}{\lambda + \lambda_4} - \frac{L_4(L_4 + 2\lambda)}{\lambda + \lambda_4} + \frac{2}{\lambda l}\,\frac{(\lambda_4 - L_4)^2}{(\lambda + \lambda_4)\left(1 + \frac{\lambda + \lambda_4}{R'\alpha_1}\right)} \text{ ohms/cm} \quad \ldots\ldots \tag{36f}$$

where λ_1 = self-impedance of fault phase as above, in ohms/cm.

On the " grid " lines at Bedford for the section tested, about 14 km, the total impedance was 9·0 ohms by equation (36*f*) (or 1·03 ohm per mile). Experiment gave an average impedance of 9·04 ohms and a power factor of about 39·1 per cent; theory giving a power factor of about 41·0 per cent.

The theory given above considers the leakage to earth due to the towers as distributed over the whole of the line. A possible variation of this scheme is to assume the distributed leakage as extending only to the middle of the end spans, treating the terminal sections as ordinary conductors. The effect of this assumption can approximately be included in the above expressions, merely by replacing R' by

$$\frac{R'}{\left(1+\frac{a_1 l_0}{2}\right)}$$

and the modification so introduced is usually small.

As an additional check on the theory the voltage induced in the two free (i.e. insulated) phase wires by the short-circuit current was calculated, the values so obtained for the Bedford tests being about 3 or 4 per cent higher than the experimental values.

If the present theory is applied to the authors' test results on the Runcorn–Ellesmere Port Line for the "multiple" earthed-phase wire and the steel earth wire, the values of earth plate resistances necessary to give agreement with observation are found to be consistent with each other and of the order of magnitude which experience in that locality suggests. No measurements could, however, be taken owing to the difficulty of insulating the steel earth wire for an earth plate test. Accordingly, actual figures are not given here.

APPENDIX IV.—WORKING FORMULÆ AND WORKED NUMERICAL EXAMPLES.

1. LINE IMPEDANCES WITH BALANCED THREE-PHASE CURRENTS.

(*a*) *Introduction.*—For single circuit towers working formulæ are given only for transposed circuits,* this being the only practical case. For double circuit towers formulæ are given for *one* time-phase sequence of currents (viz. that giving the minimum phase impedances, see Fig. 3 (*l*)) when the circuits are transposed at the same frequency, and for *two* phase sequences when not transposed. Of the latter, one phase sequence (the same as that for transposed circuits) gives minimum phase impedance, and the other (see Fig. 3 (*d*)) equal impedances for corresponding conductors (in the same horizontal plane) of the two circuits. All resistances are in ohms per mile and all reactances in ohms per mile to neutral at 50 ∼.

(*b*) *Single circuit towers.*—The resistance and reactance are equal in all phases.

$$\textit{Apparent resistance} = R_{KM} \text{ ohm/mile} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad (37)$$

$$\textit{Apparent reactance}\,\dagger = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10}\left\{\frac{\sqrt[3]{(S_{1,2}\,S_{1,3}\,S_{2,3})}}{b}\right\}\right] \text{ ohm/mile to neutral} \quad . \; . \quad (38)$$

(*c*) *Double circuit towers.*—(It is assumed that the two circuits are symmetrical about the vertical centre line of the tower and are transposed in such directions of spiral as to maintain the same relative positions of conductors carrying currents of the same time phase. For Fig. 3 (*l*) the directions are the same.)

(i) *Transposed circuits.*

Time-phase sequence of currents as shown in 2 (*l*).

$$\begin{aligned}
\text{The current in Conductor 1} &= \text{current in Conductor 4} = I_1\\
\text{The current in Conductor 2} &= \text{current in Conductor 5} = I_2\\
&= I_1(-\,0{\cdot}5 + 0{\cdot}866j)\\
\text{The current in Conductor 3} &= \text{current in Conductor 6} = I_3\\
&= I_1(-\,0{\cdot}5 - 0{\cdot}866j)
\end{aligned}$$

Circuit A.

The resistance and reactance of all phases of circuit A are equal.

$$\textit{Apparent resistance} = \left[R_{KM} + 0{\cdot}201 \log_{10}\sqrt[3]{\left(\frac{S_{5,1}\,S_{6,2}\,S_{4,3}}{S_{5,3}\,S_{6,1}\,S_{4,2}}\right)}\right] \text{ ohm/mile} \quad . \; . \; . \; . \quad (39a)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10}\left\{\frac{\sqrt[3]{(S_{1,2}\,S_{2,3}\,S_{1,3})}}{b} \times \sqrt[6]{\frac{(S_{5,1}\,S_{6,1}\,S_{4,2}\,S_{6,2}\,S_{4,3}\,S_{5,3})}{(S_{4,1}\,S_{5,2}\,S_{6,3})^2}}\right\}\right] \text{ ohm/mile to neutral} \quad . \quad (39b)$$

---

* All formulæ for transposed circuits apply to a length of line containing an integral multiple of three transpositions

† For equilateral triangular spacing with or without transposition this expression reduces to

$$\text{Reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{S_{1,2}}{b}\right] \text{ ohm/mile to neutral} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad (38a)$$

Circuit B.

The resistance and reactance of all phases of circuit B are equal.

$$\textit{Apparent resistance} = \left[R_{KM} + 0{\cdot}201 \log_{10} \sqrt[3]{\left(\frac{S_{2,4}\,S_{3,5}\,S_{1,6}}{S_{3,4}\,S_{1,5}\,S_{2,6}}\right)}\right] \text{ohm/mile} \quad \ldots \quad (40)$$

Apparent reactance:—same as equation (39*b*) above

(ii) *Non-transposed circuits.*

Time-phase sequence of currents as given above for Fig. 3 (*l*).

Circuit A.

$$\text{Phase 1: } \textit{Apparent resistance} = \left[R_{KM} + 0{\cdot}201 \log_{10} \left(\frac{S_{2,1}\,S_{5,1}}{S_{3,1}\,S_{6,1}}\right)\right] \text{ohm/mile} \quad \ldots \quad (41a)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{\sqrt[2]{(S_{2,1}\,S_{3,1}\,S_{5,1}\,S_{6,1})}}{bS_{4,1}}\right] \text{ohm/mile to neutral} \quad . \quad (41b)$$

$$\text{Phase 2: } \textit{Apparent resistance} = \left[R_{KM} + 0{\cdot}201 \log_{10} \left(\frac{S_{3,2}\,S_{6,2}}{S_{1,2}\,S_{4,2}}\right)\right] \text{ohm/mile} \quad \ldots \quad (41c)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{\sqrt[2]{(S_{1,2}\,S_{3,2}\,S_{4,2}\,S_{6,2})}}{bS_{5,2}}\right] \text{ohm/mile to neutral} \quad . \quad (41d)$$

$$\text{Phase 3: } \textit{Apparent resistance} = \left[R_{KM} + 0{\cdot}201 \log_{10} \left(\frac{S_{1,3}\,S_{4,3}}{S_{2,3}\,S_{5,3}}\right)\right] \text{ohm/mile} \quad \ldots \quad (41e)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{\sqrt[2]{(S_{1,3}\,S_{2,3}\,S_{4,3}\,S_{5,3})}}{bS_{6,3}}\right] \text{ohm/mile to neutral} \quad . \quad (41f)$$

Circuit B.

Phase 4: *Apparent resistance*:—as equation (41*e*) with sign of second term reversed.
Apparent reactance:—same as equation (41*f*).

Phase 5: *Apparent resistance*:—as equation (41*c*) with sign of second term reversed.
Apparent reactance:—same as equation (41*d*).

Phase 6: *Apparent resistance*:—as equation (41*a*) with sign of second term reversed.
Apparent reactance:—same as equation (41*b*).

Time-phase sequence of currents as in Fig. 3 (*d*).

Current in Conductor 1 = current in Conductor 6 = I_1
Current in Conductor 2 = current in Conductor 5 = I_2
= $I_1(-\,0{\cdot}5 + 0{\cdot}866j)$
Current in Conductor 3 = current in Conductor 4 = I_3
= $I_1(-\,0{\cdot}5 - 0{\cdot}866j)$

Phases 1 *and* 6.

$$\textit{Apparent resistance} = \left[R_K = 0{\cdot}201 \log_{10} \left(\frac{S_{3,1}\,S_{4,1}}{S_{2,1}\,S_{5,1}}\right)\right] \text{ohm/mile} \quad \ldots \quad (41g)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{\sqrt[2]{(S_{2,1}\,S_{3,1}\,S_{4,1}\,S_{5,1})}}{bS_{6,1}}\right] \text{ohm/mile to neutral} \quad . \quad . \quad (41h)$$

Phases 2 *and* 5.

$$\textit{Apparent resistance} = \left[R_K + 0{\cdot}201 \log_{10} \left(\frac{S_{1,2}\,S_{6,2}}{S_{3,2}\,S_{4,2}}\right)\right] \text{ohm/mile} \quad \ldots \quad (41j)$$

$$\textit{Apparent reactance} = \left[0{\cdot}0253 + 0{\cdot}233 \log_{10} \frac{\sqrt[2]{(S_{1,2}\,S_{3,2}\,S_{4,2}\,S_{6,2})}}{bS_{5,2}}\right] \text{ohm/mile to neutral} \quad . \quad . \quad (41k)$$

Phases 3 *and* 4.

$$\textit{Apparent resistance} = \left[R_K + 0\cdot201 \log_{10}\left(\frac{S_{2,3}\,S_{5,3}}{S_{1,3}\,S_{6,3}}\right)\right] \text{ ohm/mile} \quad \ldots \quad (41l)$$

$$\textit{Apparent reactance} = \left[0\cdot0253 + 0\cdot233 \log_{10} \frac{\sqrt[4]{(S_{1,3}\,S_{2,3}\,S_{5,3}\,S_{6,3})}}{bS_{4,3}}\right] \text{ ohm/mile to neutral} \quad \ldots \quad (41m)$$

2. POWER LOSSES WITH BALANCED THREE-PHASE CURRENTS.

The power loss in a "short" line (in watts/mile) = (R.M.S. current)^2 × R_{KM} × length of line in miles

The power loss on a "long" line of length l_1 miles (in watts)

$$= \frac{R_{KM}}{2}\left[(\mathfrak{J}_1^2 + \mathfrak{J}_2^2)\left(\frac{\sinh 2al_1}{2a} + \frac{\sin 2\beta l_1}{2\beta}\right) + E_r^2(\gamma^2 - \delta^2)\left(\frac{\sinh 2al_1}{2a} - \frac{\sin 2\beta l_1}{2\beta}\right)\right.$$
$$\left. + 2\mathfrak{J}_1 E_r\left\{\frac{\gamma}{2a}(\cosh 2al_1 - 1) + \frac{\delta}{2\beta}(\cos 2\beta l_1 - 1)\right\} - 2\mathfrak{J}_2 E_r\left\{\frac{\delta}{2a}(\cosh 2al_1 - 1) - \frac{\gamma}{2\beta}(\cos 2\beta l_1 - 1)\right\}\right] \quad (42)$$

where $a + j\beta = \sqrt{(cZ)}$.

c = capacity susceptance of line in mhos per mile,

Z = vector impedance per mile,

$= (R_{KM} + jx)$,

x = reactance in ohms/mile of line to neutral,

$\gamma + j\delta = \sqrt{\frac{c}{Z}}$.

$\mathfrak{J}_1$ = component of receiving-end current in phase with receiving-end voltage.

$\pm\,\mathfrak{J}_2$ = component of receiving-end current in quadrature with receiving-end voltage.

(NOTE.—Equation (42) refers to the case when the power factor at the receiver is *lagging*. For unity power factor the last term in (42) is zero, while for a *leading* power factor its sign is reversed from that given above.)

3. IMPEDANCE OF LINE WITH EARTH RETURN.

Assumptions. (*Refer to Fig.* 7.)

The short-circuit is assumed to occur from Conductor 1 to earth at Z at a distance "l" cm from the earthed neutral of the generator. The phase voltage V causes the current to flow along the phase conductor MP and to return partly through the earth along PZON and partly along the earth wire PKON. The earth wire is assumed earthed where the fault occurs, and at the supply end (see Fig. 7), but the effect of intermediate (or multiple) earthing of the towers is neglected. The frequency assumed is 50~.

Impedance of phase conductor and return path via earth and earth wire in parallel

$$= \left\{\lambda_1 + \frac{\lambda(\lambda_4 - L_4) - L_1(\lambda + L_4)}{(\lambda + \lambda_4)}\right\} \times 0\cdot161 \times 10^6 \text{ ohm/mile} \quad . \quad (43a)$$

$$\frac{\text{Current in earth wire}}{\text{Current in earthed phase}} = \frac{I_4}{J_1} = \frac{I_4}{I_4 + I_5} = \frac{\lambda + L_1}{\lambda + \lambda_4} \quad \ldots \quad (43b)$$

$$\frac{\text{Current in earth}}{\text{Current in earthed phase}} = \frac{I_5}{J_1} = \frac{I_5}{I_4 + I_5} = \frac{\lambda_4 - L_1}{\lambda + \lambda_4} \quad \ldots \quad (43c)$$

where

$$\lambda = \left\{(\pi^2 f) + j\omega\left(0\cdot5 + 4\cdot6 \log_{10}\frac{2}{\gamma K h_1}\right)10^{-9}\right\} \text{ ohm/cm}$$

$$\lambda_1 = \left\{R_{Ka} + j\omega\left(0\cdot5 + 4\cdot6 \log_{10}\frac{h_1}{b}\right)\right\}10^{-9} \text{ ohm/cm}$$

$$\lambda_4 = \left\{R_4 + j\omega\left(0\cdot5 + 4\cdot6 \log_{10}\frac{h_4}{r_4}\right)\right\}10^{-9} \text{ ohm/cm}$$

$$L_1 = \left\{4\cdot6 j\omega 10^{-9} \log_{10}\left(\frac{h_1}{S_{4,1}}\right)\right\} \text{ ohm/cm}$$

$$L_4 = \left\{4\cdot6 j\omega 10^{-9} \log_{10}\left(\frac{h_4}{S_{4,1}}\right)\right\} \text{ ohm/cm}$$

For meaning of other symbols, see Appendix I.

If there is no earth wire, i.e. all the short-circuit current returns through the earth, the total impedance is the sum of the phase conductor and earth in series

$$= \{\lambda + \lambda_1\} \times 0\cdot161 \times 10^6 \text{ ohm/mile} \qquad \ldots\ldots\ldots\ldots \quad (44)$$

4. Numerical Examples.

(*a*) *Line impedance* (*without earth return*).—As a typical example evaluate the line constants for the "grid" system, double circuit tower, both circuits transposed at same frequency and in same direction. Phase sequence as in Fig. 3 (*l*).

Dimensions of line conductor and axial spacings of cables as on Fig. 2.

Outside diameter of conductor over strands = 0·77 in. = 1·955 cm.

Number of strands = 37.

A.C. resistance of isolated conductor = 0·2505 ohm/mile.

Circuit A.

(Over an integral multiple of three transpositions.)

From equation (39*a*):—

$$\textit{Apparent resistance of any phase} = \left[0\cdot2505 + 0\cdot201 \log_{10}\left(\frac{875 \times 875 \times 774}{935 \times 636 \times 935}\right)^{\frac{1}{3}}\right] \text{ohm/mile}$$

$$= (0\cdot2505 + 0\cdot0018) = 0\cdot252 \text{ ohm/mile}$$

By equation (39*b*):—

$$\textit{Apparent reactance of any phase} = \left[0\cdot0253 + 0\cdot233 \log_{10}\left\{\frac{(398 \times 735 \times 398)^{\frac{1}{3}}}{0\cdot977} \times \frac{(875 \times 636 \times 935 \times 875 \times 774 \times 935)^{\frac{1}{6}}}{(1\,013 \times 951 \times 1\,013)^{\frac{1}{3}}}\right\}\right] \text{ohm/mile to neutral}$$

$$= [0\cdot0253 + (0\cdot233 \times 2\cdot6219)] = 0\cdot637 \text{ ohm/mile to neutral}$$

Circuit B

Apparent resistance of any phase = (0·2505 − 0·0018) = 0·248 ohm/mile

Apparent reactance of any phase:—same as Circuit A given above.

(*b*) *Evaluation of power losses.*—As an example we will calculate the power losses on the "grid" system for a line 500 miles long having a load current of 220 amperes for three values of power factor at the receiving end, namely unity power factor, and 0·8 leading and lagging. Assume voltage to neutral

$$= \frac{132}{\sqrt{3}} 10^3 = 76\,300 \text{ volts}$$

Before applying equation (42) it is necessary to calculate the values of the quantities $\mathfrak{J}_1$, $\mathfrak{J}_2$, c, Z, α, β, γ, δ, 2α, l_1, $2\beta l_1$.

(i) $\mathfrak{J}_1$ and $\mathfrak{J}_2$.

At 0·8 power factor lagging $\mathfrak{J}_1 = 0\cdot8 \times$ load current $= 0\cdot8 \times 220 = 176$ amperes. Similarly

$$\mathfrak{J}_2 = \sqrt{(220^2 - 176^2)} = 132 \text{ amperes}$$

(ii) c, Z.

$$Z = \text{impedance per mile} = R_{KM} + jx$$

From Table 2

Reactance x = 0·667 ohm/mile

Resistance R_{KM} = 0·251 ohm/mile

$$\therefore\ Z = 0\cdot251 + j0\cdot667 \text{ in cartesian co-ordinates}$$

$$= \sqrt{(0\cdot251^2 + 0\cdot667^2)} \arctan\frac{0\cdot667}{0\cdot251} = 0\cdot709 \underline{/69^\circ\,16'} \text{ in polar co-ordinates.}$$

By the ordinary text-book formulæ capacity susceptance

$$c = 4\cdot 4 \times 10^{-6} \text{ mho/mile}$$

Thus $c = j4\cdot 4 \times 10^{-6}$ in cartesian co-ordinates

$$= 4\cdot 4 \times 10^{-6}\,\underline{|90^\circ} \text{ in polar co-ordinates}$$

(iii) α, β

$$\text{By definition } \alpha + j\beta = \sqrt{(cZ)}$$

Therefore

$$\begin{aligned} cZ &= 4\cdot 4 \times 10^{-6}\,\underline{|90^\circ} \times 0\cdot 709\ \underline{/69^\circ\ 16'} \\ &= 3\cdot 115 \times 10^{-6}\,\underline{\backslash 159^\circ\ 16'} \\ \therefore\quad \sqrt{(cZ)} &= 1\cdot 765 \times 10^{-3}\ \underline{/79^\circ\ 38'} \\ &= 1\cdot 765 \times 10^{-3}\,(\cos 79^\circ\ 38' + j \sin 79^\circ\ 38') \\ &= (0\cdot 319 + j1\cdot 7355)10^{-3} = \alpha + j\beta \end{aligned}$$

(iv) γ, δ.

$$\text{By definition } \gamma + j\delta = \sqrt{\frac{c}{Z}}$$

$$\begin{aligned} &= \sqrt{\frac{4\cdot 4 \times 10^{-6}}{0\cdot 709}}\ \frac{\underline{|90^\circ} - \underline{/69^\circ\ 16'}}{2} \\ &= 10^{-3} \times 2\cdot 49\ \ \underline{/10^\circ\ 22'} \\ &= 10^{-3}\,(2\cdot 455 + 0\cdot 448j) \end{aligned}$$

(v) $2\alpha l_1$, $2\beta l_1$.

$$l_1 = 500 \text{ miles}$$

$$\therefore\quad 2\alpha l_1 = 2 \times 500 \times 0\cdot 319 \times 10^{-3} = 0\cdot 319 \text{ radian}$$

Similarly

$$2\beta l_1 = 2 \times 500 \times 1\cdot 7355 \times 10^{-3} = 1\cdot 7355 \text{ radians}$$

From tables of hyperbolic and circular functions we have

$$\begin{aligned} \sinh 2\alpha l_1 &= 0\cdot 3244 \qquad & \sin 2\beta l_1 &= 0\cdot 9855 \\ \cosh 2\alpha l_1 &= 1\cdot 0513 \qquad & \cos 2\beta l_1 &= -\ 0\cdot 1700 \end{aligned}$$

(vi) *First term in bracket in equation* (42).

$$\begin{aligned} (\mathfrak{J}_1^2 + \mathfrak{J}_2^2)\left(\frac{\sinh 2\alpha l_1}{2\alpha} + \frac{\sin 2\beta l_1}{2\beta}\right) &= (176^2 + 132^2) \times \left(\frac{0\cdot 3244}{2 \times 0\cdot 319 \times 10^{-3}} + \frac{0\cdot 9855}{2 \times 1\cdot 7355 \times 10^{-3}}\right) \\ &= 48\cdot 4 \times 10^6(0\cdot 508 + 0\cdot 284) = 38\cdot 4 \times 10^6 \end{aligned}$$

(vii) *Second term in bracket in equation* (42).

$$E_r^2(\gamma^2 + \delta^2)\left(\frac{\sinh 2\alpha l_1}{2\alpha} - \frac{\sin 2\beta l_1}{2\beta}\right)$$

$$\begin{aligned} &= 76\ 300^2(2\cdot 455^2 \times 10^{-6} + 0\cdot 448^2 \times 10^{-6})(0\cdot 508 - 0\cdot 284) \\ &= 5\ 830 \times 6\cdot 232 \times 0\cdot 224 \times 10^3 = 8\cdot 13 \times 10^6 \end{aligned}$$

(viii) *Third term in bracket in equation* (42).

$$\begin{aligned} &= 2\mathfrak{J}_1 E_r\left\{\frac{\gamma}{2\alpha}(\cosh 2\alpha l_1 - 1) + \frac{\delta}{2\beta}(\cos 2\beta l_1 - 1)\right\} \\ &= 2 \times 176 \times 76\ 300\left\{\frac{2 \times 0\cdot 455 \times 10^{-3}}{2 \times 0\cdot 319 \times 10^{-3}}(1\cdot 0513 - 1) + \frac{0\cdot 448 \times 10^{-3}}{2 \times 1\cdot 7355 \times 10^{-3}}(-\ 0\cdot 1700 - 1)\right\} \\ &= 27\cdot 85 \times 10^6(0\cdot 1975 - 0\cdot 1515) = 1\cdot 271 \times 10^6 \end{aligned}$$

(ix) *Fourth term in bracket in equation* (42).

$$= -2\mathfrak{J}_2E_r\left\{\frac{\delta}{2\alpha}(\cosh 2\alpha l_1 - 1) - \frac{\gamma}{2\beta}(\cos 2\beta l_1 - 1)\right\}$$

$$= -2 \times 132 \times 76\,300\left\{\frac{0\cdot448 \times 10^{-3}}{2 \times 0\cdot319 \times 10^{-3}}(0\cdot0513) - \frac{2\cdot455 \times 10^{-3}}{2 \times 1\cdot7355 \times 10^{-3}}(-1\cdot17)\right\}$$

$$= -17\cdot5 \times 10^6$$

(x) *Total power losses.*

0·8 *power factor lagging at receiver.*

$$\text{Losses} = \frac{0\cdot251}{2} \times 10^6\{38\cdot4 + 8\cdot13 + 1\cdot27 - 17\cdot5\}$$

$$= 3\cdot80 \times 10^6 \text{ watts}$$

Power losses neglecting capacitance (i.e. load losses alone) $= 220^2 \times 500 \times 0\cdot251 = 6\cdot075 \times 10^6$ watts

Thus $$\frac{\text{Power losses at 0·8 power factor lagging}}{\text{Load losses alone}} = \frac{3\cdot80}{6\cdot075} = 62\cdot5 \text{ per cent}$$

0·8 *power factor leading at receiver.*

$$\text{Losses} = \frac{0\cdot251}{2} \times 10^6\{38\cdot4 + 8\cdot13 + 1\cdot27 + 17\cdot5\}$$

$$= 8\cdot2 \times 10^6 \text{ watts}$$

Therefore $$\frac{\text{Power losses at 0·8 power factor leading}}{\text{Load losses alone}} = \frac{8\cdot2}{6\cdot075} = 135 \text{ per cent}$$

Unity power factor.

$$\text{Losses} = \frac{0\cdot251}{2} \times 10^6\{38\cdot4 + 8\cdot13 + 1\cdot27 + 0\}$$

$$= 6\cdot0 \times 10^6$$

Therefore $$\frac{\text{Power losses at unity power factor}}{\text{Load losses alone}} = \frac{6\cdot0}{6\cdot075} = 98\cdot8 \text{ per cent}$$

(*c*) *Impedance with earth return.*

(i) *With earth wire.*

Take the case of a short-circuit to earth from the middle phase on a single circuit tower (see Fig. 2) of the "grid" lines, distant 1 mile from the generating station. The earth conductor on the tower is not shown in Fig. 2, but is taken as on the vertical centre line of the tower 60 ft. above ground at a tower. For dimensions of earth conductor, see Fig. 2.

Assume resistivity of earth $u = 20\,000$ ohms/cm cube $= 20 \times 10^{12}$ absolute units.

Take mean height of fault phase above earth $h_1 = 1\,190$ cm (to allow for sag).

Take mean height of earth conductor above earth $h_4 = 1\,645$ cm (to allow for sag).

Take distance from axis of earth conductor to fault phase $S_{1,4} = 567$ cm.

We have $$K = 2\pi\sqrt{\frac{f}{u}} = 2\pi\sqrt{\frac{50}{20 \times 10^{12}}} = 9\cdot91 \times 10^{-6}$$

$$\lambda = 10^{-9}\left\{(\pi^2 50) + j10^2\pi\left(0\cdot5 + 4\cdot6\log_{10}\frac{2}{1\cdot781 \times 9\cdot91 \times 10^{-6} \times 1\,190}\right)\right\}$$

$$= (0\cdot492 + 2\cdot86j)10^{-6} \text{ ohm/cm}$$

$$R_{Ka} = 1\cdot56 \times 10^3 \text{ absolute ohms/cm}$$

$$R_4 = 3\cdot90 \times 10^3 \text{ absolute ohms/cm *}$$

$$b = 0\cdot98 \text{ cm}; \; r_4 = 0\cdot7 \text{ cm}$$

$$\lambda_1 = \left\{1\cdot56 \times 10^{-6} + j10^2\pi 10^{-9}\left(0\cdot5 + 4\cdot6\log_{10}\frac{1\,190}{0\cdot98}\right)\right\}$$

$$= \left\{1\cdot56 \times 10^{-6} + j0\cdot314 \times 10^{-6}(0\cdot5 + 14\cdot2)\right\}$$

$$= (1\cdot56 + 4\cdot62j)10^{-6} \text{ ohm/cm}$$

---

* 1 absolute ohm $= 10^9$ ohm.

$$\lambda_4 = \left\{3 \cdot 90 \times 10^{-6} + j10^2\pi 10^{-9}\left(0 \cdot 5 + 4 \cdot 6 \log_{10} \frac{1\,645}{0 \cdot 7}\right)\right\}$$
$$= (3 \cdot 90 + 5 \cdot 04j)10^{-6} \text{ ohm/cm}$$
$$L_1 = \left\{4 \cdot 6j10^2\pi 10^{-9} \log_{10}\left(\frac{1\,190}{567}\right)\right\}$$
$$= 0 \cdot 466j \times 10^{-6} \text{ ohm/cm}$$
$$L_4 = \left\{4 \cdot 6j10^2\pi 10^{-9} \log_{10}\left(\frac{1\,645}{567}\right)\right\}$$
$$= 0 \cdot 668j \times 10^{-6} \text{ ohm/cm}$$

Then from equation (43*b*)

$$\frac{\text{Current in earth wire}}{\text{Current in earthed phase}} = \frac{I_4}{J_1} = \frac{I_4}{I_4 + I_5}$$
$$= \frac{(0 \cdot 492 + 2 \cdot 86j) + (0 \cdot 466j)}{(0 \cdot 492 + 2 \cdot 86j) + (3 \cdot 90 + 5 \cdot 04j)}$$
$$= 0 \cdot 35 + 0 \cdot 137j$$

Numerically $$\frac{I_4}{I_4 + I_5} = \sqrt{(0 \cdot 35^2 + 0 \cdot 137^2)} = 0 \cdot 374$$

Thus 37·4 per cent of the short-circuit current in the line conductor returns through the earth wire.

From equation (43*c*)

$$\frac{\text{Current in earth}}{\text{Current in earthed phase}} = \frac{I_5}{J_1} = \frac{I_5}{I_4 + I_5}$$
$$= \frac{(3 \cdot 90 + 5 \cdot 04j) - 0 \cdot 466j}{(0 \cdot 492 + 2 \cdot 86j) + (3 \cdot 90 + 5 \cdot 04j)}$$
$$= 0 \cdot 652 - 0 \cdot 131j$$

Numerically $$\frac{I_5}{I_4 + I_5} = \sqrt{(0 \cdot 652^2 + 0 \cdot 131^2)} = 0 \cdot 665$$

(NOTE.—Numerically

$$\frac{I_5}{I_4 + I_5} + \frac{I_4}{I_4 + I_5} = 0 \cdot 374 + 0 \cdot 665 = 1 \cdot 039 = \text{Greater than unity}$$

This is because I_5 and I_4 are out of phase.)

From equation (43*a*)

Impedance of phase conductor and return path via earth and earth wire in parallel

$$= \left\{(1 \cdot 56 + 4 \cdot 62j)10^{-6} + \frac{(0 \cdot 492 + 2 \cdot 86j)10^{-6}(3 \cdot 90 + 4 \cdot 37j) - 0 \cdot 466j10^{-6}(0 \cdot 492 + 3 \cdot 53j)}{4 \cdot 39 + 7 \cdot 9j}\right\} \times 0 \cdot 161 \times 10^6 \text{ ohm/mile to neutral}$$
$$= (2 \cdot 36 + 6 \cdot 19j) \times 0 \cdot 161 \text{ ohm/mile to neutral}$$

Numerically, impedance $= \sqrt{(2 \cdot 36^2 + 6 \cdot 19^2)} \times 0 \cdot 161$ ohm/mile
$= 1 \cdot 06$ ohms/mile to neutral

Power factor of short-circuit $= \cos\left(\text{arc tan}\,\frac{6 \cdot 19}{2 \cdot 36}\right) = \cos 69° = 0 \cdot 358$

(ii) *Without earth wire.*

By equation (44)

$$\text{Impedance} = (\lambda + \lambda_1) \times 0 \cdot 161 \times 10^6 \text{ ohm/mile to neutral}$$
$$= \left\{(0 \cdot 492 + 2 \cdot 86j) + (1 \cdot 56 + 4 \cdot 62j)\right\}0 \cdot 161 \text{ ohm/mile to neutral}$$
$$= (2 \cdot 05 + 7 \cdot 48j)0 \cdot 161$$

Numerically $= \sqrt{(2 \cdot 05^2 + 7 \cdot 48^2)}0 \cdot 161 = 1 \cdot 25$ ohms/mile to neutral

Power factor $= \cos\left(\text{arc tan}\,\frac{7 \cdot 48}{2 \cdot 05}\right) = \cos 75° = 0 \cdot 26$

DISCUSSION ON

"A CRITICAL STUDY OF A THREE-PHASE SYSTEM OF UNARMOURED SINGLE-CONDUCTOR CABLES."*

Dr. H. B. Dwight: In equations (118) and (119), formulæ are given for the sheath eddy-loss for cables in one plane, and these are credited to a paper by Dr. F. W. Carter published in 1928 in the *Proceedings of the Cambridge Philosophical Society*. While the omission of the reference to the earlier publication was doubtless made inadvertently, these formulæ (118) and (119) are the same as the first terms of formulæ for cable sheaths in Section V of my paper on "Proximity Effect in Wires and Thin Tubes," published in the *Transactions of the American Institute of Electrical Engineers* (1923, vol. 42, p. 856).

Messrs. E. B. Wedmore, P. D. Morgan and **S. Whitehead** (*in reply*): Mention should have been made of Dr. Dwight's earlier work in the portion of our paper to which he refers. The purpose of Appendix V of the paper was to show the application of Dr. Carter's method to the particular problem concerned, and reference to Dr. Dwight's work in which the same result was obtained by a different method was unfortunately omitted.

---

* Paper by Messrs. E. B. Wedmore, P. D. Morgan and S. Whitehead (see vol. 67, page 359).

DISCUSSION ON

"NOTE ON SHEATH LOSSES IN SINGLE-CORE SINGLE-PHASE CABLES." *

Dr. H. B. Dwight: In the first paragraph of this paper the authors discuss the calculation of the loss and e.m.f. in cable sheaths, and state that it is unlikely for the loss and voltage conditions to change suddenly when contact is made between the sheaths. On the contrary, when two points in an electrical network are suddenly connected, any e.m.f. which previously existed between them becomes zero and may be said to be used up in driving an additional current through the network. This is a well-known principle and is useful in solving some network problems. Thus, the open-circuit voltage between sheaths is not zero just before they touch, and need not be expected to be zero. Reference is also made in the same paragraph to the question of a discrepancy in the tests published by Mr. Dunsheath† in 1927. These tests, however, seem to have been made originally as commercial tests, and no claim for precise accuracy appears to have been made by Mr. Dunsheath. This is borne out by the fact that the mutual inductance of certain non-magnetic cables computed from Table D (vol. 65, p. 493 and Fig. 17) shows 30 per cent variation, whilst the only change reported is that the current increased from 150 to 300 amperes. This can be seen by dividing each value of measured e.m.f. by the corresponding current. A serious discrepancy in this set of measurements is thereby shown, for the mutual inductance of non-magnetic conductors is a constant for constant frequency and varying current. Another similar set of measurements given in Table A and Fig. 5, which have been used in the discussion of conflicting calculations, also shows internal evidence of inaccuracy, since it is impossible to plot the readings as a smooth curve. Much more consistent tests will be found in the paper by Messrs. W. S. Clark and G. B. Shanklin in the *Transactions* of the American Institute of Electrical Engineers (1919, vol. 38, p. 917). In view of the discussion as to the correct formula for the open-circuit e.m.f. between cable sheaths, it is noteworthy that a complete formula including proximity and shielding effects has apparently not been published. I have recently derived such a formula which is comparatively short and yet practically complete. The zero-frequency inductance of a sheath in the single-phase case can be taken directly from it, and is $2 \log_e (d/r)$. The terms involving frequency to higher powers have a slight effect on the result, but even in the case of 2 000 000-circular-mil cables at 60 cycles and 10 cm spacing, their effect is only 0·16 per cent, which is practically negligible. This can be said to prove the case for the expression $2 \log_e (d/r)$ as against any expression of the form $\log_e [(d-r)/r]$.

Prof. W. Cramp and **Mr. G. M. Harvey** (*in reply*): It is with great pleasure that we take this opportunity of acknowledging the work of Clark and Shanklin, published in 1919, and of Dr. Dwight himself, which appeared in 1924. The former was published before our own early work, but we did not see it until long afterwards. We have definitely said that, in the absence of any new evidence to the contrary, the use of $\log (d/r)$ is satisfactorily established for all practical purposes and requires no further proof. Clearly, Dr. Dwight fully endorses also our conclusions (*a*) and (*b*) on page 336 (vol. 67) of the *Journal*. It is true, as he points out, that in an electrical network a potential difference often exists between two points, and that this disappears when contact is made, causing a corresponding change or re-distribution of current and of losses. A change of this kind is precisely what we sought but (for reasons given) failed to find; and we know of no published figures which give definite information on the matter. Clark and Shanklin afford no help, since they do not appear to have used a spacing less than 3 in. with cables having an overall diameter of 2·47 in. We agree with Dr. Dwight's declaration that no complete formula has yet been published, and we look forward to his new solution, which we hope will complete the theory of this problem. We confess to a certain feeling of trepidation when we see that he only describes his new formula as "practically" complete; but we shall continue to hope for the elimination of the adverb.

DISCUSSION ON
"DIRECT GENERATION OF ALTERNATING CURRENT AT HIGH VOLTAGES."*

EAST MIDLAND SUB-CENTRE, AT LEICESTER, 29TH OCTOBER, 1929.

Mr. B. A. M. Boyce: In spite of the ingenuity spent on the design of this alternator, I do not consider it to be the best solution for a modern machine. The authors have not given any winding temperatures, and I feel that, however easily the conductors are rated, the temperature of the bull will be very high as there are three temperature gradients in series above the tooth iron before the bull is reached, and differential expansions must take place. The insulation is impregnated; hence the insulation has something besides mica in its composition which may cause air pockets due to the temperatures and expansions mentioned above, with the consequent formation of ozone. If this occurs, serious trouble will follow. The authors have carefully explained the low voltage between the outer conductors and earth; but if, as I understand to be the case, the neutral is not earthed, I contend that it is necessary to insulate the whole winding equally from earth if the same factor of safety is desired. I cannot see how the efficiency of the author's machine can compare with that of a low-voltage machine coupled to transformers. I also feel that the presence of transformers is a distinct advantage in the event of surges taking place, as they act as buffers. I suggest that the best design for any turbo-alternator is one having 1 bar per slot, and that the voltages should be chosen to meet this condition and then stepped up to the required value by transformers. The firm with which I am associated has made several sets, using 1 bar per slot, in which the current per set is from 8 000 to 10 000 amperes. The insulation is mica 0·08 in. thick, so that the temperature gradient is small. The breakdown voltage on these bars was 26 000 volts.

Mr. E. A. Mills: There has been a gradual increase in generator voltage, extending over a number of years, the higher voltages being mainly due to the increase in generator capacities. Factors contributing towards the use of larger machines are the increased efficiency obtainable, which is of far greater importance in the larger machines than with the smaller units, and the difficulties experienced in dealing with the machine leads. The authors have produced a machine to generate at a pressure of 33 000 volts. This pressure has been in use in this country for the interlinking of systems and, on some of the larger systems, as a distribution pressure, and, as the authors point out, in certain areas a saving would be effected by direct generation at this pressure. The success of generating direct at a pressure of 33 000 volts will depend entirely on reliability being assured, and on the achievement of an efficiency at least equal to that obtainable with lower-voltage machines.

Mr. L. H. L. Badham: By means of a novel development of the intersheath principle, the authors have obtained a stator winding such that, in the core portion, the electrostatic conditions do not differ appreciably from those of machines of normal voltages. This, however, has necessitated a weak arrangement of joints at the overhang. The right-angle joints appear to be such that they would have to be made with clips or soft solder, in order to avoid damaging the insulation; also, these joints do not lend themselves to effective sealing. As regards the overhang, this is practically a standard arrangement and it would be interesting to know whether any corona was visible when the machine was completely erected. Experiment shows that corona may be visible when a machine is stationary and that this disappears when the machine is running and consequently the windings are in a strong draught of air. I recently inspected in India the 22 000-volt synchronous condensers which were built at Rugby, after they had been in commission for 2½ years. These were of special design to eliminate corona and were quite successful. There was no smell of ozone and no sign of marking on the insulation. The damaging effect of corona is due to the formation of nitrous compounds from combination with the air, which attack the insulation. If, therefore, the machines were designed to be ventilated and cooled with some other gas, the ill effects of corona could be reduced. Hydrogen has been found to be a satisfactorily medium for rotatory machines, since the windage losses are considerably reduced, its cooling properties are very superior to those of air, and corona effects are very small. For very-high-voltage machines it seems that development will involve the use of some cooling agent other than air.

Mr. C. A. Brearley: Some of the critics of direct generation at high voltages with direct coupling to the line have expressed doubts as to the wisdom of eliminating the transformer because of the effect of the latter in reducing short-circuit currents. May not the elimination of the transformer, where, as in this case, the generator appears to have ample inherent reactance and mechanical strength to cope with short-circuits, be of direct advantage in eliminating one piece of apparatus where higher harmonics may be introduced or accentuated? Do the authors think that this may be one of the causes helping to account for the very satisfactory operation of the 33 000-volt generator at Brimsdown in dealing with line disturbances? Perhaps useful information on this point might be obtained if oscillograph records could be taken on both sides of the transformer coupled to the 11 000-volt set, and studied in conjunction with oscillograph curves of the 33 000-volt set.

Mr. R. H. Wilmot: The authors have certainly advanced a strong case for the 33 000-volt alternator, and it must be admitted that this is a very definite step forward in the history and knowledge of electrical generation. Certain electrical engineers have questioned the possibility of satisfactory insulation at such a voltage. Surely, apart from the generally recognized success of 33 000-volt underground-cable insulation and practice, the use of concentric conductors and the method of insulation put forward by the authors, together with its admitted practical success at Brimsdown, should be a sufficient guarantee of security and reliability for even the most sceptical critic. Assuming that the reliability of the 33 000-volt alternator is equal to that of the 11 000-volt alternator and transformer, the next question to be faced is that of initial cost, and closely linked with this is operation efficiency and running cost. The authors have shown that the approximate reduction in initial cost, using the 33 000-volt alternator scheme, is £10 000 (for a 75 000-kW plant). Assuming capital charges at 15 per cent (to cover interest, depreciation, maintenance, repairs, rent, rates and taxes), the extra annual running cost with the 11 000-volt alternator and transformer scheme is £1 500. This represents an additional cost of 0·00109d. per kWh, assuming 50 per cent load factor. With regard to the question of efficiency, it would appear that the full-load efficiency of a 25 000-kW 11 000-volt alternator would not exceed 97·5 per cent. The efficiency of 11 000/33 000-volt transformers could not be taken at much more than 99 per cent, which makes the overall electrical efficiency of the 11 000-volt scheme 96·53 per cent. From Fig. E (vol. 67, page 1136) of the authors' reply, the full-load efficiency of the 25 000-kW 33 000-volt alternator is given as 97 per cent. Hence the additional losses with the 11 000-volt scheme would appear to be $97 - 96{\cdot}53 = 0{\cdot}47$ per cent of 75 000 kW = 350 kW. This represents £640, or an additional cost of 0·00047d. per kWh, assuming 50 per cent load factor and taking losses at 0·1d. per unit (as assumed in the paper). It would therefore appear, taking into account the initial and running costs for the 75 000-kW plant considered, that the annual running cost of the 11 000-volt alternator and transformer scheme is £1 500 + £640 = £2 140 (representing 0·00156d. per kWh) more than that of the 33 000-volt direct-generation scheme. Surely this in itself, particularly at the present time when power station engineers are searching for every possible means of improving station efficiency, would commend the 33 000-volt direct-generation scheme for serious consideration. Direct generation would therefore seem to be very advantageous in cases where distribution at 33 000 volts is being carried out. At higher transmission voltages, such as 150 000 volts, it is essential to use a transformer, and for such cases it would appear that there is no advantage to be gained by generating at 33 000 volts rather than at 11 000 volts, as step-up transformers would be required in either instance.

---

* Paper by the Hon. Sir CHARLES A. PARSONS and Mr. J. ROSEN (see vol. 67, page 1065).

Sir Charles Parsons and **Mr. J. Rosen** (*in reply*): Replying to Mr. Boyce, the heat to be dissipated per unit area from the conductors is lower than that in a conductor of normal design, so giving low losses, low temperature-rises and high efficiency. This was explained in reply to previous discussions. No difficulty has been experienced with ozone.

We are glad to have Mr. Mills's views. The fact that the high-voltage alternator at Brimsdown continues to run very satisfactorily at 34 500 volts indicates that machines of this voltage can be designed to be equally as reliable as low-voltage plant.

In reply to Mr. Badham, the wires from the conductors are stemmed into the loops formed in the end-connections in a very similar manner to that adopted in our standard alternator construction. This joint has proved to be sound. There has been no sign of corona on any occasion with the alternator excited up to its full voltage. We agree that hydrogen might be used with advantage, but it is at present unnecessary to depart from the usual method of air circulation.

We are in agreement with Mr. Brearley on the question of elimination of transformers, so avoiding the danger of accentuating harmonics which might then become a source of trouble. The wave-forms of the high- and low-voltage alternators are practically the same, but it has not yet been possible to obtain oscillograms so as to ascertain the effect of step-up transformers on the wave-form of the low-voltage machine.

We are glad to have the figures which have been submitted by Mr. Wilmot. On the whole they agree very closely with our own figures and show clearly the advantage, both in initial outlay and in operating costs, of direct generation at high voltages. The method of calculation adopted demonstrates very clearly the economic advantages of the high-voltage generator.

PROCEEDINGS OF THE INSTITUTION.

792ND ORDINARY MEETING, 21ST NOVEMBER, 1929.

(Joint Meeting with the Institute of Fuel.)

Colonel Sir T. F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 7th November, 1929, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A general discussion took place on the subject of "Low-Temperature Carbonization of Fuel, with special reference to its Combination with the Production of Electricity" (see page 229), with introductory papers by Mr. S. McEwen (see page 205), Prof. P. Rosin, Dr. Ing. (see page 212), and Messrs. E. H. Smythe and E. G. Weeks (see page 219).

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.45 p.m.

793RD ORDINARY MEETING, 28TH NOVEMBER, 1929.

Captain J. M. Donaldson, M.C., Vice-President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 21st November, 1929, were taken as read and were confirmed and signed.

A paper by Mr. H. W. Taylor, Member, entitled "Voltage Control of Large Alternators" (see page 317), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7 p.m.

INSTITUTION NOTES.

Faraday Medal.

The Council have made the ninth award of the Faraday Medal to Sir Ernest Rutherford, O.M., F.R.S.

Lending Library.

A new edition of the Lending Library Catalogue has been published. Copies can be had on application to the Secretary.

The Benevolent Fund.

The Committee of Management desire to draw the attention of the members to the appeal for funds which will be found on the last page of the cover of this issue of the *Journal*.

Informal Meetings.

115TH INFORMAL MEETING (28TH OCTOBER, 1929).

Chairman: Colonel Sir Thomas F. Purves, O.B.E.

Subject of Discussion: "Systematic Research by Industrial Undertakings" (introduced by the President, Col. Sir Thomas F. Purves, O.B.E.).

Speakers: Messrs. J. R. Bedford, W. A. Erlebach, E. S. Ritter, J. F. Shipley, A. F. Harmer, P. Dunsheath, O.B.E., W. Day, W. A. Gillott, A. N. D. Kerr, W. Lang, T. Wadsworth, W. E. Warrilow, J. G. Hines, C. G. Garton, T. N. Riley, H. Craske, F. Ockenden.

116TH INFORMAL MEETING (4TH NOVEMBER, 1929).

Chairman: Mr. J. R. Bedford.

Subject of Discussion: "Paris and the Pyrenees: Notes on some of the Technical Features of the I.E.E. 1929 Visit" (introduced by Mr. R. Borlase Matthews).

Speakers: Mr. Ll. B. Atkinson, Major T. Rich, Mr. A. F. Harmer, Mrs. H. E. Hall, Messrs. A. J. Cridge, E. S. Ritter, W. R. Rawlings, Miss Atkinson, Messrs. W. G. C. Jackson, R. S. Downe, A. C. Brown, J. R. Bedford.

117TH INFORMAL MEETING (11TH NOVEMBER, 1929).

Chairman: Mr. W. Lang.

Subject of Discussion: "Temporary Expedients in Engineering" (introduced by Mr. W. E. Highfield).

Speakers: Messrs. J. F. Shipley, A. Morgan, M. Whitgift, W. J. Minton, G. F. Bedford, A. F. Harmer, N. Prentice, E. S. Ritter, L. J. Gooch, T. H. Dennis, W. A. Erlebach, G. C. Allingham, A. N. D. Kerr, A. J. N. Kennett, S. B. Jackson, D. J. Watkins, W. Lang.

118TH INFORMAL MEETING (25TH NOVEMBER, 1929).

Chairman: Mr. R. Grierson.

Subject of Discussion: "Wooden Poles for Overhead Transmission Lines and their Preservation" (introduced by Mr. C. Wade.)

Speakers: Messrs. R. Grigg, G. V. Twiss, A. F. Harmer, R. H. Herford, E. S. Ritter, S. C. Bartholomew, R. G. Bennett, N. Prentice.

119TH INFORMAL MEETING (9TH DECEMBER, 1929).

Chairman: Mr. W. E. Bradshaw.

Subject of Discussion: "To Earth or Not to Earth" (introduced by Messrs. T. C. Gilbert and W. R. Rawlings).

Speakers: Messrs. A. H. Dykes, A. F. Harmer, Dr. K. Ekstrom, Messrs. H. W. Ellis, E. S. Ritter, C. J. Banister, S. W. Melsom, A. J. Bousfield, F. E. Phillips, D. J. Watkins, B. Higgs, W. Lang, W. A. Ritchie, A. Morgan, A. Edwards, W. E. Bradshaw.

THE ELECTRICAL PLANT AND NETWORK OF THE SOCIÉTÉ ÉLECTRIQUE DE LA SIDÉRURGIE LORRAINE.

By L. A. E. SÉKUTOWICZ and A. EVAIN.

(*Paper received 12th September, and read at the Joint Meeting of* THE INSTITUTION *and the* BRITISH SECTION *of the* SOCIÉTÉ DES INGÉNIEURS CIVILS DE FRANCE, *12th December*, 1929.)

SUMMARY.

The history and development to 1929 of the pooling arrangement by which some 60 per cent of all the electric generating plant in the Lorraine steelworks is regulated and the electricity sold is generally described. Of the 3 600 000 cubic metres of blast-furnace gas available, half is used for processes in the various works and the other half for generating electricity. Most of this electricity is used in the works. Nominally some 100 000 kW are available for export sale.

An overhead network interconnects, through substations, 10 power stations with an output of 125 000 kW, all working in parallel. Some 65 per cent of the power is developed by gas engines whose want of overload capacity throws too much of the inevitable load fluctuation on the gas-fired steam-turbine sets. These latter are being increased to a capacity of 74 000 kW distributed in 7 works, and some of the boilers are not being fired only with blast-furnace gas but, if desired, also with pulverized fuel. The whole working is controlled by telephone by a load dispatcher.

TABLE OF CONTENTS.

Introduction. Historical note; object.

Conclusion.

INTRODUCTION.

As far back as 1918, and therefore during the course of the War, the Mining and Metallurgical Technical Commission of France foresaw the necessity for the reconstruction of the mines and works which had been devastated in the Lorraine region and for the construction of a network to transmit electrical energy to them during the period of reconstruction.

Apart from the provisional help that could be given to the victimized companies by constructing a transmission network coupling their installations together, the ultimate aim of the promoters of the scheme was the realization of a permanent pooling of the means of production of electrical energy by running the metallurgical power stations in parallel in order to ensure the regularity and continuity of the supply of energy to the works; the transmission lines were also to be designed to allow of the sale of the energy generated in the power houses by surplus blast-furnace gas.

The firms which were brought under consideration comprise, at the present time, excluding the Belgian and Luxembourg works:—

8 pig-iron foundries (excluding steelworks), with 30 blast furnaces; and
12 complete works, with blast-furnaces, steel-producing plant and rolling mills, comprising 70 blast furnaces.

These works are capable of supplying annually 7 million tons of cast iron, which corresponds to a total output of 3·6 million m^3 of blast-furnace gas per hour.

Deducting from the above the needs of the blast-furnace services proper (the heating of the cowpers, blowers and accessories), it should theoretically be possible to dispose of 1·8 million cubic metres of gas per hour for purposes other than blast furnaces, which is equivalent to 240 tons of coal per hour of a calorific value of 7 000 calories per kg. This should produce from 300 000 to 400 000 kW according to the system employed, i.e. gas engines or turbines.

If we take into account the amount of energy required for the purposes of the central stations themselves, we can estimate a surplus amount of energy available for sale of up to 100 000 kW.

The installations that have so far been completed comprise 10 works, which include 60 blast furnaces.

In order to carry out this programme the principal metallurgical companies and the Omnium Lyonnais (a firm which specializes in the industrial applications of electrical energy and which would provide the technical service of the future company) grouped together to form a technical department for the construction of future schemes and in 1920 created the Société Électrique de la Sidérurgie Lorraine, with a capital of 8 million francs.

Negotiations with the Government which were commenced in 1920 were only successfully concluded in 1924. The concession to transmit applied to the creation of an overhead ring-main at 65 000 volts tied-in to the State station at Landres, which was built earlier by the State on the 120 000-volt line which connected some Swiss works and the works in the French Ardennes and the network at 65 000 volts from the mines of La Houve (Fontoy substation). These two distribution concessions gave rights for a ring main at 30 000 volts to connect the mines (and the less important works) to 65 000/30 000-volt substations which were connected to the high-tension network.

The network and an outline of the distribution area of the Société are shown in Fig. 1. This indicates the geographical position of the installations of the company between the super-power stations, either built or under consideration, of La Houve, Strasbourg, Kembs and Vincey, and is designed to allow of large interchanges of energy.

The initial programme, which is still being carried out, should be completed very shortly by the installation of new power stations designed to utilize the surplus gas products in each of the metallurgical works forming part of the group.

Part (1). Description of the Installations.

(1) *Technical Basis of the Scheme.*—The first detailed examination in 1919 showed that the company would be able to dispose of surplus energy which to all intents and purposes would increase and develop in proportion to the technical progress made in the metallurgical works. It was expected, however, that new processes (electro-metallurgical, electro-chemical, etc.) would perhaps create such a large local demand for power in the works that they might in time even absorb the increasing surplus of power, and this would be detrimental to the financial efficiency of the undertaking. It was therefore necessary to consider the technical part of the programme very cautiously, and in such a way that the whole scheme would be particularly elastic not only from the commercial but also from the technical point of view. On the other hand, the company could only bring in its constituent members successively, and certain of those who subscribed to the undertaking in its initial stages hesitated when it approached fruition.

From the technical point of view the idea of the general parallel running of interconnected power stations involved difficulties and objections which do not seem to be overcome everywhere, even to-day, for in 1928 a German technical journal stated that central stations driven by blast-furnace gas engines cannot run satisfactorily under these conditions.

Now it was only by adopting the programme as a whole that the advantages of this system could be fully realized. In order to appreciate this, the basis of operation of these works must be remembered. The number of blast furnaces in operation in a works only varies over a relatively long period in such a way that their cycle is relatively constant. If we leave out of consideration for the moment the inevitable variation of quantity and quality due to ordinary running troubles, the repercussion of which diminishes as the number of blast furnaces in use increases, the daily and annual production of gas is sufficiently constant. The amount of gas used for heating the cowpers may momentarily upset this regularity. On the other hand, it has been noticed that this type of apparatus is relatively elastic; they act as heat accumulators and can be used to regulate to a certain extent the amount of gas available for power purposes. These gases are always surplus in pig-iron works that do not produce steel.

At the present time, in complete works comprising steelworks and rolling-mills the last-named work in two or three shifts during the 24 hours. During the change-over periods there is a surplus of gas because the gas blowers of the steelworks and gas-heating appliances are more or less completely shut down. The rolling-mill and accessory motors are also out of service. Therefore a complete works disposes of a surplus amount of power and energy during at least a part of each day of the week. During the whole of Sunday, when the steel production is at a standstill, the total amount of gas production is available.

During the working periods there is also surplus energy, but this surplus varies considerably during the course of an 8-hour shift, as it represents the difference between a relatively constant total production and the extremely variable needs of the steel-producing plant and of the rolling-mills.

The steelworks blower takes from 1 800 to 2 000 kW and is only worked intermittently. An electric rolling mill may absorb 12 000 kW instantaneously and 4 000 kW practically constantly. The running-up of gas engines corresponds to an increase in the available power of from 2 000 to 4 000 kW, and their shutting down to a corresponding decrease. These sudden peaks are a very serious problem for an isolated metallurgical power station, the continuous rating of which may be 10 000 kW, with 15 000-kW peaks and a total installed capacity of, say, 18 000 kW. The shape of the load curve resembles rather closely that of a traction supply. On account of the small amount of elasticity in gas engines, which cannot take an overload without slowing up, and which consequently cause a large variation in the voltage and frequency of the network, all the apparatus connected to the network is adversely affected.

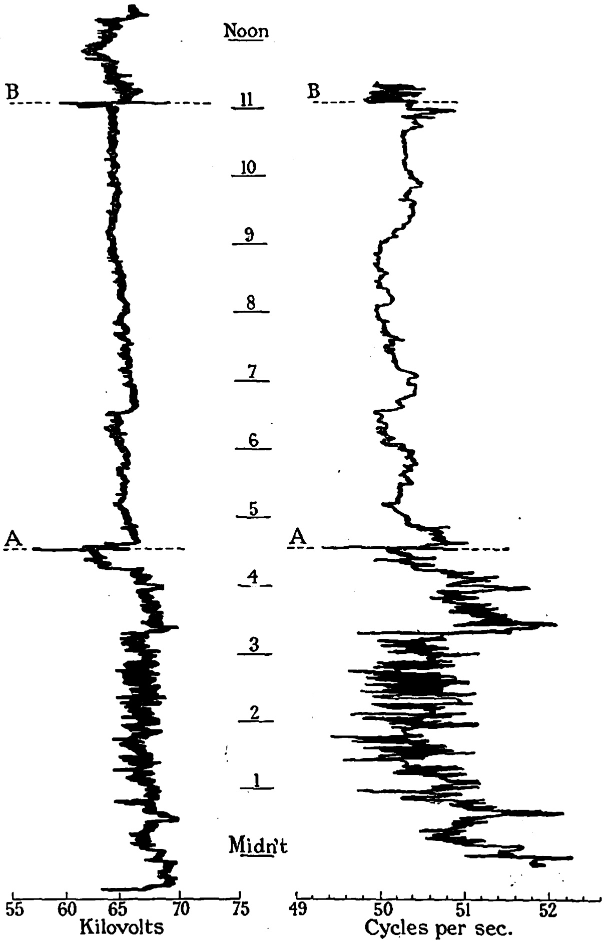

Fig. 2.—Voltage and frequency charts of the company's network for the 5th August, 1929.

General parallel running attenuates very considerably the relative importance of these peaks and regularizes the voltage and frequency (see Fig. 2). Experience has shown that this allows of a considerable increase in the production of rolled steel; this has given much advantage to the steelworks connected to the network of the company. On the other hand, when these stations are not interconnected power peaks give rise to loss of gas and general inefficiency in utilizing the product, for there are practically no gas reserves in works at the present day. Furthermore, the running in parallel of a number of power stations allows a reduction in the amount of stand-by plant which has to be installed in each one of them, as at any time and nearly everywhere at certain hours there is a surplus amount of gas. This method of running produces further energy at no cost other than that which corresponds to a reinforcement of the gas-washing plant.

All the above advantages, including the very great advantage of being able to dispose of the total number of generators and to run on light load only those whose efficiency is satisfactory under these conditions, have been known for a long time [*] and have not been lost sight of by the promoters of the company. The possibility of mutual interchange of power in the case of accident is of further advantage to the system.

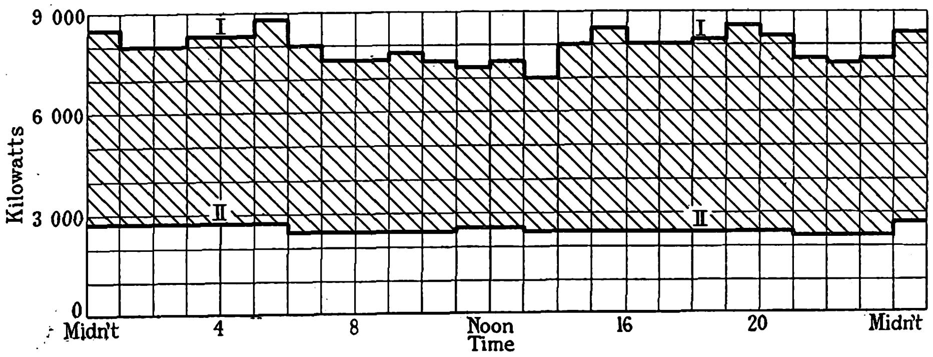

FIG. 3.—Load curve of a pig-iron works without steel manufacturing or rolling-mills.

Curve I = Total output of machines. Curve II = Power utilized in the Company's works.

The area between Curves I and II represents the output supplied to the network.

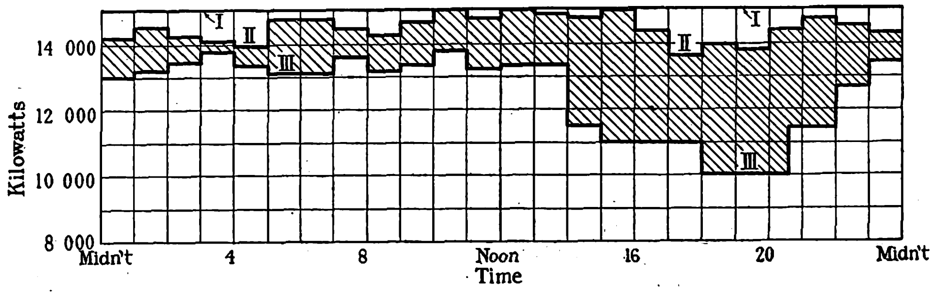

FIG. 4.—Load curve of a complete metallurgical works.

Curve I = Capacity of machines in service. Curve II = Total power supplied. Curve III = Power utilized in the Company's works.

The area between Curves II and III represents the output supplied to the network.

But however advantageous the recuperation of energy during working hours may be, the utilization of the energy which can be produced by employing waste gas, particularly during the change-over periods, is even more important.

Figs. 3 and 4 show the means available in a works, (*a*) without steelworks or rolling-mills; and (*b*) with steel plant and rolling-mills.

On account of labour difficulties the off-periods are grouped during the night hours when the available energy is unfortunately difficult to utilize on the neighbouring distribution networks. In order to obtain a market for the surplus it is necessary to feed a very large area in such a way that some steam power stations may close down entirely during the night.

Another method of overcoming the difficulty would be by shifts rotating with respect to each other. For instance, a rotation covering several complete works each having two shifts would allow practically constant production in the 24 hours and of energy being supplied to electric furnaces, for instance. It is even possible to arrange this rotation in such a way that when the peak load comes on to the distribution company's station the amount of surplus energy available in the steelworks would be the maximum, and this is very important from the commercial point of view.

Such methods as these are only possible in practice if, when all the stations are running in parallel, the works production, and therefore the consumption, can be regulated at will.

The incorporation in such a general scheme of a stand-by coal station, or even a hydro-electric station with a large reservoir, would be of very great advantage, but could only produce its full effect if the parallel running were general. This point will be dealt with later in the paper.[*]

---

[*] See in particular the work of Mr. Courtoy, the promoter of the Union des Centrales de Liége.

[*] The late Mr. de Loisy showed in particular that there is no practical economic means of storing either blast-furnace gas or steam, or even their heat or their energy, in order to overcome peaks or to store available quantities produced during the off-periods. However, one of the works of the group which has a coking plant has just installed a gasometer for coke-furnace gas which will hold the equivalent of 10 000 kW, but in order to reap the best advantage it is necessary at certain times to substitute blast-furnace gas for coke gas for heating. The use of the lower levels of the mines, in order to vary artificially the amount of pumping required, only provides, when it can be adopted, an insufficient palliative.

Up to the present time the construction of steam power stations as general reserves has been postponed, and a call has been made on the turbo-alternator sets of the various members of the company and on the neighbouring steam power stations. This is now being remedied by installing in the power stations of several of the members of the company a number of turbo-alternators having a total capacity of 74 000 kW with gas-heated boilers, one of these being so designed that pulverized coal may also be used. If the general parallel-running scheme is in operation the sets will be able to run at their full efficiency. To illustrate this point, Fig. 5 gives a curve showing the hourly output available at the present time, and Fig. 6 the shape of the load curve of a large distribution company.

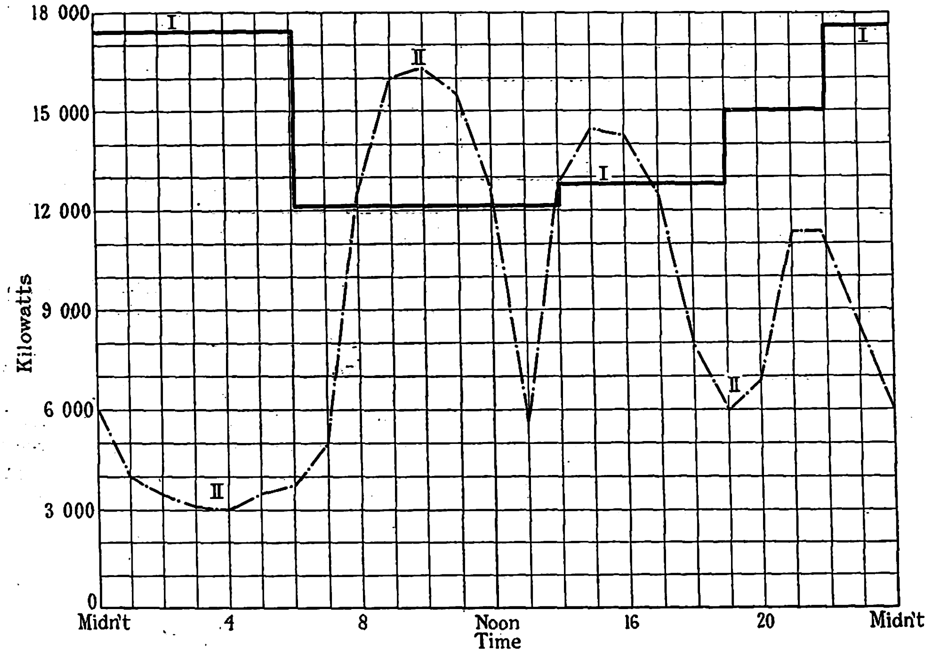

FIG. 5.—Diagram showing the power available on the company's network throughout the day.

Curve I = Power available for disposal. Curve II = Typical load curve of distribution network.

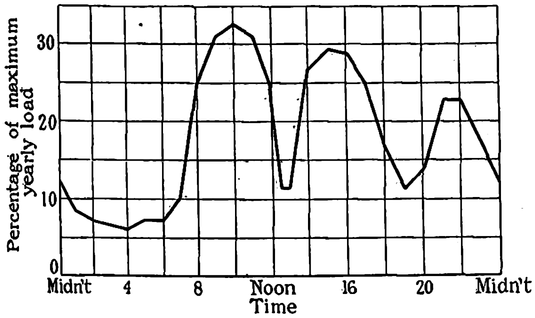

FIG. 6.—Summer load curve of a steam power station.

The advantages of general parallel-running as between works and with neighbouring distribution companies were well established from the beginning, but objections were always raised by those who feared that operation would be difficult or impossible in practice. These fears were based on the irregularity of the generating sets (4-stroke blast-furnace gas engines with either 2 or 4 single or double tandem cylinders).

The relative importance of peaks decreases with the number of interconnected production centres as and when developed. In regard to gas engines, the possibility of running them in parallel in some works when subjected to heavy peaks was well known. It was therefore sufficient to connect them together by a sufficiently small impedance and to run the machines under conditions which would approach parallel running with short connections from terminal to terminal. The impedance of the company's 65 000-volt lines is of the order of 0·42 ohm per km.

Two further difficulties remain. On the one hand steam power stations of neighbouring distribution companies would become connected to the metallurgical power stations by a network of lines and substations, the total impedance of which is not negligible and, on the other hand, gas engines would have to run in parallel with powerful steam-turbine stations which have a practically fixed frequency and would work under conditions slightly different from those which existed formerly. This difficulty will be referred to again later in the paper.

It appeared that the installation of steam sets in metallurgical stations would simplify the problem. It was thought that the adoption of a pressure of 65 000 volts * was sufficient to allow the first condition to be satisfied, and experience has confirmed this view. A higher voltage would have resulted in stations being too expensive in relation to their power, whereas a lower

---

* Although not standard in France this voltage has been adopted because it is that of the nearest distribution company which agreed to serve as the first stand-by, and because at that time this voltage could have been used for single-core underground cables if the latter had to be employed at certain points.

voltage would have given rise to regulation difficulties and a greatly increased amount of copper. It would also have made the development of the network more difficult.

For the secondary networks, after a period of indecision as to whether to adopt voltages of between 15 000 and 17 000 volts, and on account of the amount of power required by certain mines, the company decided to adopt a voltage of 30 000. This was the highest voltage that could be used at that time, and if it was proved necessary in certain places to use 3-phase cables, such a voltage allowed the design of economical transformer stations, and well-designed and well tried-out gear at this voltage was obtainable. It was also felt that certain supporters of the scheme might be tempted to employ second-rate 10 000- or 15 000-volt plant which would not be sufficiently good for the service, whereas it is practically impossible to obtain second-rate 30 000-volt plant.

Practice has entirely justified the choice of these two voltages. Furthermore, it is only in very rare cases that the company has had to employ underground cables (generally at 6 000 volts) for connecting the works substations to the corresponding generators, which in general are at a distance of less than 200 metres. In some cases very short lengths of 30 000-volt cables are utilized at the ends of lines inside certain substations.

The adoption of 65 000 volts also allowed the use of rigid insulators. This type of insulator was chosen for reasons of economy. These insulators have had to be reinforced, and on the last line, erected in 1929, the suspension type was employed.

Rigid insulators, as such, have not really given rise to any trouble (with the exception of the breakage of a number of petticoats), but numerous short-circuits have ruptured a number of insulators and have even fused the line. This difficulty has been overcome by gradually and carefully earthing the neutral at a certain number of points on the network.

The results of this protection have not yet been sufficiently definitely established, but up to the present no disadvantages which can be traced to the earthing of the neutral have become apparent.

The interruptions to the supply caused by the above troubles would very probably have been avoided if from the outset a balanced selective protection scheme had been adopted, more particularly as all the company's poles were designed to carry six conductors and two earth wires.

It was for reasons of economy and on account of the high cost of the necessary outdoor transformers for operating the relays that the installation of this selective protection scheme was provisionally postponed. Since then the supply has utilized the two circuits separately, for reasons which are probably of a transient nature and which will be explained later. As a consequence the company is experimenting with impedance relays.

The factor of safety of the insulators in so far as puncture voltage is concerned was made sufficiently high to avoid the risks of perforation even for a voltage much in excess of the flash-over voltage. In the substations, surge protective gear was limited to the adoption of shunted inductance coils connected to each outgoing feeder,* and the transformers were so designed that their insulation to earth was very high (sufficient for 3 times the working voltage) and the insulation between turns was designed to withstand the full working voltage. Thus the insulators work rather effectively as voltage-limiting devices, although this is not their role. However, the lack of selective protection has made itself felt, as mentioned above. This question is now under consideration, as are also the questions of the general earthing of the neutral and the methodical reinforcement of the insulators in the more exposed regions, the data for which have been collected with the experience of the last few years of operation. The company is also examining very closely the effect of a recent theory which has been put forward to see whether these sections do actually correspond to zones in which the geological formation of the earth's sub-strata shows peculiarities.

With regard to the substations, the outdoor system was adopted from the beginning, not only from the point of view of economy but also to facilitate any reorganization or extensions to the network, as it was difficult to foresee what method of development would be adopted. In spite of the production by certain works of conducting dust in very large quantities, this system has given rise to no accidents in operation and has effected certain economies in building up the network which might have been paralysed at its inception by the financial crisis of the franc.

The works substations (65 000/6 000 volts) are simply liaison substations for the network and at the same time serve as disconnecting or by-passing substations. They are designed for one incoming and one outgoing feeder, each having 6 conductors. Each station is connected across the general ring main and can be disconnected from the circuit without interrupting the continuity of the ring.

The interconnecting station at Fontoy is a substation transforming the voltage from 65 000 to 30 000 for feeding the mines network, and at the same time for four 65 000-volt 6-conductor lines connecting the Micheville--Thionville and Landres stations, and has a local outgoing 65 000-volt feeder to a local station.

In all these substations the transformers are of the outdoor type with forced oil circulation of the external-tube water-cooled type. The first transformers were designed for 6 000 kW and were of the 3-phase core type. The later transformers were of the 3-phase shell type designed for 10 000 kW. Although the first transformers have given entire satisfaction the company is experimenting with the shell type, which appears to be stronger and to be better able to withstand the effects of short-circuits.

The whole of the control is operated by means of batteries from a small board placed in a shelter. The rupturing capacity of the circuit breakers was chosen to be very large on account of the great amounts of power available.

STABILITY OF THE INTERCONNECTED STATIONS.

The interconnected stations run along the frontier (Chiers Valley) and in the valleys of the rivers Fentsch and Orne, which are tributaries of the Moselle. The distance between the furthest stations does not exceed 60 km. This distance is small on account of the large amount of power interconnected, the voltage adopted and the cross-section of the lines.

---

* The capacity of the substation constitutes a certain measure of protection against surges.

Of the 15 stations situated in the French part of the mining area, 10 are connected to the network. The total amount of power of the latter is of the order of 125 000 kW, but all the units are not permanently connected to the network.

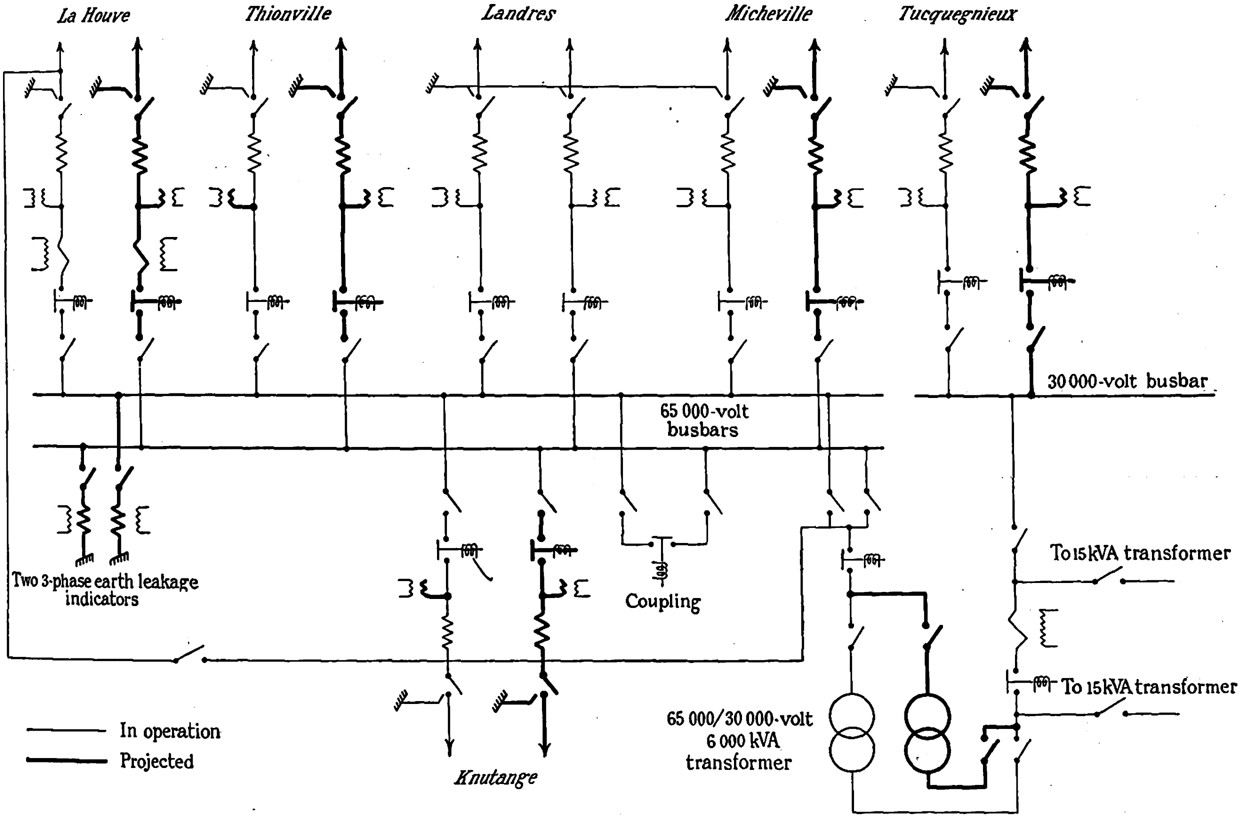

FIG. 7.—Diagram of connections of Fontoy outdoor substation.

The machines are as follows:—

5 four-cylinder gas engines	22 000 kW
20 two-cylinder gas engines	50 000 kW
15 turbo-alternators	45 000 kW
6 convertor groups connecting up works which run on direct current	9 200 kW

(The total power of these d.c. works is approximately 30 000 kW.)

The total power connected to the network is therefore supplied by 40 miscellaneous units, in the following proportions: gas engines 56 per cent, steam turbines 36 per cent, and convertors 8 per cent. If we include the generating units in the stations supplying the convertors the proportion of steam turbines drops to 32 per cent.

The gas engines are invariably of the 4-stroke type at 94 r.p.m. (with a few exceptions at 107 r.p.m.). The type of machine varies from one station to another. Efforts are being made to generalize scavenging, which up to the present is not employed except on a few of the units and which, amongst other advantages, increases the power of the engine.

Ignition is of the contact-breaker type from a separate source. The governor acts, according to the make of gas engine, either on the composition of the mixture or on the amount of inlet and, in certain cases, upon the time of ignition.

DEVELOPMENT OF THE COMPANY'S INSTALLATIONS.

In the first period of its development (1920–1923) the company concentrated its attention more particularly on the interconnection between the mines in order to facilitate pumping-out. To this end they constructed substations and local lines at 30 000 volts.

In 1924–1927, after having adopted the general plan of the network, 65 000-volt lines were constructed between Auboué–Landres and Fontoy–Thionville, and in 1925 the Fontoy substation on which the first test for paralleling between the Auboué and Thionville stations was carried out. In the following year Fontoy was connected to Micheville and Landres by 65 000-volt lines.

In the beginning of 1928 the majority of the larger works of the company were connected together, and the third period (1928–1929) began. This consisted of duplicating the lines, which were still provisionally of the 3-wire type, and completing the ring, more particularly by two new lines between Landres and Saulnes and Auboué and Thionville. In 1929 a new and greatly extended programme was established, including the installation in the 8 principal metallurgical centres of high-pressure turbo-alternators, which will be dealt with later.

When this programme is completed a sum of more than 45 million francs will have been spent by the company on the lines and for the substations, without taking into consideration the installations that have been carried out in the members' own premises (which amount to 63 million francs for new units only), a total of nearly 100 million paper francs (the gold value of which varied during the course of the work) having been invested in the scheme.

Below are given details of the more important installations which were designed in accordance with the principles mentioned above (see also Figs. 6 and 8).

65 000-*Volt Lines* (140 km).—These lines are on steel lattice poles, and are of the 6-wire type with rigid pin-type insulators having 4 petticoats.

	70 000-V type	80 000-V type	5-element suspension type (per element)
	kV	kV	kV
Puncture voltage ..	275	290	115
Dry flash-over voltage	165	185	240
Wet flash-over voltage*	115	136	162

* Resistivity of water assumed to be 4 000 ohms.

The average figures per km of line are as follows:—

Insulators: 40.

Copper (six 50-mm^2 wires): 2·7 tons.

Steel: 12 tons.

Cement (approximately 125 tons of foundations): 15 tons.

Inclusive cost: 80 000 francs (approx.).

30 000-*Volt Lines* (80 km).—These are also on steel lattice-work 6-wire poles with rigid pin-type insulators having 3 petticoats.

Puncture voltage: 115 000 volts.

Dry flash-over voltage: 110 000 volts.

Wet flash-over voltage: 45 000 volts.

Landres–Saulnes 65 000-*Volt Line* (25 km).—This line is of the 2-circuit type on steel lattice-work poles with 5-element suspension-type insulators.

Puncture voltage: 115 000 volts per element.

Dry flash-over voltage: 85 000 volts per element.

Wet flash-over voltage: 45 000 volts per element.

65 000/30 000-*Volt Substation at Fontoy.*—This station comprises five outgoing 2-circuit feeders; two of these are entirely equipped and three are as yet only equipped with the necessary gear for three wires and one outgoing 30 000-volt feeder equipped for three wires but with provision for six.

One 65 000/30 000-volt 6 000-kVA transformer interconnects these two networks.

The State Substation at Landres.—This substation places at the disposal of the company, in exchange for a subsidy supplied by the latter, three outgoing 6-wire feeders, two of which are fully equipped, and four 30 000-volt 3-wire outgoing feeders. In addition, the company has permission to use several lines which belong to the State network at the outgoing side of the Landres substation, including three outgoing 3-wire feeders which are equipped for 120 000 volts but are at present used at 65·000 volts, and which eventually may be used at a voltage of 150 000.

The installations are completed by 10 works substations, five of which are already equipped for 10 000 kVA and three more which are provided with 6 000-kVA transformers, in general at 65 000/5 500 volts, and are connected to the switching stations between the high-tension feeders. The most typical substation is that at Rombas. This contains a 10 000-kVA transformer, with provision for two more.

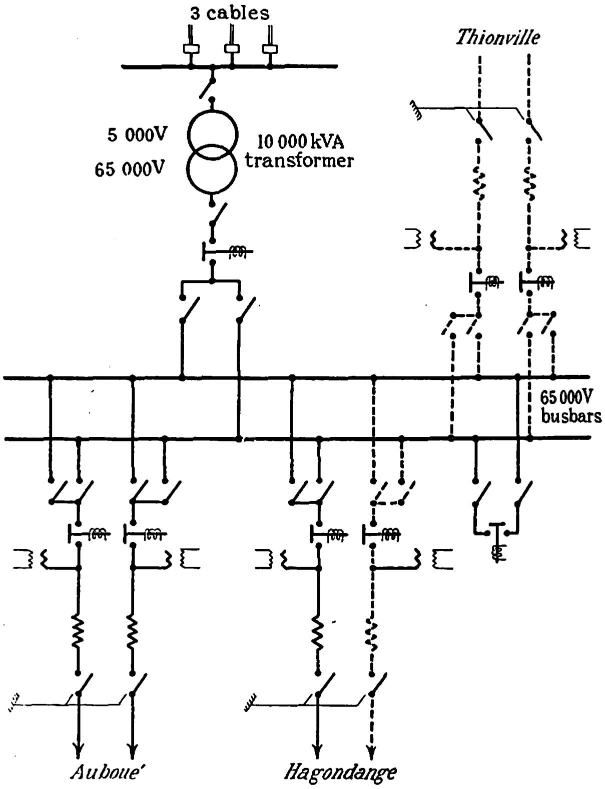

FIG. 8.—Diagram of connections of Rombas substation.

The telephone network of the load dispatcher is entirely distinct from the power network and is installed on the French State poles; it is equipped with selective calling apparatus supplied by the Western Union Telegraph Co.

Part (2). OPERATION OF THE NETWORK; PARALLEL RUNNING AND UTILITY OF THE NEW STEAM UNITS.

The first industrial test in connection with the parallel running of metallurgical central stations was carried out on the 25th March, 1925 (between Auboué and Thionville). These two were blast-furnace stations and were approximately 50 km apart; they were interconnected (provisionally at 30 000 volts) by a 3-conductor line (each conductor being of 50-mm^2 cross-section) and by two 6 000-kVA 30 000/6 000-volt transformers which fed a network supplying power to the mines. In August 1925 the 60 000-volt network of the Houve mines, fed by a 40 000-kW power station 70 km away from the above-mentioned power stations, was connected to the other network, the voltage of which had been increased to 65 000. The Micheville works were connected to the network in January, 1926. The Micheville station is a typical example of a complete steelworks with blast furnaces and rolling-mills, and contains a power station of 18 000 kW capacity.

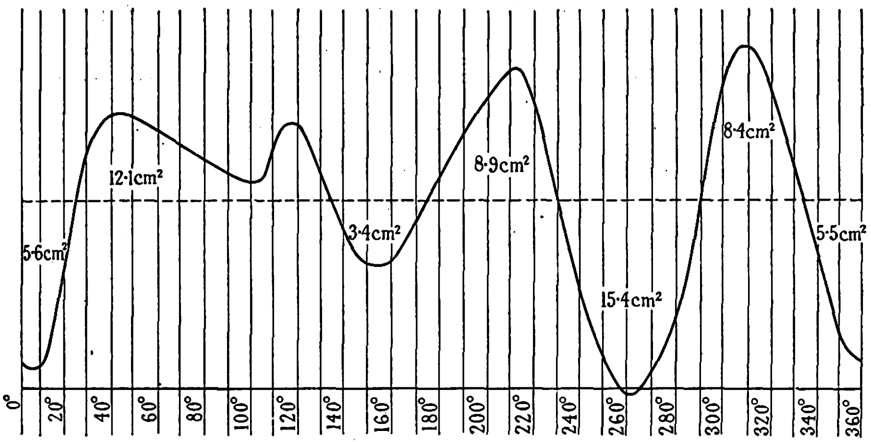

FIG. 9.—Torque curve of a 4-cylinder 4-stroke gas engine with 90° cranks.
1 cm = 30·02 kg.

Finally, since 1926, the Lorraine metallurgical group has been connected up to the distribution network of the Lorraine Electrical Co., fed by a steam power station of 50 000 kW at about 140 km from Landres. It already runs in parallel with a group of Swiss hydro-electric power stations. In the ordinary course of events the operation of these stations is eminently satisfactory * (see Fig. 2, which shows the frequency and voltage between the hours of 5.30 and 11 a.m.). For two reasons, however, a temporary service is adopted. The variation of the amount of power available on the metallurgical group's network, and the lack of elasticity of the gas engine, force the steam stations of the adjacent distributing companies to take up automatically the role of peak-load or buffer stations, for which they are not prepared. Again, if the load dispatcher of the company runs up a set without sufficient precaution after the breakers have tripped out, it is quite possible that the safety valves on the boilers in the steam stations may start to blow off. The remedy consists in the generalization of steam stations in the metallurgical stations by giving, if possible, to these new units a degree of sensibility of regulation which is closer than that of the units in the neighbouring companies' networks. Perhaps it will be necessary to consider a systematic modification of the degree of sensibility of the latter, the devices being so designed that they come into operation automatically as soon as parallel running with the metallurgical network commences. However, this remedy, which is very effective in connection with short peaks, requires elasticity in the production of the metallurgical stations. On account of the impossibility of storing the available gases this cannot be accomplished in the way that it should be done, i.e. ensuring a supply which is perfectly constant according to a predetermined time-table.

The difficulty is a commercial and not a technical one, and is eased somewhat by equipping the boilers of a certain number of the metallurgical stations with a means of using pulverized fuel.

The second difficulty is caused by peaks of short duration but of a periodic character, giving rise to a certain amount of hunting, which in turn affects the lighting and on rare occasions may make the defective generator fall out of step. This would not occur if all the units were in a perfect state of maintenance and if they were automatically tripped out as soon as their running became irregular. It is hoped to achieve this result by means of a reverse-power relay, and already parallel running has had the advantage of directing the attention of the station superintendents to these irregularities, which attentive local supervision cannot allow to pass. An examination of this phenomenon of hunting is not without interest and one of the authors' colleagues, Mr. Fournier, has analysed it experimentally in a very thorough manner.

His research may be summarized as follows: We know that a rotary electric generator possesses a certain period of oscillation which is a function of constant factors for a given machine (the moment of inertia of the rotating parts, the number of poles and the normal torque) and of a variable factor which depends both upon the machine and upon the network (the ratio of the impedance of the lines connecting the unit to the network to the internal impedance of the machine). The inherent period therefore depends to some extent upon the network. In our case it can cause a variation of the order of ± 25 per cent. If a rhythmic disturbance of a periodical character occurs, the frequency of which is of the same order as the inherent frequency of oscillation of the alternator, this machine will oscillate about

---

* In particular the normal variations of load have never given rise to any difficulty in maintaining the normal voltage at the points where the supply is used, nor has it been necessary to install any synchronous condensers or induction regulators.

the position which corresponds to its running in synchronism with the network,* and hunting can occur which may at times produce reverse power and may cause the machine to fall out of step.

Now the complete cycle of operations of a 2- or 4-stroke gas engine running at 94 r.p.m. recommences every two revolutions, that is to say, 47 times per minute. These characteristic irregularities correspond to the following frequencies (see Figs. 9 and 10):—

188 per minute (cycle of work done by gas in the cylinders).
94 per minute (angularity of connecting rod).
47 per minute (pre-ignition, misfiring, unbalancing in a cylinder).

The inherent frequency of oscillation of a turbo-alternator unit being of the order of from 90 to 140 per minute, there is but little danger of resonance, for the irregularities at frequencies of 94 and 188 are generally of small amplitude. In the case of flywheel-type alternators driven by gas engines the normal inherent frequency is of the order of 70 to 75 per minute and occasionally 60, and for certain conditions of connections of the network there is risk of this frequency approaching the figure of 47, which is the frequency of the most violent irregularites in running (pre-ignition in a cylinder).

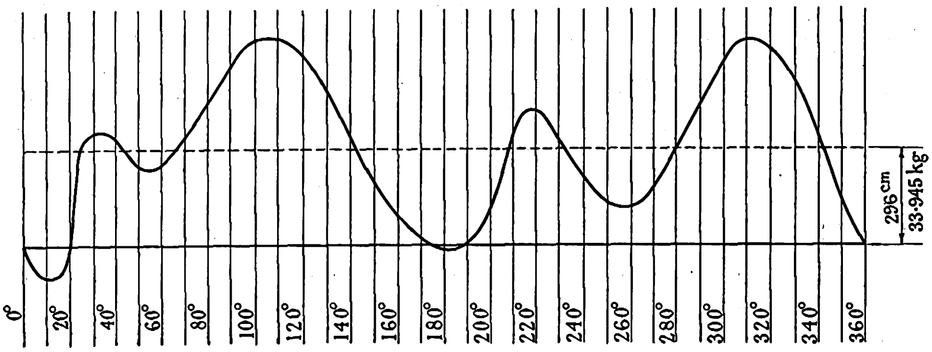

FIG. 10.—Torque curve of a 2-cylinder 4-stroke gas engine.

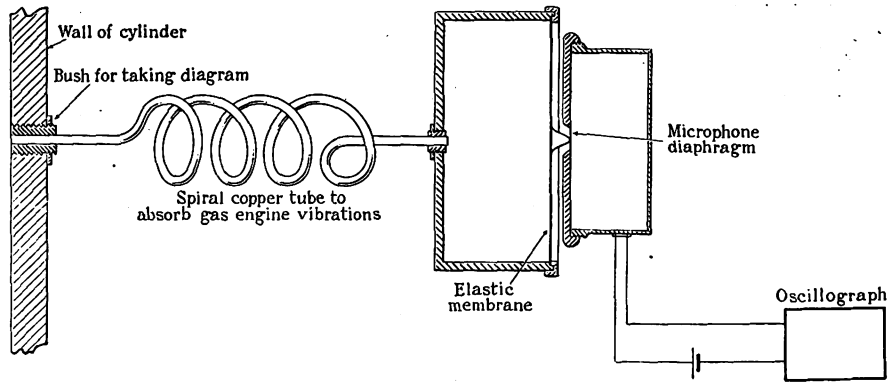

FIG. 11.—Piezo-microphonic device for recording the pressure in gas-engine cylinders.

Oscillographic records have confirmed these conclusions. When stations are run singly, hunting is not of much importance and relatively little attention is paid to the voltage or the frequency. The inertia of the flywheels takes its part in the regulation of the system and gives rise to what is sometimes considered as an improvement, that is to say the adoption of a very small coefficient of cyclic irregularity by using a considerable moment of inertia. (In practice the machines with the highest moment of inertia are precisely the type which give rise to the most dangerous hunting. This is very easy to explain on account of the preponderating importance that they assume in times of disturbance, owing to the exchanges of kinetic and electrical energy in the network.) Therefore for parallel running it is an advantage that all the units should have a reasonable moment of inertia, and that the moment of inertia should not vary very greatly. On the other hand, damping windings, by reducing the angular displacement during the hunting, amplify the oscillation of the alternator wattmeter.

It can also be shown that the greater sensitiveness of the turbo-alternators causes them to take part in these rhythmic exchanges of energy and that their distance apart does not protect them, but on the contrary can, on account of the impedance of the interconnecting line, produce conditions favourable to hunting. The remedy consists in developing the power of the turbo-alternator sets installed in the individual stations. This installed power represents practically 60 per cent of the total output. These theoretical considerations become quite clear in the light of the tests carried out by the authors' colleague, Mr. Fournier,* by means of an oscillograph connected to the alternator of a gas-engine unit and also by means of a device recording with another oscillograph the instantaneous pressure in one of the cylinders of the same gas engine, employing a microphone connected in such a way as to make it sensitive to variations in pressure (Fig. 11)*.

---

* These oscillations are quite visible by the stroboscopic method when several flywheel-type alternators are close together.

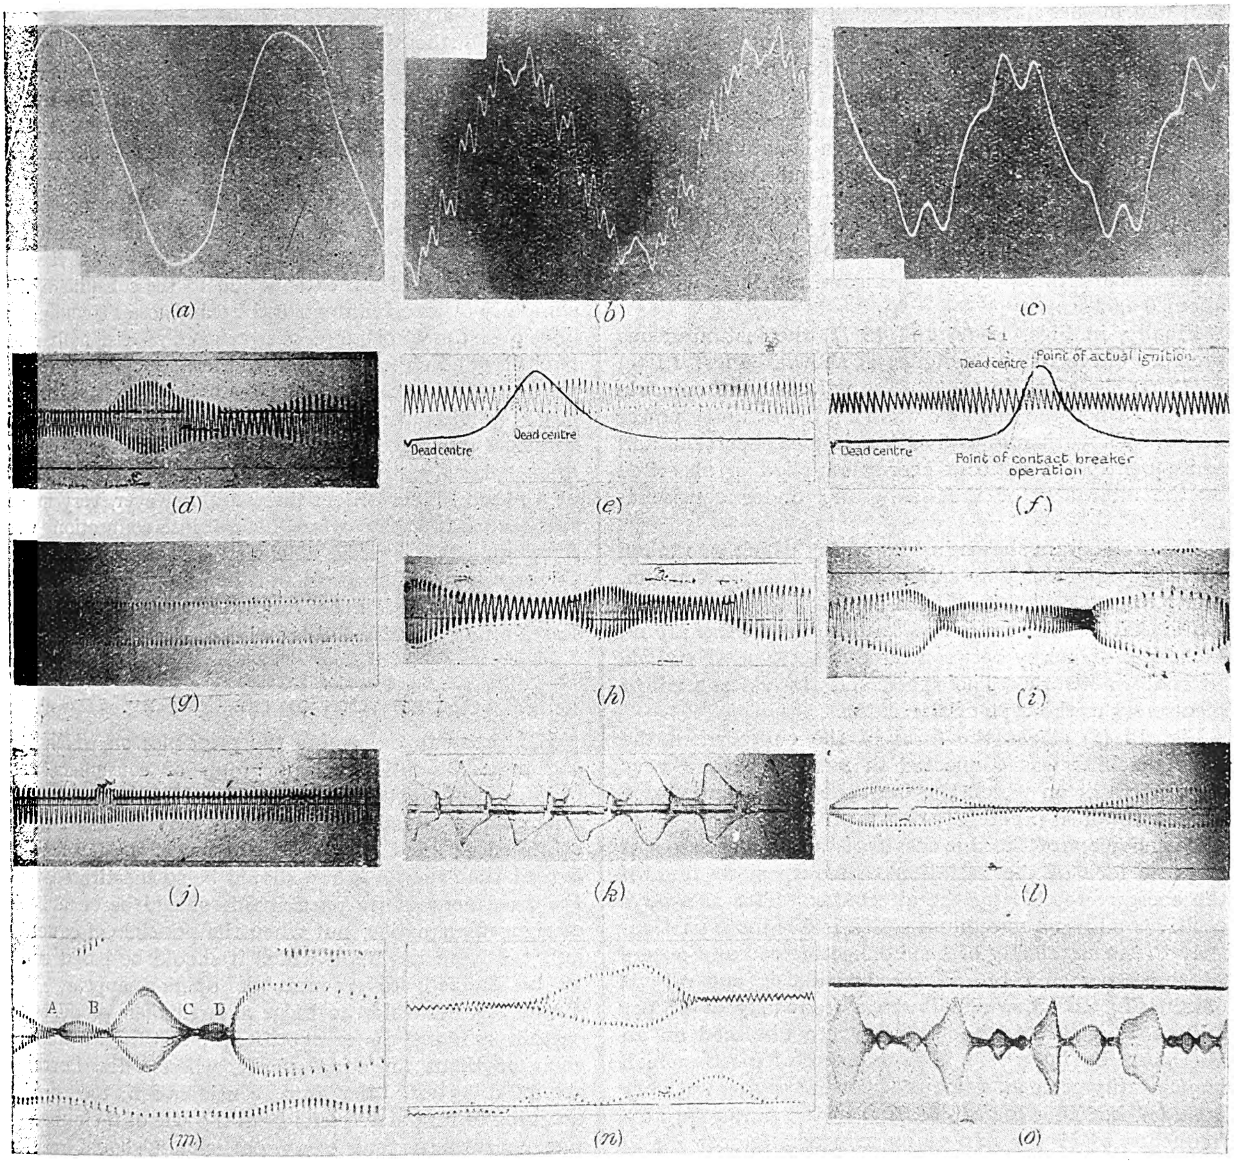

FIG. 12.—Oscillograms in connection with a gas-engine driven alternator running in parallel with the general network.

(a) Voltage curve of network.
(b) Tooth harmonic curve (gas-engine group) (artificially magnified).
(c) Tooth harmonics (turbo set) (artificially magnified).
(d) Ignition record.
(e) and (f) Instantaneous pressure curve in one of the cylinders.
(g) In-phase current of alternator feeding an independent local network.
(h) In-phase current of alternator feeding a large network (normal conditions).
(i) Pulsation at a frequency of 47 (per minute).
(j) In-phase current of alternator having high moment of inertia (normal operation).
(k) In-phase current, but influenced by a pulsation at a frequency of 47 (per minute) set up by another machine.
(l) In-phase current of a set running under normal conditions on a network, producing hunting. The energy supplied cancels itself out almost periodically.
(m) Reversal of power. At AB and CD the machine runs as a synchronous motor.
(n) In-phase current supplied by a station connected to the network, without periodic reversal of power.
(o) In-phase current supplied by a station connected to the network, with periodic reversal of power.

These results are shown in Fig. 12.

---

* These tests would have been quite complete if Mr. Fournier had been able to record simultaneously the speed or the angular acceleration of the rotor. Nevertheless this research has contributed very largely to our knowledge of what happens in gas-engine groups during disturbances and has also indicated a practical remedy.

* The variations of pressure inside a gas engine cause the membrane to oscillate. The oscillations are transmitted by means of a small boss on the microphone disc, and consequently a microphonic current proportional to the pressure in the cylinder is recorded on the oscillograph. The oscillogram obtained thus shows to a given scale the variation of pressure inside the cylinder.

Figs. 12 (*a*, *b* and *c*) are instantaneous voltage diagrams, the first two being taken on the company's networks, and the third on a circuit fed by turbo-alternators only. (*a*) is the fundamental. In Figs. 12 (*b*) and 12 (*c*) the tooth harmonics have been artificially magnified. They are somewhat numerous but are less accentuated than in networks fed by turbo-alternators only. Fig. 12 (*d*) shows how the ignition points were recorded by means of a third oscillograph excited at the precise instant of ignition. It is seen that this causes a kick in the oscillogram. During these tests it was found that the time necessary for a contact breaker to operate after it is connected to the supply is equal to two cycles (0·04 sec.) and that two cycles later the spark takes place. Ignition takes place with surprising precision and is effected in about 0·002 sec.

Finally, in Figs. 12 (*e*) and 12 (*f*) the instantaneous pressure curve of the cylinder is shown. Figs. 12 (*g*) to 12 (*i*) show the instantaneous value of the currents recorded when the machine was running at unity power factor. They therefore give the in-phase current and consequently the ratio of energy supplied or absorbed by the alternator of the gas group under consideration.

The oscillogram shown in Fig. 12 (*g*), which was taken on a 2-cylinder double-action engine (simple tandem, 94 r.p.m., 50 cycles, feeding a separate local network), shows that the current is constant, because there are no exchanges of energy between the flywheel and the whole alternator network. The speed and the voltage adapt themselves to the type of alternator.

Fig. 12 (*h*) shows the form of the curve when the same machine was connected in parallel with a very large network on which the frequency and the voltage were maintained practically constant.

The envelope of the sine curves of the in-phase current gives an idea of the variation with respect to time of the energy supplied by the alternator. This is always positive and has a maximum which is due more particularly to the angularity of the connecting rod and occurs 94 times per minute. If the ignition is cut off we obtain Fig. 12 (*i*), which shows a frequency of 47 per minute. Figs. 12 (*j*) and 12 (*k*) were obtained on an alternator having a very high moment of inertia which momentarily gives an amount of power varying but very little (*j*), but showing a pulsation in the power (*k*) at a frequency of 47 per minute as soon as the network to which it is connected has impressed upon it a periodical variation at the frequency of 47 per minute due to another machine. This phenomenon is accentuated in Fig. 12 (*l*) by the exchanges of kinetic and electric energy, although the machine is quite normal. In this case the power supplied by the unit is cancelled out nearly periodically. In Fig. 12 (*m*) a reversal of power can be seen. During intervals of time such as BC, the alternator gives a certain output; on the other hand it receives a certain amount of energy from the network during the intervals AB and CD and at such times acts as a synchronous motor. Finally, Figs. 12 (*n*) and 12 (*o*) were taken by connecting the oscillograph to the interconnecting line between the metallurgical stations of the network and show that the in-phase current gives maxima and minima 47 times per minute. Fig. 12 (*n*) shows no reversal of power, but Fig. 12 (*o*) shows a periodical variation.

The curves in Fig. 12 which show this phenomenon correspond to hunting at the frequency of 47 per minute mentioned above.

In the authors' opinion the difficulties encountered are not sufficiently serious to cause the advantages of parallel running in general to be lost sight of. By increasing the total interconnected power to its maximum, the relative importance of these disturbances is diminished and the peaks are reduced. Finally, this plan will reduce to a minimum the losses of gas which may occur in works or parts of works which are interconnected. But in the present state of the art, and with a view to giving the maximum satisfaction to the consumers, the company takes advantage of the existence of 6-conductor lines over the whole of its network and provisionally runs two distinct circuits. The first of these interconnects pure blast-furnace works and runs in parallel with the large neighbouring supply companies. The second connects the steelworks to its network and consequently is subject to variations in voltage and frequency of a much higher order; these are, however, very much smaller than they were before interconnection was adopted. The overall efficiency of the installation is thereby greatly improved and the production of finished metal is increased under conditions which would themselves almost justify the enterprise.

OPERATION OF THE COMPANY.

It is easy to determine the principles on which the commercial relations of a group of consumers and producers of electrical energy should be based, but it is much more difficult to lay down the relations and to establish a fixed plan. For instance, it is generally agreed that such a group should be so constituted that the treatment of its participants should be on a basis of rigorous equality, but when the principle of equality and the elements upon which it should be based come to be defined, divergences of opinion appear. The Union des Centrales de Liége allowed their producers a certain amount of competition, but they assured to each of them an equal profit, whereas the Lorraine group did not take into consideration the profits accruing to its participants from the sale of their energy, but guaranteed that every participant should receive equality of treatment as regards quantity and price.

The Union des Centrales de Liége functions as a co-operative society, whereas the Lorraine metallurgical group functions as a clearing house. The Union des Centrales de Liége supplies through its network industries of very diverse natures; some of these are producers and others consumers. The service rendered by the Union by taking energy from the former and delivering it to the latter has therefore a very particular characteristic; the operations of buying and selling are confined to the co-operative partners and thus lose all commercial appearance. The Lorraine metallurgical group, however, supplies through its networks, almost exclusively, metallurgical concerns which are producers of energy. In this case it is not purely a question of mutual exchanges between the participants, or, if there are such exchanges, they are a secondary consideration and do not constitute the *raison d'être* of the group.

The network of the Société is, as has been indicated, a network of producers, and the agreement binding these had to be established in such a manner that it would not interfere with the commercial activities of the company; on the contrary it had to give the maximum of elasticity. The formula is a simple one. The starting point is the estimate that is made in each of the works of the amount of power available. By "power available" is meant the power that each individual station can produce with the gas at its disposal, allowance being made for a certain reasonable amount of reserve and subtracting therefrom the amount of works power that it consumes. This figure is fixed every year by a commission of experts whose decisions are final; in this way a quota is arrived at for each works, and remains in force throughout the year, to determine what proportion of the total energy required the station must deliver.

The Société has, of course, the exclusive right to sell the current produced in the works of its individual stations; it draws up agreements with consumers and remains free to negotiate with other supply companies such agreements as it may think fit and proper. In fact, the company acts in the same way as any producer would act; the energy sold is distributed among the various adherents in such a way that at the end of the year the distribution is proportional to the quota. This distribution is made for every category of supply, for which the charges are not necessarily the same; it therefore follows that, in particular, the supplies handled by the company in its own network are sold direct to its customers and are not supplied under the conditions that have to apply when energy has to be transported over several hundred kilometres. The company informs the works of the price adopted in every case and therefore fixes the tariffs which are paid to the works.

In practice, however, the operation is not quite so simple. It is clear that the role of sales clearing house for electrical energy played by the Société has assumed a very great importance, for it is from this that all natural developments should commence, but it has not been forgotten that the adherents are chiefly metallurgists and that the sale of electrical energy is of interest to them, although only of secondary interest. The network should first and foremost supply its industries and ensure that the works of its adherents receive the electrical energy that they require. At the commencement the function of the Société was simply to act as a buffer to increase the stability and the continuity of the central stations and, more particularly, ensure the feeding of iron mines. It still possesses this function, and the commercial formulæ which correspond to it have been designed with this end in view.

The supply of energy to an iron mine belonging to one of the adherent works is done by a system of toll; the mine has a certain maximum demand and consumes monthly a certain number of kWh. The Société simply requests the station to supply it with the same number of kWh, to which are added the transmission losses at the same instantaneous demand, which is deducted from the amount of power available for the determination of the quota; the accounts are adjusted from month to month and the company receives for this service a fixed payment per kWh.

The formula for this payment is not applied exclusively to mines, that is to say, to the firms served by the network. It is also applied to all the other consumers in the supply area of the Société, and agreements have been made between the company and neighbouring supply companies. Thus central stations situated near blast furnaces can, to-day, ensure the production of electrical energy necessary for certain works situated 100 km and even further away. The transmission of energy between the blast furnace and the works is ensured by the lines belonging to the Société as far as the State substation at Landres and from there by main transmission lines and, if necessary, by other distribution lines until it arrives at the point of utilization.

A system of tariffs to cover exchanges of energy between stations was more difficult to establish, as also was a formula which would express the service given in this way to gas-driven central stations.

Of what does the exchange or buffer service to a station consist? When a certain number of metallurgical works are connected in parallel to a network, the maximum power utilized, or, in other words, the peak on the whole system, is less than the sum of the individual peaks of each works, which, generally speaking, occur at different times and therefore are not superposed; as the total power is distributed among all the central stations, each will have to cope with a production peak which is less than the peak it would have had to supply to its own metallurgical works if it had been running isolated. A central station connected to the network can thus reduce the number of running machines by taking from the network the peak energy; on the other hand it delivers to the network the energy which the same station can supply during its hours of low local load. It is evident that the amounts of energy consumed by the works at the instant of peak load and the amounts of energy supplied by the works at the instant of minimum load are altogether different. The supply to the works, therefore, does not have its counterpart in the kWh delivered to the network, which for the latter has an almost negligible value.

The formula adopted by the Société makes but little difference to the tariffs applied to these two classes of load, but it taxes the half-hourly power taken from the network, i.e. the number of kilowatts utilized by the works for its buffer services.

This empirical tariff system, which has only the merit of simplicity, is applicable only to works which have not a continuous amount of available power to contribute to a network. For this type of station no buffer is, in fact, required, or, rather, there are no exchanges of energy with the network, since their stations have always more energy available than is required by the works.

As the role of producer tends to become general amongst the participating stations of the Société, all of which can dispose of large quantities of surplus gas, the buffer formula will have a steadily decreasing application.

THE ROLE OF THE LOAD DISPATCHER.

In order to ensure the best conditions of parallel running of a number of central stations and to obtain the best results from interconnection, each of the central stations must be constructed, not only with its own overall efficiency in view, but also with a view to the stability and efficiency of the whole of which it is only a part; hence the necessity of establishing between the central stations a control which will at every instant be informed by each of the stations of all the factors which are likely to influence the operation of the network, and which will transmit in the same manner to each of the interconnected stations the information resulting from the examination of all the details.

The dispatcher should know at every instant:—

(1) The amount of power supplied to the network by each of the stations.

(2) The power consumed.

(3) The amount of reserve power.

The Société's load dispatcher must at every instant possess the necessary data for him to determine as closely as possible these three elements. To this end, each works compiles and sends to the dispatcher a weekly list of machines available for parallel running on the network and also a list showing its daily consumption. The power available is deduced from these figures. It goes without saying that every incident at a works which may modify either its means of production or the importance of its consumption is immediately reported to the dispatcher.

The dispatcher is situated in the centre of the network at Briey, and has power to control the running of the machines if necessary; in particular he can have any machine stopped which causes any disturbance in the network, and he can also order another machine to be connected to a network, provided one is available. The dispatcher arranges the running of the machines and, in particular, the supply of wattless current. In his office there is no apparatus for measuring energy, but only certain hand-operated panels which show him the state of affairs at every part of the network and the condition of the machines in the various stations; in addition he is connected by telephone to all the switching stations and to all the central stations, and he periodically receives information as to the running of the network.

As and when the importance of the central stations and the loads of the networks increase, the role of the dispatcher will become more and more complicated. His task is, in fact, to ensure continuity of service. All metallurgical networks are liable to a further cause of disturbance in addition to those which exist in all other networks. The central stations are fed by blast-furnace gas and any disturbances in this supply of gas have an effect on the network. At the present moment this difficulty is but little felt because only a portion of the blast-furnace gas is used and any accident to a blast furnace leaves a sufficient quantity of gas to feed the station. This state of affairs will be changed when the new stations are put into service and they have been installed to utilize the total amount of gas available. When this occurs the dispatcher will have to be informed by every works, not only as to the state of the machines, but also as to their output of gas, and he will have to take all precautions to ensure that at any instant the reserve machine and the reserve of fuel necessary for the continuity of service are available.

In order to ensure this, the company has under consideration the inauguration in the works of a special organization in connection with each service interested, and will thus be informed minute by minute of all the variations in the feed gas and in the production of current in the stations; this organization will be in continuous communication with the Société's load dispatcher, who, in this way, will possess all the necessary information to enable him to follow the production of energy. As soon as a works utilizes the whole of its gas, the associated station finds itself in exactly the same position as a hydro-electric station without reserve water; the production of energy of the gas station depends, in fact, on the output of gas at any instant. A stoppage of a blast furnace in a metallurgical works connected to the network must be avoided in order to prevent disturbances in the feeding of energy to the network. It is the task of the dispatcher to guard against all such incidents and obviously he cannot do this unless he is kept informed of the details of the running of each station.

NEW POWER STATIONS OF THE SOCIÉTÉ ÉLECTRIQUE DE LA SIDÉRURGIE LORRAINE.

The central stations which have been connected to the network since 1923 existed a long time before this date and had been designed to cope with the internal needs of the works; the output of these machines had been calculated by taking into account the basis of energy consumption corresponding to the needs and not to the possibilities of production which were given by blast-furnace gas. In consequence of this, in nearly all the works belonging to the company there was a surplus of gas which was not utilized, the whole of which constituted for the company a source of energy capable of supplying about 50 000 kW. In order to exploit this it was necessary to install in every works the necessary means of production. The question was whether gas engines or steam turbines should be installed.

The battle between the champions of the gas engine and of the steam turbine has altered in character several times during the last 20 years, and every time with a marked preference in favour of the gas engine with the turbine as an auxiliary. The defenders of the gas engine admitted that this type of machine lacked a certain amount of elasticity and was not suitable to deal with such an irregular amount of consumption as that required by a rolling-mill. They therefore added to their gas engine a turbine partially fed by the steam produced by boilers placed on the exhaust; they had thus the double advantage of regularizing the running of the gas engine by means of the turbine, which was done in such a way as to absorb the peaks and to increase the thermal efficiency of the installation from 23 to 26 per cent (for engines without scavenging). On the other hand, a steam turbine fed by high-pressure boilers has an efficiency of 21·6 per cent.

Translated into cubic metres of blast-furnace gas, these figures give the following consumptions:—

Gas engines with regenerative boilers—3·8 cubic metres of gas per kWh at the terminals.

Steam turbines with high-pressure boilers—4·6 cubic metres of gas per kWh at the terminals.

In other words, 100 cubic metres of blast-furnace gas will give, with gas engines, 26 kWh and with turbines 21·7 kWh. Therefore the gas engine shows an efficiency in kWh which is 20 per cent better than that of the turbine. In spite of this advantage, which is to a very great extent compensated by the high cost of manufacture and operation, the solution based upon the use of turbines has been adopted for the technical reasons given above, in order to reduce the proportion of gas engines running in parallel on the network.

At the present time the power produced by gas engines represents 56 per cent of the total power installed in interconnected stations; the importance of the turbines which are running is too small to enable a practically constant frequency to be maintained. The new installations will reduce the above figure to 40 per cent and will give the turbines a preponderating effect without which the network would be liable to cause disturbances in neighbouring networks.

The steam turbine has a further advantage. Instead of depending very closely upon the blast furnace as does an internal-combustion engine, and reflecting every disturbance which occurs in the production or consumption of gas, the turbine has associated with it a boiler. The effect of variations in the calorific value or pressure of the gas is therefore less direct and can be entirely compensated by the intervention of coke-furnace gas or by pulverized fuel, which can be put into service in boilers specially designed for gas without any very great increase in cost.

The stability of running of the turbine as compared with gas engines, which are subject to rather frequent stoppages, is a final argument for the adoption of the steam turbine when it becomes a question of metallurgical works delivering current to a network on which continuity of service is the most important factor. The authors' remarks on this subject do not, of course, indicate a definite solution to the problem of the production of metallurgical energy and do not condemn the gas engine, which, under certain conditions, and more particularly in connection with isolated works, may be preferable to the turbine on account of its higher efficiency. Turbine central stations are, at the present moment, being installed in seven works belonging to the group. Their total power will be 64 000 kW distributed over seven turbo-alternator units, five being of 10 000 kW and two of 7 000 kW. Each station will comprise one group only, but provision has been made for installing eventually a second unit which most probably will be of a more powerful type.

The steam characteristics are a pressure of 35 kg/cm^2 (497 lb./sq. in.) and a superheat of 425 deg. C. The feed-water is brought up to a temperature of 130° C. by being passed through reheaters fed by steam bled from the turbine. The air necessary for combustion is reheated to 180° C. by means of Ljungström heaters placed at the back of the economizers. In works which have coke furnaces at their disposal, burners are provided for employing blast-furnace gas or coke-furnace gas, it being possible to use these two gases either together or separately. Automatic regulators placed in each boiler will maintain a constant pressure of steam and will not call upon the coke-furnace gas until the whole of the blast-furnace gas has been utilized. This device has a very great advantage in that the automatic intervention of coke-furnace gas in order to maintain the load on the station will allow a better utilization of blast-furnace gas to be made.

To the best of the authors' knowledge it is the first time that 10 000-kW units have been installed in France in metallurgical works. The tendency up to the present has been to make the combined power of the units equal to a small fraction of the total power of the works. Moreover, gas engines could not be built for outputs of more than from 2 000 to 4 000 kW. Now that in works in Lorraine 10 000-kW units are being installed which correspond on an average to half of the productive capacity of the station, certain stations will have only one unit running in order to ensure their service, and this would appear to be the practice of the future, viz. to install in the works steam-generator units of a capacity such that the whole of the output of blast-furnace gas can be utilized at any moment, and to allow these boilers to feed a high-power turbo-alternator set designed with a heavy overload capacity. Such an installation is quite capable of producing, under the best conditions of continuity, the current required in the works, on condition that sufficient reserves can be maintained. The works which produce their current with a single machine should have means of stopping periodically and at the same time allowing their gas to be utilized on other sets. This difficulty is not prohibitive. Without entering into prolonged economic considerations, however, it may be said that a 10 000-kW group costs less to install than a 2 500-kW gas engine. Stand-by reserves, i.e. units which can be ready at any instant to take their share of the load in the event of a sudden stoppage of the main group, are somewhat difficult to ensure. If five works are equipped in the same manner with a single unit the network will continue to operate as if it were served by only one station equipped with five similar units. Therefore, in order to take precautions against a sudden stoppage of one of the stations and at the same time to maintain the production, it is necessary that at every instant the remaining four units should have a sufficient overload capacity, which in this case would be 25 per cent. This condition, however, is not sufficient, and in most cases the overload can only be obtained by using fuel which is independent of the works, and this fuel can only be pulverized fuel.

This is the system that has been under consideration for the operation of the new steam stations of the company. Each of the five units of 10 000 kW is designed for an economical load of 8 000 kW and for a continuous overload of 12 000 kW in four of the stations. The supplementary load of 4 000 kW can be obtained exclusively with pulverized fuel. The stoppage of one of the turbines can therefore be entirely compensated by forcing the others with, if necessary, the utilization of pulverized fuel until the station in which the stoppage has occurred has taken steps to put its reserve units into service.

CONCLUSION.

The Société Électrique de la Sidérurgie Lorraine has solved the problem put to it and has been able to overcome the difficulties inherent to this programme, not only from the technical but also from the commercial point of view.

Exchanges of energy have developed regularly and since 1928 have exceeded the figure which was predetermined at the outset as being necessary in order to make a sufficient return on the capital invested.

The number of kWh transmitted by the network of the company from the commencement is as follows:—

1923	7 931 074
1924	22 413 015
1925	36 555 028
1926	65 703 130
1927	89 732 038
1928	112 403 727

These figures include the toll energy and the buffer energy; for example, the figures for 1928 can be divided as follows:—

Normal supply	72 052 663 kWh
Toll supply	36 003 009 kWh
Compensation supply between works	4 348 055 kWh

For 1929 the total production will reach 130 million kWh, and in 1931 will exceed 200 million kWh.

From the present time the amount of energy taken into account, which has been almost entirely produced by waste gas, represents annual receipts of the order of 20 million francs.

The company is of opinion, however, that it has not yet done all that is possible; new stations which will be in service during 1930 will considerably increase the amount of energy available and will permit the company to increase its radius of action. When that occurs new markets will have to be found, more particularly for utilizing the energy available at night. The new units will help to improve the operation of the existing stations and of the network in such a manner as to ensure that the amount of current produced by the metallurgical works will be as regular and give the same continuity of service as the current supplied by the thermal or hydro-electric stations which feed the distribution networks.

This result will certainly be attained and even exceeded: a hydro-electric station operated by running water is incapable of providing its own reserve and, should the flow of the river become insufficient, it is obliged to turn to another source. On the other hand, a metallurgical station, if it is equipped with boilers and steam turbines, is sufficient in itself and can cope with variations in the output of blast-furnace gas by utilizing coke-furnace gas or coal. For this reason it possesses, without immobilizing large amounts of capital, surplus energy which can be used at any time when necessary.

In order to ensure new outlets for the increased production of energy the company has already interconnected two large distribution networks in Alsace and Lorraine and in the Vosges, and has participated in the creation of two new companies which are constructing high-tension lines to join up with the Parisian region and the north of France via the Ardennes.

DISCUSSION AT THE JOINT MEETING OF THE INSTITUTION AND THE BRITISH SECTION OF THE SOCIÉTÉ DES INGÉNIEURS CIVILS DE FRANCE, 12TH DECEMBER, 1929.

Mr. N. G. Hackney: I should like to express, as President of the British Section of the Société des Ingénieurs Civils de France, the great pleasure and gratification we feel at the presentation of this paper before the leading society of experts in this country in the subject with which it deals. This is the second or third paper dealing with electrical matters which has been read at a joint meeting of the Société and the Institution, and I hope that we shall have further ones in the future, just as we hope to have papers on other branches of engineering read before institutions dealing with those other aspects of the subject.

Mr. I. Scott Mackenzie: I have read the paper with very great interest, because at the Devonshire Works of the Staveley Coal and Iron Co., near Chesterfield, we have been running for about five years three large (5 000-kW) gas-driven alternators similar to those mentioned by the authors. The late chairman of the Company, Mr. Charles Markham, saw engines of this type operating in Belgium at Liége and Seraing, and formed the opinion that it would be a good thing to install them at Staveley with a view to making the best possible use of the blast-furnace gas which, owing to its low calorific value (about 100 B.Th.U.), could not be sold like coke-oven gas, and had to be used, more or less inefficiently, for firing Babcock and Wilcox boilers. Our electrical system at Staveley now consists of a large station at Devonshire Works, containing three 5 000-kW gas engines and 10 000 kW of steam turbine plant, which feeds into a ring connecting up our other works and collieries, some of which have mixed-pressure turbine generating plant of their own. It was thought at first that it would be difficult to run low-speed gas engines at about 90 r.p.m. in synchronism with turbines, but in actual practice we have not found this to be the case, particularly since our system has been connected up with that of the Derbyshire and Nottinghamshire Electric Power Co., which has a very large power station at Spondon, near Derby. I am fully in agreement with the authors that in order that gas engines may run satisfactorily on a system, turbine plant, which heavily preponderates, must operate in synchronism with them; I would go even further and suggest that the relative proportions should be:— turbines 70 per cent and gas engines 30 per cent. Whilst admitting the high thermal efficiency of gas engines, particularly when the steam which can be raised by utilizing the exhaust gases from the engines is taken into account, I am of opinion that they are more expensive to buy than a complete turbine plant of similar capacity, although the gas-engine makers submit that this is not the case. The capital cost of our gas engines at Staveley, including the very elaborate gas-cleaning plant which had to be installed, was approximately £22 per kW, as compared with the complete cost of a modern station such as Padiham, Lancashire, which was, I understand, between £13 and £14 per kW. The gas engines themselves have not given us much trouble, but we have had a great many breakdowns in connection with the exhaust pipes and the boilers, which are fired by means of the exhaust gases. I should be very grateful if the authors would say what their experience has been in this connection, and whether they can suggest any means of overcoming the difficulties which we have experienced. One more drawback which we have found to gas engines is that they cannot be started up and shut down like turbines, mainly because of the aforementioned difficulty with exhaust pipes. As a result of our experience, we find the best plan is to start up a gas engine and run it on full load as long as possible, which, on the average, is about 12 weeks. The longest run we have ever had is 15 weeks, but a 12 weeks' run may be taken as a fair average, and at the end of that time an engine has to be shut down for cleaning. Although we have three 5 000-kW gas-driven alternators installed, we have hitherto never run more than two at a time, keeping one in reserve, and this, of course, has tended to increase our generating costs, because, although only two engines were running, the cost figures had to include the depreciation of three engines. Now, however, that we are connected up with the power company's system we shall be able to run all our gas engines at all possible times. The authors do not refer to the question of

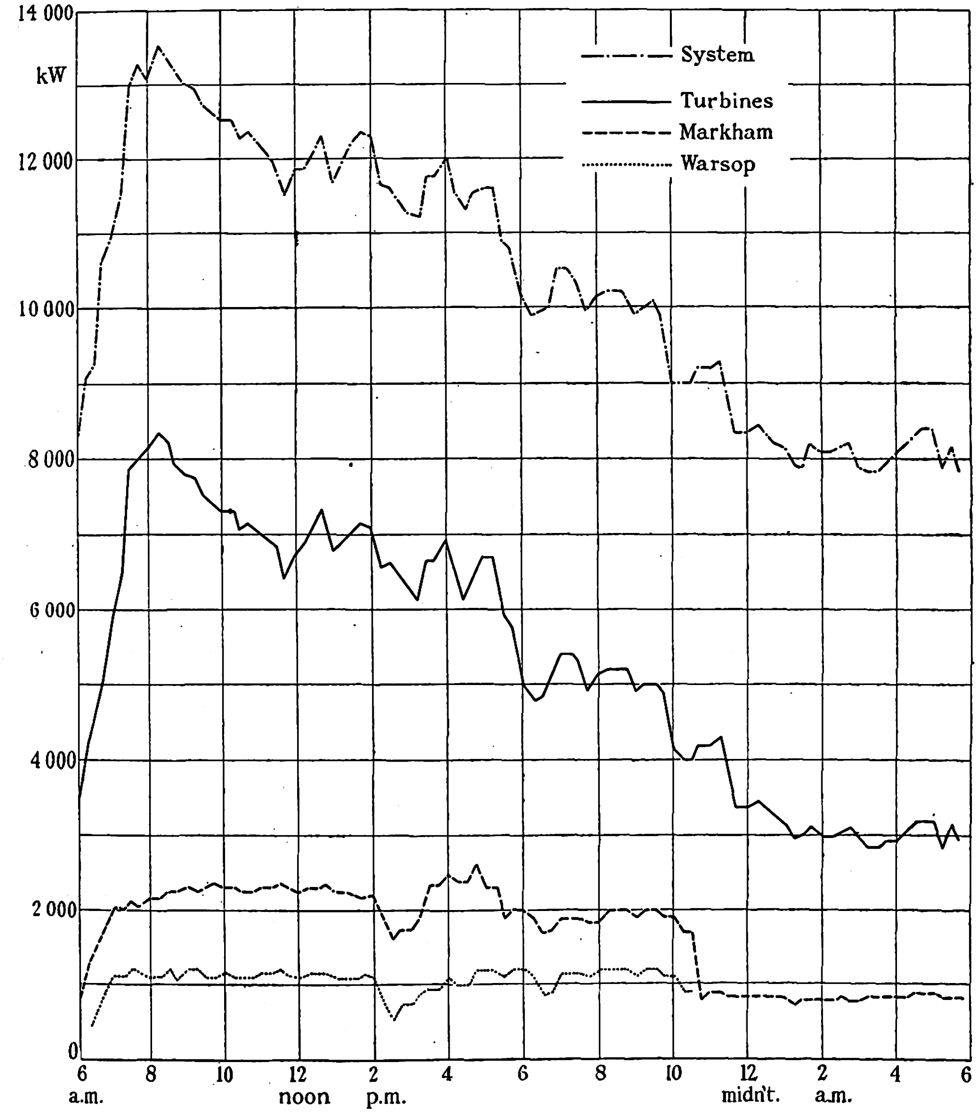

FIG. A.—Load curves for the 6th December, 1929.

costs, and I feel that it may interest the members to learn the figures of costs obtained at Staveley. In the appended costs is included an allowance for the value of gas consumed by the gas engines and turbines, at the rate of 1 lb. of coal for every kWh generated by the gas engines and 2½ lb. of coal for every kWh generated by the turbines. It may be thought that 1 lb. of coal for the gas engines and 2½ lb. of coal for the turbines are high figures, but our turbine plant is not particularly up-to-date, and I had to make the best terms I could with the engineers who run our blast furnaces. Taking an average for the last 6 months, our "all-in" cost of generating electricity, including coal and other fuel, oil, waste, water, stores, wages, repairs and maintenance, depreciation, establishment and management charges, and all auxiliaries (including gas cleaning, which is an important item in connection with gas engines), came to 0·25d. per kWh at the busbars of the station for the gas engines and 0·35d. per kWh for the turbines. In a way, it is not quite fair to compare these two figures because, as will be seen from the load curves shown in Fig. A, we run the gas engines at full load the whole time, and take up any peaks or other variations by means of the turbines. The voltage and frequency charts (Fig. B) show that we are able to maintain quite steady voltage and frequency. Before our system was connected to that of the undertaking to which I have already referred, the cyclical variations of the gas engines produced fluctuations of voltage which were rather troublesome, but since we have been running in synchronism with the other system these troubles have disappeared almost entirely. It may be of interest if I mention that we generate at two different frequencies at Staveley, i.e. 30 and 50 cycles per sec., our total output being about 90 million kWh per annum. Our original plant, which was installed over 20 years ago, was all at 30 cycles, but recently, owing to our giving a supply to various outside consumers, including the Derbyshire undertaking, we have had to install frequency-changers. Two of our 5 000-kW gas engines generate at 30 cycles and one at 50 cycles, and the two systems are connected up through two large 2 500-kW reversible frequency-changers, which can run at either 30/50 cycles or 50/30 cycles or, in some cases, merely "float" between the two systems. We have experienced no trouble whatever with running the electrical part of the plant, particularly, as I have already mentioned, since we have been connected up with the large network and generating station of the Derbyshire and Nottinghamshire Electric Power Co. The authors' remarks in connection with the oscillograph records shown in Fig. 12 are particularly interesting, and I am fully in agreement with the authors that, for the parallel running of gas engines and alternators, it is an advantage that all units should have a reasonable moment of inertia, and that this should not vary very greatly. In practice, there can be no doubt that machines with the highest moment of inertia are precisely the type which give rise to the most dangerous hunting, on account of the preponderating importance that they assume in times of disturbance owing to the exchanges of kinetic and electrical energy in the network. The piezo-microphonic device for recording the pressure in gas-engine cylinders, shown in Fig. 11, is very ingenious.

Mr. Roger T. Smith: The problem of the use of waste heat from blast furnaces for the production of electric power, either for domestic use in steelworks or for sale outside to a network, is shown in this paper to be one of extraordinary difficulty. Owing to the great cost of starting a blast furnace, the cycle of operations of a large group of blast furnaces is, as the authors have pointed out, relatively constant. The daily and the annual production of gas are fairly well known, and the more furnaces there are the better it is for the system. The paper clearly explains the variation in the quantity of gas per shift and per day, but the peaks in the load and those in the supply of gas do not coincide. I should like to ask the authors how far they have succeeded in making the shifts fit in with the variation of load. It is not quite clear from the paper whether the variation of the shifts is an accomplished fact. The interconnection of the electrical distribution side is a great help in smoothing-out peaks in the load, but the result of some years of working shows that the gas engine, with no overload capacity, must not preponderate over the steam turbine as a source of power. One of the most interesting points in connection with this system, on which the paper does not say very much, is the question of safety. How far is it possible to submit to breakdowns, and how frequently do they occur? There is the intrinsic liability to failure due to overhead lines, of which we at present in this country know very little, but with which in a few years' time we may become much more familiar. In Lorraine, matters are not helped by the use of single lines, with provision for duplicating, nor by pin insulators on a 65 000-volt line. The network is further handicapped by the fact that so far it has not been possible to install either a balanced selective system of protection or the impedance system of protection which are being studied. I believe it is a fact that in Mr. Mackenzie's system at the Staveley ironworks there is no protection of the lines, but only protection of the generators. Then also, from the point of view of safety, there is the switching of substations. Fig. 8 shows the high type of double-busbar substation, with alternate feeders connected to the double-busbar and there are arrangements for changing the feeder from one bar to the other through rotating links. If a feeder switch breaks down there is, however, no bypass link to connect the feeder temporarily to the bars while the switch is being repaired. I should like to know whether trouble has been caused by the failure of switches after short-circuit, owing to the impossibility of connecting the feeder to the bars while the switch is being repaired. The Rombas substation is fairly typical of such a modern substation as would be used on our own grid system, with the exception I have mentioned; but in Fig. 7, representing the Fontoy substation, alternate feeders are connected to alternate busbars with no arrangement for changing a feeder from one bar to the other. Both transformers are connected through one switch to either busbar, and it is not possible to have one transformer on one bar and one on the other. Again, the potential transformers

(a) Output of 5 000-kW turbo-alternator.
(b) Voltage.
(c) Output of gas-engine-driven alternator No. 3.
(d) Frequency.

are connected on the high-voltage side, whereas in the British grid system we connect them on the low-voltage side and compensate for the loss of voltage in the main transformer. I should be glad to hear whether there has been trouble, at least at substations, from these comparatively small voltage-transformers being connected on the high-voltage side with no protective system and a not very elastic switching system. Breakdowns, when they occur, must be fairly complete. One dislikes to speak of breakdowns, but it is important for other engineers to hear of them, and I hope that the authors in their reply will speak about the sort of breakdowns that do occur and about their frequency. Mr. Mackenzie gave the arranged price which his electrical department was charged for the blast-furnace gas. I should like to know whether the Lorraine Société have a uniform agreed figure for all kinds of blast-furnace gas used in the gas engines, and, if so, what it is in terms of kilograms of coal per kWh.

Major T. Rich: This paper is very interesting, for it brings out a second case where the amount of power generated does not depend exactly on the amount which is required but on that which is available. It is rather like the water power in the Pyrenees, where different power stations use the water. In this case, the gas available from time to time is used. Water power has the advantage that it can be stored where the configuration of the land permits, but blast-furnace gas has such a low calorific value that it is very difficult to store it. In the Pyrenees a large proportion of the power is used for electrochemical work, and here in the east of France the bulk of the power is used for steelworks, the balance being sold outside. There is a remarkable spirit of co-operation all over France. In the rural districts half-a-dozen farmers will buy a threshing machine and form a small company to run it. They work together and arrange their dates in an extraordinary way. In the same way in the Pyrenees, in this steelworks area and elsewhere, we find the same spirit of practical co-operation, without interference from Government or outside organizations. It is a great advantage to the nation as a whole. Other points which the paper brings out are the questions of the cost of power and thermal efficiency. In this country we very often go too far in the way of thermal efficiency and believe that the saving of a fraction of a pound of coal in steam generation or heat utilization is the main object. We find here that a lower thermal efficiency is more useful from one point of view and, as is frequently the case in power stations, unless the load curve is very good one can easily get too high a thermal efficiency and have to pay very heavily for it in capital outlay. A point in connection with the utilization of steelworks power in general networks is that where, as in France, the national trade policy does not make for violent fluctuations in the steel market, it is more easy to make arrangements in advance over a long period to enable such surplus power to be used. If there are great variations and a possibility of the closing of large numbers of blast furnaces, as we find in this country, it may not be worth while to spend large sums on capital outlay. It appears from the paper that, having started with 65 000-volt pin insulators and continued with 85 000-volt pin insulators, they are now adopting suspension insulators for the 65 000-volt mains. With regard to overload capacity, it must be very interesting to use gas-fired boilers and arrange for the possibility of pulverized-fuel firing. There are some cases in this country where oil fuel is used to supplement stoker firing. This shows the extraordinary elasticity of the modern thermal arrangements of the steam-turbine plant. Have the authors ever considered the question of steam storage? We hear a good deal from time to time about marvellous steam-storage apparatus which will revolutionize power-station operation; if steam storage ever does all that is promised it will be possible to utilize the surplus gas until outside demand or the peak load comes on, and then to make use of it where it can be of the greatest value.

Messrs. L. A. E. Sékutowicz and **A. Evain** (*in reply*): The information given by Mr. Scott Mackenzie is interesting and shows that alternators driven by gas engines are quite capable of feeding a public supply network and of maintaining an almost constant output when operating in parallel with suitably regulated steam turbines. The difficulty experienced in Lorraine arises from the predominance of rolling-mill motors, the stopping, starting and running of which produce frequent variations in demand of much greater extent than those shown by Mr. Scott Mackenzie's load curve (Fig. A). We notice that the characteristics of the Staveley day-load curve are particularly advantageous from the point of view of economical running. We are in agreement with Mr. Mackenzie as to the desirability of having a preponderance of steam turbines, also as regards their lower first cost and the necessity for having a large reserve in the case of gas engines. The cost of operation quoted by Mr. Mackenzie for gas engines seems to us to be low and, as he states, steam turbines are at a disadvantage in the comparison because they alone provide the peak supplies and their efficiency has been taken at far too low a value. With modern installations we reckon to obtain, in the case of gas engines and regenerative boilers, a consumption of 3 500 calories per kWh (equivalent to 0·5 kg of coal at 7 000 calories per kg) and, with high-pressure steam turbines [30 kg per cm^2 (483 lb. per sq. in.), the steam being superheated to 400°C.] a consumption of 4 400 calories per kWh (equivalent to 0·63 kg of standard coal). Such coal costs in France about 160 francs per ton, so that the above consumptions are equivalent to a cost of 8 and 10 centimes per kWh respectively. Taking into account essential stand-by plant, the cost of maintenance and renewals and the capital charges amount to a smaller total in the case of turbines, for a similar period of use. The capital expenditure for turbines is, in fact, only about one-half, and the importance to be attributed to the equipment for purifying the gas which must, on the other hand, be provided is far from compensating for the difference involved by an outlay larger by 45 per cent. Attendance and maintenance are also less costly in the case of turbines.

Mr. Roger Smith, to whom we are indebted for reading the paper at the meeting, has drawn attention to several important points which we may not have made quite clear. Fig. 5, which refers not to an average day but to one selected at random, shows that it was not possible to provide for any rearrangement of working between 6 a.m. and 2 p.m. From 2 p.m. to 10 p.m. resumptions of work are always spaced out, and the ratio of the minimum to the maximum (about 0·7) is notably higher than it would have been if the concession that one of the most important steelworks should be shut down for one shift during the day and should work one shift during the night had not been obtained.

With regard to reliability, the system is satisfactory in practice and never gives any cause for serious complaint. The metallurgical works had already separated their internal equipment into several circuits before they were linked up for parallel working. One of these circuits, the safety circuit, grouped together the essential works plants and several steam-driven generators. Interruptions, when they occur, only interfere with the output for the duration of the fault itself. These interruptions are not frequent. In 1929 there were only 9 breakdowns on the 65 000-volt grid, and only one accident due to a meter transformer. On the other hand, there were some interruptions of the works plant as the result of overloads, which were remedied by finer setting of the relays. In the same year only 9 insulation faults occurred with 4 000 insulators, accompanied in 7 cases by damage to the cable. The arrangements briefly described in the paper constitute the basis of the protective system. Because they have so far been satisfactory in practice the installation of balanced selective protective apparatus has been postponed, but the possibility that such equipment may be necessary is kept in view. Since the inconvenience to external consumers due to surges and sudden variations of load has been greater than that arising from damaged lines the double network has provisionally been used for isolating the steelworks. Future events will show whether the rarity of line faults, the efficacy of the impedance relays and the earthing of the neutral justify the retention of this provisional solution, or whether, on the other hand, progress in the maintenance of gas engines and a greater use of turbines will bring about a return to a network using 6-conductor lines working in parallel; such a scheme would allow of better use being made of the copper in the lines. It would be inaccurate to say that there is no risk of breakdowns with overhead lines. Voltage-rises—the causes and attendant circumstances of which we are investigating (particularly with the aid of a "klydonograph")—produce, in fact, distortion and fracture of the insulators. Suspension insulators, which we are trying on the latest line, are no more effective than rigid insulators in combating this trouble. If the line insulation was strengthened too much the transformers would suffer. As regards the planning of the substations, simplicity has been the first consideration; this was all the more essential since at the outset it was not definitely settled what connections would ultimately be necessary. Only once has a circuit breaker exploded. The voltage transformers have not given any trouble. We have continued, however, to test apparatus of this kind on high voltages in view of the risks involved and of the installation of selective relays which might have been rendered necessary. As Mr. Roger Smith observes, the design of the stations (such as the one at Fontoy) constructed at the outset has not the flexibility desirable to-day. Simple apparatus of that kind was adopted primarily for reasons of economy. It was estimated that the financial return on the system would be completely assured when the output reached 100 million kWh. This forecast has been entirely confirmed by the facts and, while retaining its essentially co-operative character, the Société is able to pay a dividend of 6 per cent. It intends to continue to complete and gradually to perfect its equipment, and this has already been achieved in the new stations. Attention is especially concentrated upon the adoption of modern methods of telecommunication for supplying the load dispatcher with all the information that may prove useful to him.

Major Rich has drawn attention to a very important aspect of the problem—the difficulty of accumulating sufficient energy to make the supply equal to the demand. It should be observed that even if steam storage were unable, under the prevailing conditions of space and cost, to cope with the needs of a group such as our own, and if the blast-furnace gas were of such poor quality as not to make storage worth while, nevertheless coke-oven gas is of sufficient value to allow of the use of gasometers of reasonable cost and volume. It is possible in some measure to achieve the end in view by temporarily substituting one gas for the other in suitable services and by storing gas of high calorific value. Installation of electric furnaces and grouping of chemical industries round the coke-works will, no doubt, provide further facilities for this. Major Rich has also drawn attention to the risk of an enforced stoppage in the metallurgical processes of production. The risk of insufficient output also exists with hydro-electric power during periods of insufficient rainfall. It may be that, in the case of the metallurgical works, the energy demands (especially for mines and industrial processes) will diminish simultaneously with the output. The installation of pulverized-fuel boilers and interconnection with collieries may serve, in addition, as effectual solutions of the problem.

WATER PENETRATION EFFECTS IN LEAD-SHEATHED POWER CABLES.*

By E. A. BEAVIS, B.Sc., Associate Member.

(*Paper first received* 21*st March, and in final form* 12*th November*, 1929.)

SUMMARY.

The immersion in water of lead-covered cables, with a view to the detection of faults in the lead sheathing, is discussed. Tests of the time taken to show up these defects in power cables at different water pressures are given for various cable samples. The conclusions drawn are that, except possibly in the case of low-voltage cables, no such defects will be discovered during factory routine, and that for high-voltage cables, at least, water immersion should be definitely discontinued.

INTRODUCTION.

In the normal course of cable manufacture it is customary to immerse drums of lead-cased cable in water for at least 24 hours previous to the carrying out of any electrical tests. This has been the recognized routine on all cables for many years, and is incorporated in the British Standard Specification.

The reasons for "tanking" cable in the lead-cased stage are twofold; first, to enable electrical tests to be taken at a uniform temperature, and secondly, to test the soundness of the lead sheathing. In the large tank that is necessary to cope with a batch of cable drums, the water temperature varies very little over the course of months, and the time of immersion enables the cable to take up the steady uniform temperature which is so essential for the accuracy of the electrical tests. Should the water penetrate any pin-holes or other defects in the lead sheathing and thus enter the insulating material, the electrical tests will be expected to locate it.

In regard to power cables, however, with an impregnated-paper insulating material, it is extremely improbable that any such defects in the sheathing will be discovered by the subsequent testing, except perhaps in the case of the lowest-tension cables. With the advent of super-tension cables it became fairly obvious that no water could possibly penetrate sufficiently into the thickness of insulating material concerned within the given time, to be subsequently discovered by any electrical tests; and so in many cases for cables of 22 kV and above the question of "tanking" has been entirely waived.

It must be conceded that if the water immersion test is incapable of showing up any defects in the sheathing, it is not only useless but constitutes a positive danger, since any water penetrating the insulating material must be sealed therein permanently by the further manufacturing processes of compounding, armouring and serving the lead-cased cable. It is quite probable, too, that such an occurrence will not manifest itself until long after the cable is laid and in operation, but that it will inevitably create trouble is certain, whereas with cable that has not been subjected to the water test the chances of any such defect in the lead showing up at a later date are remote, and consequently the possibilities of experiencing trouble are appreciably lessened.

EXPERIMENTAL INVESTIGATION.

In order to obtain some definite data on this subject of water penetration, it was decided to carry out experiments on various cable samples of different thicknesses of insulating material, the lead sheath in each case having a central puncture in the form of a small hole exposing the outer layer of the insulation. Routine a.c. voltage tests and d.c. insulation tests were to be carried out periodically in the ordinary way until breakdown occurred, in order to ascertain the time required to show up the fault under the practical specified conditions. However, a few preliminary attempts showed at once that the investigation was likely to prove an extremely protracted and tedious business if carried out under the normal conditions, and in these circumstances the continued application of periodic voltage tests might complicate matters by weakening the insulating material. Arrangements were therefore made to place the samples

in a hydrostatic tube to enable various pressures to be applied and so shorten the time required for breakdown. The samples were about 6 ft. long, one end being sealed with a lead cap filled with compound, and the other end trimmed for testing. The testing end was brought out through the gland of the tube, and a watertight joint was made by means of a lead plug wiped on the cable sheath and covered with a layer of gutta-percha. The results tabulated in this paper have been obtained from a general analysis of the test figures on two different types of cable samples, and the illustrations indicate the trend of the values both for breakdown and for particular comparative insulation tests. In a few of the initial tests the water was drained off nightly and at week-ends, so that the test values may be somewhat modified by this procedure; in the case of all the others, however, the pressure was maintained continuously until the completion of the test. Owing to the general nature of the experiments the results cannot be expected to attain a high order of accuracy, but they indicate plainly the nature of the conclusions to be drawn from the investigation. One of the preliminary attempts

mentioned above, in which a sample of single-core 33-kV cable had been used, was completed in the course of time. This sample, which was about 20 ft. long, had a piece of lead 3 inches in length cut out of the centre, and was then bent into U shape and placed in an open tank of water, the two ends being left exposed. Routine voltage tests, combined with prolonged insulation tests with direct current from a battery of 300 cells, were carried out daily. The final breakdown occurred after a period of almost three months. Some of the test results obtained are given in Table 1.

The breakdown took place at the defective place and it was found that the water had penetrated the outer papers for at least 2 ft. on either side of the fault. The daily insulation tests show that after about 3 weeks the electrification becomes unsteady and a great deal of

variation takes place day by day. One cannot place too much reliance on these tests, however, owing to the small deflection obtained, and also owing to the possibility of insulation weakness caused by the voltage tests.

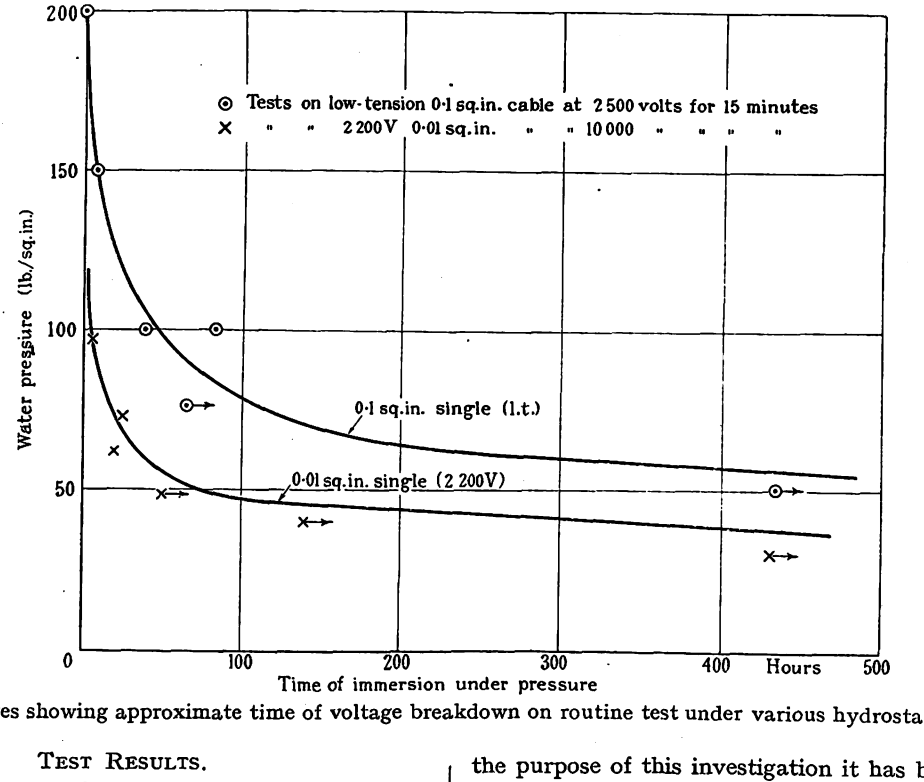

FIG. 5.—Curves showing approximate time of voltage breakdown on routine test under various hydrostatic pressures.

TEST RESULTS.

The insulation tests for three samples are given in Figs. 1, 2 and 3, the thick lines on these curves corresponding to the actual periods of test. It is probable that a small part of the variation obtained may be due to slight daily changes of temperature, but it will be seen that there is a tendency for the values to fall initially with time after a certain period, and then to become unsteady with, however, a falling characteristic. For the purpose of this investigation it has been considered that the insulating material becomes defective on showing signs of progressive deterioration, and the first of the tests, indicating appreciably lower values of insulation resistance that continue to decline, denotes the start of faulty insulation. The time taken to show up defective insulation in this way by the battery test is indicated in Table 2, together with the actual values of insulation resistance at this stage. The time taken for complete breakdown of the cable by the a.c. 50-cycle voltage periodic test is also noted, and in each case the total time during which each sample was under actual water pressure is given. Approximate comparison between samples tested at different pressures has been attempted, by noting from the insulation-test curves the time required by each to attain to stated values for dielectric resistance, namely 2 000 megohms and 200 megohms respectively. In these cases the true periods of time for the samples under actual hydrostatic pressure only have been considered, and are given in Table 3. The period for voltage breakdown of the samples is also included for direct reference. Curves are plotted from these results. Fig. 4 shows the pressure/time characteristic for defective insulation in connection with the battery tests, and Fig. 5 the same characteristic with respect to the cable breakdown by voltage test. The curves are of the exponential type and indicate a pressure varying inversely as some function of the time.

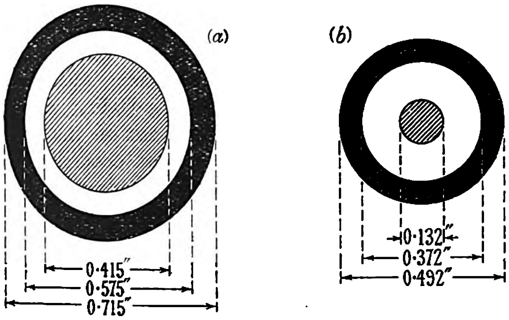

Fig. 6.—Cable sections.

Dielectric volume per inch:—
(a) 0·1 sq. in. low-tension cable.—$\pi(0\cdot2875^2 - 0\cdot2075^2) = 0\cdot1243$ cub. in.
(b) 0·01 sq. in. 2 200-V cable.—$\pi(0\cdot186^2 - 0\cdot066^2) = 0\cdot0951$ cub. in.

Although in these results the indication of water penetration with respect to thickness of insulating material alone is somewhat misleading, since the samples of the higher-voltage cable have in most cases given the lower values, it is naturally to be expected that the thicker insulation will in general take longer to show up any defects, as witness the tests on the 33-kV sample. The insulation values of the greater thickness of insulating material are necessarily of a higher order, and the defect is much more difficult to detect with any certainty, particularly in the early stages. It is unfortunate in this instance that the cables are so dissimilar in conductor section, but owing to restrictions connected with the gland and hydrostatic tube it was impossible to make use of high-voltage cables of a useful comparative size. It is quite probable, however, that, since the water does not penetrate directly through the insulation in a radial direction —in any case at low pressures—but enters via the gaps between the paper tapes, the actual volume of the insulating material partially governs its rate of progress. This is only surmise, but it is interesting to note that in Fig. 6, which shows the cable sections of the two types, the thicker insulating material has the lower volume.

CONCLUSIONS.

In the case of a thin insulating material such as that used in low-tension cables, the insulation resistance is soon affected by the penetration of moisture. With increasing numbers of insulating papers constituting a greater thickness of insulating material the effect is not so marked, and the time required to show up any defect in the lead sheathing becomes seriously prolonged under normal working conditions. This may occur to such an extent as to make it extremely unlikely for routine tests to detect the fault, and unless breakdown takes place on over-voltage test the defect must remain undiscovered in the factory.

With the thicknesses of insulating material necessary for high-voltage cables it naturally follows that the immersion test is useless from the point of view of testing the soundness of the sheathing. In order, therefore, to avoid the unnecessary risk encountered by this procedure it is advisable to discontinue the test for any but the lowest-voltage cables. In view of the fact that until recent times high-voltage cables have been immersed in water in the lead-cased stage (and in many cases specifications still call for this requirement) it seems reasonable to suppose that some of the faults that develop long after the cables have been in operation may be attributable to this cause.

GENERAL REMARKS.

As already pointed out, the tanking of cable drums also enables electrical tests to be carried out at a uniform temperature, and the question naturally arises as to how the elimination of the tanking process generally will affect these conditions. Before venturing any suggestion with regard to this point, it is as well to look into the matter of the routine tests carried out on all drums of cable in the lead-cased state. The normal specification requires an a.c. voltage test for 15 minutes at about 2½ times working voltage at supply frequency, followed by d.c. battery tests for capacity, insulation resistance and conductor resistance. The results of these latter tests have usually to conform to certain limited requirements, varying with the size of conductor and type of cable, particularly so with the capacity and copper resistance which also thereby act as a check on the actual drum length under test. The a.c. voltage and d.c. insulation tests—the latter consisting of 1 minute's electrification, which may be further prolonged if necessary—endeavour to determine the presence of weak spots in the insulating material that might be occasioned by faulty manufacture, imperfect drying and impregnation, etc. The insulation resistance is mainly a question of the composition of impregnating compound, and with the varying constituents favoured by the different cable makers for low- and high-tension cables it is quite possible to obtain values for cable insulation that vary from a few megohms to some thousands of megohms per mile. Nowadays it is not usual, therefore, to set any general limits to this characteristic, but not many years ago high values for insulation were regarded with some suspicion. It is doubtful whether the d.c. tests of insulation resistance are of any real use save as an indication of uniformity of production, except possibly in the case of low-tension cables. The electrical tests taken after lead sheathing are repeated in the armoured stage, in which case the cable drums are usually standing in the testing area of the cable shop. During the process of compounding, armouring and serving, the cable undergoes various temperature changes and may require a matter of 12 hours or more to attain the shop temperature. Experience in connection with comparison of tests of the lead-covered cable in tank and in the finished condition, combined with a careful record of shop temperatures, show that the cable insulating material has a big time-lag with regard to changes in external temperature. As comparatively rapid variations may take place in the ambient air-temperature of the shop during the course of day and night, the thermometer affords only a very approximate idea of the true cable temperature at any particular period, on account of the slowness of the change taking place within the insulating material. There is some difficulty, therefore, in determining the correct temperature of drums of cable in the open shop, but in actual practice experience has shown the allowance to be made generally for insulating material lag, and in consequence it is possible to obtain satisfactory tests on armoured cable that can be reasonably accurately checked with those of the lead-cased stage. The cable insulation-resistance varies indirectly with temperature, and on account of its higher temperature coefficient it is most susceptible to local variations of temperature. The d.c. capacity test includes a certain amount of absorption effect, which, however, has only a very slight effect on the results within the normal range of shop temperatures. The conductor resistance test is the most reliable guide to the cable temperature and is the one usually accepted in practice. It is quite possible, however, for this value to be appreciably incorrect in cases where the insulating material has undergone drastic temperature changes, such as would be occasioned by special heating tests like those undertaken on super-tension cables—either by current loading or in a heated oven—unless the full time necessary for the insulation to attain a steady state is allowed in every case. For routine work, however, the conductor resistance can be looked upon as the chief characteristic with respect to cable temperature; that being so, it is this test which needs mainly to be considered in relation to the altered conditions involved by eliminating the tanking arrangements. It is hardly necessary to take into account the other battery tests, as in reality these decline in importance as the voltage for which the cable is designed increases, and it is not proposed that the water immersion should be abolished for the lower-tension cables. With regard, therefore, to those cables which it is deemed inadvisable to submit to tanking for the reasons put forward in this paper (let us say those of 6 600 volts and over), they will require to be tested at shop temperature. After lead casing, therefore, the cable will take at least about 30 hours to attain the surrounding temperature before any satisfactory tests can be obtained.

The time suggested here is only an average figure, as the rate of cooling is dependent upon factors concerned with the length and size of cable and the drum dimensions; and the actual period that need elapse before testing will again depend upon the type and accuracy required of the results. Voltage tests are not affected by temperature conditions, but it is rare that any battery tests are in any case reliable under less than 24 hours from the time of sheathing. An appreciable time is required for the cable drum to steady down over the last few degrees drop in temperature, and as variations of the conditions in the vicinity will probably have taken place over this period it is doubtful whether the true cable temperature can be known to within a degree or so. For the resistance of the copper conductor, which increases 0·22 per cent per degree F. rise, the question of a degree or two is relatively unimportant, as it is barely within the accuracy of the measuring apparatus, quite apart from the matter of the permissible stranding allowance of the conductor. Although the variations in shop temperature, excluding any local effects that take place with the advent of the different seasons, are much greater than those occurring in the water tank, experience has shown that it is quite possible to carry out the work of testing in the open shop, with satisfactory results that meet the toleration required in general practice. There is therefore no adequate reason for the tanking of cable drums to be considered essential, and, as already suggested, for high-tension cables it should be definitely avoided. It is always possible, of course, where any doubt arises regarding test-results, to revert to the old order, or if necessary to effect a compromise in special cases and arrange for a certain percentage of drums to be tanked, thus lessening to some extent the risk due to possible defects in the lead sheathing. The matter is one that concerns the cable maker chiefly, as he is generally liable under maintenance guarantee for any faults of this description; and it may not be so vital to the interests of the customer or his consulting engineer, who are satisfied if the cable meets the required specification in the factory. Nevertheless, faults that develop under service conditions are disconcerting to all parties, and anything which is capable of removing some of the danger of such occurrences, and which can with advantage be carried out in the factory, should be given every consideration.

The author's thanks are due to Messrs. Siemens Bros. and Co., Ltd., for permission to publish the results of this investigation, which was carried out in the testing departments of their Woolwich works.

THE PRESSURES ON THE DIAPHRAGM OF A CONDENSER TRANSMITTER IN A SIMPLE SOUND FIELD.*

By W. WEST, B.A., Associate Member.

(*Paper received 7th August*, 1929.)

SUMMARY.

It has been observed that the free air pressures of a sound wave may be increased at the diaphragm of a microphone in a ratio greater than 2 : 1 at certain frequencies, when there is concavity in the face of the microphone. A method of calculating the magnitude of this increase is applied to a condenser transmitter of the Wente type, and close agreement is found with experimental results. The calculations involve certain simplifying approximations the validity of which is discussed.

SECTION (1).

The condenser transmitter has been in use for many years in the perfected form, the design of which is due to Wente,† but although it is frequently required for the purpose of measuring sound pressures in free air its performance is usually measured in terms of a uniformly distributed pressure actuating the diaphragm. This type of instrument satisfies, to a greater extent than any other now in existence, the essential requirements to be met in a large class of acoustical measurement, as typified, for example, in the testing of loudspeakers for frequency characteristics. In order that accurate measurements of sound pressures (or intensities) may be made, it is necessary for the calibration of the transmitter to be obtained in terms similar to those required in its use. The difference that exists between the performance of a transmitter of this type when measured in terms of actual pressures on the diaphragm, and in terms of pressures in free air, has been discussed by Mr. A. J. Aldridge of the Post Office Research Section, with reference to characteristic curves obtained for a particular instrument.‡

In the present paper it is proposed to show that the characteristic for free air pressures may be deduced, with fair accuracy, from a calibration of actual pressures —when certain simplifying assumptions are made. There are two important corrections to be made; one of these is due to the augmentation of the sound pressures at the face of the transmitter as a consequence of the obstruction presented to the sound waves, and the other is required to take into account the fact that the pressure at the face of the transmitter is not necessarily the same as that on the diaphragm, which is recessed. Of these corrections the former has recently received attention,§ but the latter has to a large extent been ignored or overlooked; it is therefore the subject chiefly to be dealt with.

SECTION (2).

The calculations necessary to take into account the effect of the recess in front of the diaphragm are based on the conception of acoustical impedances and of reflection factors at the ends of a tube in which sound is sustained. The method has been applied to the measurement of acoustical impedances.† Consider a short tube the ends A and B of which are terminated by acoustical impedances having reflection factors (for velocities or pressures) of g_A and g_B respectively. The length l between the ends may either be taken as the distance between surfaces at which reflection takes place without change of phase (as at a rigid surface), or it may refer to the distance between the actual terminations of the tube. In the former case the factor g is simply a numerical ratio which may have any value between ± 1; in the latter case it is understood to be the product of such a ratio and a term ϵ^{-2ika}, where $i = \sqrt{(-1)}$; $k = 2\pi$ divided by the wavelength, and a is the "end correction" of the tube (dimension length). Adopting the second notation, assume that sound is maintained by the motion at end A of an absorbing piston the velocity of which is $V\epsilon^{i\omega t}$. The air velocity at A is the sum of the velocities at A of all the waves passing up and down the tube, namely,

$$v_A = V\epsilon^{i\omega t} - Vg_B\epsilon^{i(\omega t - 2kl)} + Vg_Ag_B\epsilon^{i(\omega t - 2kl)} - Vg_Ag_B^2\epsilon^{i(\omega t - 4kl)} + \ldots \text{ to infinity}$$

$$v_A = \frac{V\epsilon^{i\omega t}(1 - g_B\epsilon^{-2ikl})}{(1 - g_Ag_B\epsilon^{-2ikl})} \quad . \quad . \quad . \quad . \quad (1)$$

The pressure at end A is similarly given by

$$p_A = \rho cV\epsilon^{i\omega t} + \rho cVg_B\epsilon^{i(\omega t-2kl)} + \rho cVg_Ag_B\epsilon^{i(\omega t-2kl)} + \rho cVg_Ag_B^2\epsilon^{i(\omega t-4kl)} + \ldots$$

$$p_A = \frac{\rho cV\epsilon^{i\omega t}(1 + g_B\epsilon^{-2ikl})}{(1 - g_Ag_B\epsilon^{-2ikl})} \quad . \quad . \quad . \quad (2)$$

where ρ = density of air and c = velocity of propagation of sound in air. The pressure at end B is

$$p_B = \rho cV\epsilon^{i(\omega t-kl)} + \rho cVg_B\epsilon^{i(\omega t-kl)} + \rho cVg_Ag_B\epsilon^{i(\omega t-3kl)} + \ldots$$

$$p_B = \frac{\rho cV\epsilon^{i(\omega t-kl)}(1 + g_B)}{(1 - g_Ag_B\epsilon^{-2ikl})} \quad . \quad . \quad . \quad (3)$$

---

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[†] See Reference (1). [‡] *Ibid.*, (2). [§] *Ibid.*, (3) and (4).

[†] See Reference (5).

The impedance per unit area at end A of the tube is

$$Z_1 = \frac{p_A}{v_A} = \frac{\rho c(1 + g_B\epsilon^{-2ikl})}{(1 - g_B\epsilon^{-2ikl})} \quad . \quad . \quad . \quad (4)$$

and the pressure ratio

$$\frac{p_A}{p_B} = \frac{1 + g_B\epsilon^{-2ikl}}{(1 + g_B)\epsilon^{-ikl}} \quad . \quad . \quad . \quad . \quad (5)$$

Equation (4) may be put into the form

$$Z_1 = \rho c\left[\frac{(1 - g_B^2) - i\,.\,2g_B \sin 2\,kl}{1 + g_B^2 - 2g_B \cos 2kl}\right] \quad . \quad (6)$$

If reflection from end B takes place as from a substantially rigid surface, $g_B = 1$ and

$$Z_1 = -\,i\rho c \cot kl \quad . \quad . \quad . \quad . \quad (6a)$$

while

$$p_A/p_B = \cos kl \quad . \quad . \quad . \quad . \quad (5a)$$

Now suppose that end A is open and provided with an infinite flange, then the total impedance per unit area at A is $Z = Z_1 + Z_0$, where Z_0 is the impedance per unit area due to the reaction of the air outside the tube. (The electrical analogue is therefore a simple circuit comprising two impedances in series.) If the total sound pressure applied at end A is p, then it follows that the ratio

$$\frac{p}{p_A} = \frac{Z}{Z_1} = 1 + \frac{Z_0}{Z_1}$$

and

$$\frac{p}{p_B} = \frac{p}{p_A}\cdot\frac{p_A}{p_B} = \left(1 + \frac{Z_0}{Z_1}\right)\cos kl \quad . \quad . \quad (7)$$

The impedance Z_1 is given in equation (6*a*), and Z_0 is known to consist of a resistance component R per unit area due to radiation of sound, and a reactance component $im\omega$, where m is the added mass per unit area due to the presence of the external air. Hence

$$\frac{p}{p_B} = \cos kl - \frac{m\omega}{\rho c}\sin kl + \frac{Ri}{\rho c}\sin kl \quad . \quad (7a)$$

The average values of R and m for a circular piston of radius r have been evaluated.*

Thus

$$\frac{R}{\rho c} = 1 - \frac{J_1(2kr)}{kr} \quad . \quad . \quad . \quad . \quad (8)$$

and

$$\frac{m}{\rho r} = \frac{K_1(2kr)}{2(kr)^3} = \frac{\mathbf{H}_1(2kr)}{(kr)^2} \quad . \quad . \quad . \quad (9)$$

(Tables for the functions $J_1(x)$ and $\mathbf{H}_1(x)$ are available. Both are to be found in "The Theory of Bessel Functions," by G. N. Watson.)

SECTION (3).

Reference will now be made to measurements of the frequency characteristics of a condenser transmitter (No. 47) of the 370W type. The results of similar measurements on another instrument (No. 111) of the same type have already been published,† but they refer to the calibration of the instrument with its protecting cover in position. This cover consists of a metal cap fitting over the face of the transmitter, with a recessed wire-gauze shield covering the diaphragm. The presence of the cover somewhat increases the depth of the recess and reduces the diameter.

As the result of a recent investigation (see Reference 4) a special source of sound has been designed to enable measurements to be made at higher frequencies. This source of sound operates on the same principle as a Bell type of telephone receiver, but its diaphragm, being clamped on a diameter of 1·9 cm, has a fundamental natural frequency of about 3 600 cycles per sec. The external diameter of the instrument is limited to 4 cm. The adjustment of a small acoustical resonator in front of the diaphragm enables measurements to be made over a frequency range of 2 500 to 5 000 cycles per sec. The apparatus and methods of carrying out the measurements do not otherwise differ from those previously described.*

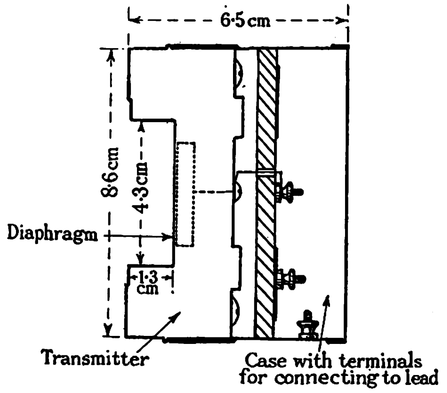

FIG. 1.—Outline of cross-section of condenser transmitter.

On the back of the condenser transmitter was mounted a short cylindrical case to provide mountings for terminating the lead to the amplifier and to act as a screen. No description of the instrument beyond that of its external geometrical shape and dimensions is necessary for the present purpose. These are sketched in Fig. 1, which shows an outline of the cross-section including the case at the back. The general form is that of a short cylinder having a cylindrical cavity in the front face.

Frequency characteristics of this instrument, obtained by means of the Rayleigh disc, are shown in curves (1) and (2) of Fig. 2, curve (1) being obtained in terms of sound pressures in free air and curve (2) in terms of actual pressures on the diaphragm. Curve (3) shows the maker's calibration (by thermophone) for the *type* and is introduced in justification of the form of extension of curve (2) beyond 3 300 cycles per sec., which was the highest frequency at which readings were taken for this condition of test. Obviously, the difference between curves (1) and (2) cannot be accounted for solely by the effect of the obstruction of the instrument to the sound waves.

---

* See Reference (6), par. 302.

† *Ibid.*, (2).

* See Reference (4). The transmitter was so located in the testing cabinet (Fig. 5 of this reference) that, while it faced the source of sound, secondary or reflected waves from its surface would be incident more or less at right angles to the plane of the Rayleigh disc, and would therefore not affect a measurement of the primary wave.

SECTION (4).

The corrections, mentioned in Section (1) as being necessary to correlate the two curves, may be applied if certain simplifying assumptions are made, discussion of which will be deferred to Section (5). Firstly, if the existence of the cavity in the face of the transmitter is ignored, there will be at this face an increase in pressure due to obstruction of the sound field; it will be assumed that the pressure will be increased in the same ratio as would occur at the point nearest to the source of sound on a solid spherical obstacle, 10 cm in diameter. This correction factor, or ratio of actual to free air pressure, can be calculated, and it is plotted against frequency in curve (1) of Fig. 3. In making the calculations the value of c, the velocity of propagation of sound, was taken as 34 000 cm per sec. Points on the curve at frequencies above 2 500 cycles per sec. ($k \times$ radius of sphere > 2) were obtained from the table published by Ballantine (see Reference 3), the remainder chiefly from calculations supplied by Rayleigh (see Reference 6, chap. 17).

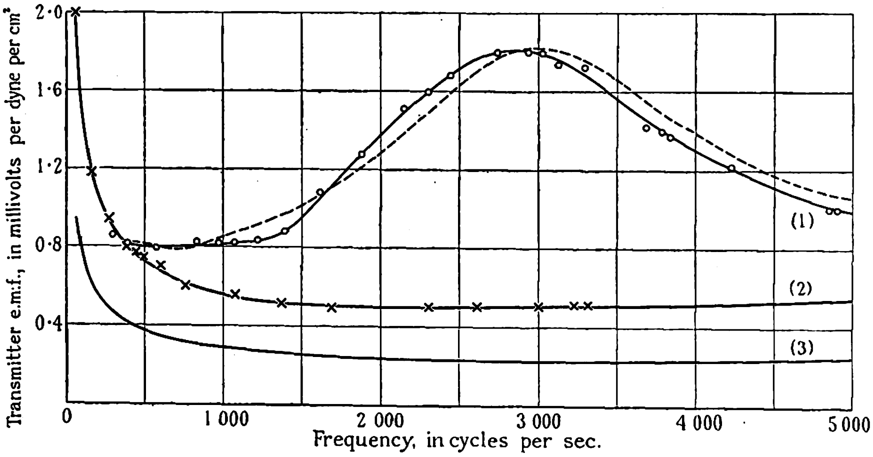

FIG. 2.—Frequency characteristics of condenser transmitters.

Curve (1).—In terms of free air pressures.
Curve (2).—In terms of pressures on the diaphragm.
Curve (3).—Maker's curve for the type (by thermophone).
Dotted curve.—Calculated curve for free air pressures (based on Curve 2).

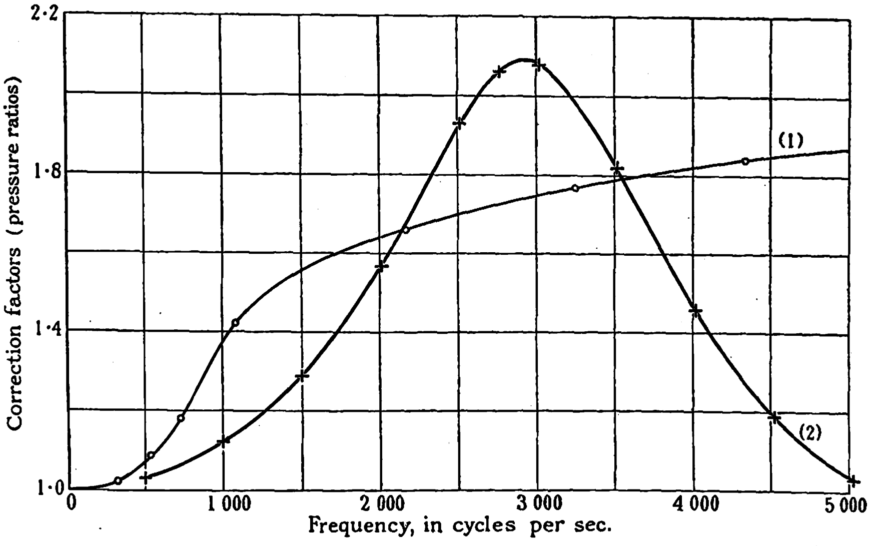

FIG. 3.—Correction factors for reducing pressures on the diaphragm into terms of free air pressures.

Curve (1).—Calculated ratio of actual to free air pressures on a sphere of 10 cm diam.
Curve (2).—Calculated ratio of pressures on diaphragm to pressures at aperture of condenser transmitter.

Secondly, the ratio of the pressure p at the face of the transmitter to the pressure p_B on the diaphragm may be calculated from equation (7a), with the assumptions that the motion of the diaphragm is insignificant and that the external acoustical impedance at the aperture of the cavity is equivalent to that on (one side of) a piston enclosed by an infinite baffle. In order to simplify the calculation put $R' = R/(\rho c)$ and $m' = m/(\rho r)$, these values being obtained from equations (8) and (9). Then equation (7*a*) may be rewritten

$$\frac{p}{p_B} = \left[\cos kl - m'kr \sin kl\right] + i\left[R' \sin kl\right] = X + iY$$

and the numerical value of $p_B/p = \left[X^2 + Y^2\right]^{-\frac{1}{2}}$, where $X = \cos kl - m'kr \sin kl$ and $Y = R' \sin kl$.

Details of the calculations are given in the table, and the values of the correcting factor p_B/p are plotted against frequency in curve (2) of Fig. 3.

TABLE.

($l = 1{\cdot}3$ cm, $r = 2{\cdot}15$ cm)

Frequency	kr	kl	$\cos kl$	$\sin kl$	m'	R'	X	Y	p_B/p
500	0·2	0·12	0·993	0·120	0·840	0·020	0·973	—	1·03
1 005	0·4	0·24	0·971	0·238	0·807	0·078	0·894	—	1·12
1 505	0·6	0·36	0·936	0·352	0·770	0·170	0·773	0·060	1·29
2 010	0·8	0·48	0·887	0·462	0·714	0·288	0·623	0·133	1·57
2 515	1·0	0·60	0·825	0·565	0·647	0·423	0·460	0·239	1·93
2 765	1·1	0·66	0·790	0·613	0·610	0·495	0·379	0·304	2·06
3 015	1·2	0·72	0·752	0·659	0·571	0·567	0·301	0·374	2·08
3 520	1·4	0·84	0·667	0·745	0·493	0·708	0·153	0·528	1·82
4 020	1·6	0·96	0·573	0·819	0·414	0·837	0·031	0·685	1·46
4 525	1·8	1·08	0·471	0·882	0·338	0·947	−0·065	0·835	1·19
5 025	2·0	1·20	0·362	0·932	0·267	1·030	−0·136	0·960	1·03

The application of both of the correction factors to the calibration of the transmitter in terms of actual pressures [curve (2) of Fig. 2] results in the broken curve shown in the same figure. No ordinate on this curve differs from the corresponding ordinate on curve (1) by as much as 10 per cent.

SECTION (5).

It was first assumed that the effect of the transmitter as an obstacle in the sound field created pressures at the surface equivalent to those on a sphere 10 cm in diameter. Since such an effect has been calculated only for a spherical shape, the assumption of an " equivalent sphere " is essential. Although it is not to be expected that the true effect will take the exact form shown in curve (1) of Fig. 3, it is very probable that the differences at all points will be small, at least in the case of a short cylindrical obstacle, provided that a suitable diameter is chosen for the equivalent sphere. There is also some confirmatory experimental evidence of this (see Reference 4). In estimating the diameter of the equivalent sphere the presence of the recess may be ignored since it is given separate consideration, i.e. the cavity may be considered to be filled with solid to the front face of the transmitter. As a result of previous experience, the author has estimated that for pressures at the centre of a flat face of a short cylinder (the length of which is, say, less than the radius) the circumscribing sphere forms a useful approximation. For the transmitter the circumscribing sphere has a diameter of 10·8 cm, but the length is greater than the radius. Ballantine (see Reference 3) proposes an estimate based on equal volumes of sphere and obstacle, when the obstacle " occupies a volume of reasonable (say cubical) shape " (presumably when extreme dimensions taken through the centre do not differ too greatly). On this basis the diameter of the equivalent sphere would be 9 cm, but as this hardly exceeds the actual diameter (when taken over the slightly projecting ridge) no account would be taken of the comparatively more gradual streamline presented by the sphere, and this value would probably underestimate the effect. For these reasons the intermediate value of 10 cm was chosen for the diameter of the equivalent sphere, though either of the other values mentioned could be used without greatly affecting the result.

Secondly, the motion of the diaphragm is neglected in the assumption that $g_B = 1$, i.e. that the mechanical impedance of the diaphragm is very great as compared with the characteristic impedance of a tube (ρc per unit area). In this type of instrument the diaphragm is stretched and the fundamental natural frequency exceeds 10 000 cycles per sec. The chief constraint to motion is imposed by the air cushion at the back, for which some impedance values are quoted by Crandall.* These were calculated for an early form of condenser transmitter probably of similar dimensions and construction, and will serve to indicate the degree of approximation that has been made. For example, at 3 000 cycles per sec. the mean resistance per unit area is about 5 000 and the mean stiffness per unit area about 3×10^8 [reactance $= 3 \times 10^8 \div (2\pi \times 3\,000) = 16\,000$]. This takes no account of the stiffness of the diaphragm *per se*, or of its mass, but it will serve to assume an impedance of, say, $5\,000 - i\,10\,000$. This impedance per unit area may be related to g_B by putting $l = 0$ in equation (4), and it will be convenient to separate g_B into the form $g_B = g\epsilon^{-2ik\alpha}$, where g is simply a numerical ratio. Hence

$$\frac{\rho c(1 + g\epsilon^{-2ik\alpha})}{(1 - g\epsilon^{-2ik\alpha})} = 5\,000 - i\,10\,000$$

---

* See Reference (7), art. 11, Fig. 5.

Equating real and imaginary parts,

$$\frac{\rho c(1 - g^2)}{1 + g^2 - 2g \cos 2ka} = 5\,000$$

and
$$\frac{\rho c \,.\, 2g \sin 2ka}{1 + g^2 - 2g \cos 2ka} = 10\,000$$

Since ka is very small, $\sin 2ka = 2ka$
and $\cos 2ka = 1 - \frac{1}{2}(2ka)^2$, with sufficient accuracy.

The solution of these equations gives $g = 0{\cdot}997$ and $2ka = 0{\cdot}006$, or $a = 0{\cdot}005$ cm. The sign of a is positive and the correction therefore tends to increase the length of the tube.

It may also be concluded that the performance of the transmitter cannot be appreciably affected, at the frequencies considered, by changes of the impedance imposed by the external air. Such an effect has been observed (see Reference 4) in the case of a very light diaphragm, but it applies chiefly to the position of the fundamental natural frequency, which is well beyond the frequency range dealt with and is, moreover, less liable to alteration for the greater density of the diaphragm.

The only other approximation of any consequence was that the impedance, looking outwards from the aperture of the transmitter, was assumed to be equal to the average impedance over the surface of a piston, of the same area, surrounded by an infinite baffle. This assumption is somewhat bold, but a consideration of such information as is available indicates that it is more reasonable than would appear at first sight. Consider first the resistance component, retaining for the time being the fiction of piston motion at the aperture. It is known that at very low frequencies the value of R' with a small baffle is one-half of that given by equation (8), applicable to an infinite baffle. It probably increases towards this value in much the same way as curve (1) of Fig. 2 approaches the value 2 as the frequency is raised. It can be seen from the table on page 444 that the term Y, involving this component, has little or no influence below, say, 2 000 cycles per sec., and above this frequency errors in the value of R' are probably less than 20 per cent (as deduced from curve 1 of Fig. 2). All dissipative forces other than that due to radiation have been neglected as being comparatively very small, but in so far as such do exist they will tend to reduce this error.

At low frequencies at any rate, the mass component m' is also overestimated, though not to so great an extent as the resistance component, since it plays no part in radiating sound and, being more influenced by local conditions, it probably does not require so large a baffle for the practical equivalent of one that is infinitely extended. Thus at very low frequencies the addition of an infinite baffle on the end of a tube, initially without any baffle at all, is known to increase the value of m' only in the ratio $0{\cdot}82$ to $0{\cdot}6$, or about $1{\cdot}37$ to 1. Since the presence of the flange forming the face of the transmitter may be expected to exert an influence even at low frequencies, it seems probable that the admitted overestimate of m' at low frequencies is rapidly reduced as the frequency is raised into the range where the correction factor becomes important. At the higher frequencies the conditions are less certain, but the term X, involving the mass, has little influence on the correction factor from about 3 500 to 5 000 cycles per sec.

In discussing the assumption of piston motion at the aperture * it may be recalled that at very low frequencies it involves an error in the "end correction," i.e. in m', in the ratio of $0{\cdot}85$ to $0{\cdot}82$ when applied to an open-ended tube with an infinite flange. This appears to be a comparatively small effect, but an element of uncertainty is introduced when the irregular distribution of impedance over the surface of the piston is considered. It is this irregularity which chiefly causes the actual motion at an aperture to depart from that of a true piston, and in assuming the impedance per unit area to be equal to the average value of that on a piston no account is taken of the form of the distribution. This is important if (the length of the tube being short) an irregular distribution of pressure is created on the diaphragm, since the effects of pressures at the centre are stronger than of those nearer the edge. Under the actual conditions, however, it is probable that variations of impedance appear as variations of velocity at different parts of the aperture rather than as variations of pressure. Warren † has drawn attention to the differences in impedance at the centre and at the edge of a circular piston. He shows that the impedance at the centre is greater than that at the edge, and observed increases in amplitude or velocity towards the edge of an aperture may thus be accounted for.

SECTION (6).

The close agreement reached between the calculated and the experimental curves has the double value of inspiring confidence in the methods of calculating the corrections, and of providing an additional check on the accuracy of the Rayleigh disc methods of calibration, there being (as far as the author is aware) no direct alternative method at present available for effecting a calibration in terms of free air pressures.

In a more recent form of Wente condenser transmitter the recess has been reduced to $0{\cdot}85$ cm in depth, the radius remaining the same. That the effect of the recess is still appreciable is shown by a calculation at 3 500 cycles per sec., at which frequency the correction factor for the recess has a value of $1{\cdot}63$, which is probably nearly the maximum value attained.

The calibration and use of a transmitter in terms of free air pressures require that sound shall emanate from a single source; this necessitates the absence of reflecting surfaces, that is the carrying out of experiments in open air, or the acoustical equivalent. The latter alternative is available by covering all the solid surfaces in a testing cabinet with a sufficient quantity of a material suitable for accepting and absorbing sound.

The value to acoustical engineering practice of the conception of acoustical impedances is generally recognized; it would be increased by a more definite knowledge of the actual magnitudes of the impedances in some

---

* At the lowest frequency calculated (500 cycles per sec.) the assumption of piston motion results in a value ($0{\cdot}84$) of m' in excess of that calculated by Rayleigh for an open-ended tube with an infinite flange, namely $0{\cdot}82$, but at this frequency the correction is, in any case, very small.

† See Reference (8).

common cases (e.g. of apertures surrounded by finite flanges) where direct calculation has failed. Experimental methods are available which would serve to furnish data of this kind.

The measurements which have been recorded were carried out at the Post Office Engineering Research Station and are published by permission of the Engineer-in-Chief of the Post Office.

ALTERNATING-CURRENT TESTS ON HIGH-SPEED TELEGRAPH CABLES.*

By E. W. Smith, Ph.D., B.Sc. (Eng.), Associate Member.

(*Paper received* 7*th June*, 1929.)

Summary.

This paper is concerned with the alternating-current characteristics of loaded telegraph cables and their relation to transmission capacity. The general principles of transmission are reviewed, and by the use of periodic theory the performance which may be expected from a cable of given a.c. characteristics is estimated.

Methods of testing are described by which complete data of the a.c. constants may be obtained during the process of manufacture. The effects of frequency, current, temperature and pressure are investigated, and the results of tests on the core for a long high-speed cable are discussed and used to estimate the performance of the cable when laid.

Apparatus and alternative methods for testing the laid cable are detailed and a method of deducing the primary constants from attenuation and propagation-time tests is developed; values determined are compared with results of factory tests. Deductions regarding the value and regularity of the inductance loading are made from impedance tests.

Departure and arrival curves for loaded cables are constructed from theory and compared with records obtained by test.

Finally, the assumed criteria for satisfactory working, expressed in terms of attenuation, are verified by transmission tests.

Table of Contents.

List of Symbols.
(1) Introduction.
(2) Review of general principles.
  (*a*) Telegraphic equation, transient and periodic conditions.
  (*b*) Applicability of periodic condition to speed estimates.
  (*c*) Distortion, interference, and the practical standard of satisfactory transmission.
(3) Tests on cable during manufacture.
  (*a*) General.
  (*b*) Inductance and effective resistance by self and mutual inductance methods.
  (*c*) Capacity and leakance by series and parallel resistance methods.
  (*d*) Corrections arising from length of test coils.
  (*e*) Tests under pressure and at low temperature.
  (*f*) Variations of the primary constants with frequency, current, temperature and pressure. Experimental data.
  (*g*) Prediction of attenuation and head-end loss from factory tests.

Table of Contents—*continued.*

(4) Tests on cable after laying.
  (*a*) General.
  (*b*) Measurement of impedance.
  (*c*) Measurement of attenuation and head-end loss.
  (*d*) Measurement of propagation time.
  (*e*) Method of determining constants and comparison with data obtained during manufacture.
(5) Arrival curves.
(6) Transmission capacity of the cable.
  Validity of assumed standard of satisfactory transmission.
(7) Conclusions.

List of Symbols.

B = flux density.
C = capacity to earth, per unit length of cable.
d = diameter of loading wire.
E = voltage applied to cable.
G = leakance to earth, per unit length of cable.
H = effective magnetizing force.
h_1 = voltage head-end loss.
h_2 = current head-end loss.
I_r = current at receiving end.
I_s = current at sending end.
I = current in cable.
L = inductance, per unit length of cable.
l = length of cable.
f = frequency of impressed voltage = $\omega/(2\pi)$.
$P = \sqrt{\{(R + j\omega L)\ (G + j\omega C)\}}$ = "propagation constant" = $\alpha + j\beta$.
α = attenuation constant.
β = wavelength constant.
R = resistance of unit length of the cable.
R_{ad} = added resistance, comprising:—
R_{ae} = resistance due to after-effect.
R_h = resistance due to hysteresis.
R_{cc} = resistance due to eddy-current.
r = mean radius of loading spiral (cm).
S = speed, in letters per minute.
V = voltage-drop in cable.
V_r = voltage at receiving end.
V_s = voltage at sending end.
$Z_0 = \sqrt{\{(R + j\omega L)/(G + j\omega C)\}}$ = "characteristic impedance."
Z_r = receiving impedance of cable.
Z_e = effective impedance of cable.
μ = permeability of loading material.
ρ = resistivity of loading material.
σ = impurity coefficient.

The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(1) INTRODUCTION.

The electrical testing of submarine telegraph cables has, up to within a few years of the present time, been confined to direct-current measurements of resistance, capacity and insulation. Accurate data of the resistance of the conductor and its capacity to earth enabled the speed capabilities of the cable to be determined, and was essential for the localization of faults; while observation of the insulation of conductor to earth indicated the quality of the dielectric and ensured that leakage should be kept within a limit which would have no adverse effect on the speed of working.

The art of "loading," or adding inductance to telegraph cables, was advocated by Oliver Heaviside as long ago as 1885, but did not become a practical proposition until 1924, when the first long-distance loaded cable was manufactured.* The resultant greatly increased speed of working was obviously no longer determined by d.c. resistance and capacity alone; the cable could no longer be considered as a medium for the diffusion of impulses of direct current, for its electrical condition in operation approximated more nearly to that of a line carrying alternating current. Consequently, while the old d.c. tests were still required for reasons other than speed estimates, they had to give place in importance to a.c. measurements, upon the results of which the performance of the cable could be accurately predicted.

It is proposed in this paper to describe the development and application of means of testing which have accompanied recent progress from the unloaded low-speed cable, capable of transmitting a few hundred letters per minute, to the loaded high-speed cable working at speeds up to 2 000 letters. The tests necessary to ensure a complete knowledge of the electrical properties of the new type of cable, both during manufacture and after laying, will be described, and test data will be examined for such consistent behaviour as may be generalized for future use as the basis of cable design.

(2) REVIEW OF GENERAL PRINCIPLES.

(*a*) *Telegraphic Equation.*—In Fig. 1, A represents the conductor and B the insulator of a cable of length l. The conductor has resistance R and inductance L per unit length, and its leakance and capacity to earth are G and C respectively. For any small section of length δx, at distance x from the source of an applied voltage E, the constants are $R\delta x$, $L\delta x$, $G\delta x$ and $C\delta x$. Let the current-change in the section be $-\delta I$ and the voltage-change $-\delta V$. Considering the decreasing voltage,

$$-\delta V = R\delta x I + L\delta x(dI/dt)$$

where d/dt is the time differentiator and the current-change is small enough to be neglected. Or, when δx becomes dx,

$$-dV/dx = RI + L(dI/dt) \quad . \quad . \quad . \quad (1)$$

Similarly, considering the decreasing current,

$$-\delta I = G\delta x V + C\delta x(dV/dt)$$

and $$-dI/dx = GV + C\,(dV/dt) \quad . \quad . \quad . \quad (2)$$

Transient Condition (*Unloaded Cable*).—For an unloaded low-speed cable, L and G are negligibly small, and in this case

$$-dV/dx = RI \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and $$-dI/dx = C(dV/dt) \quad . \quad . \quad . \quad . \quad (4)$$

Hence, by differentiation,

$$d^2V/dx^2 = RC(dV/dt) \quad . \quad . \quad . \quad . \quad (5)$$

and $$d^2I/dx^2 = RC(dI/dt) \quad . \quad . \quad . \quad . \quad (6)$$

From equation (5) or (6) is derived an expression* for the current I_r at the receiving end of the cable:

$$I_r = \frac{E}{Rl}\left[1 + 2\sum_{m=1}^{m=\infty} \epsilon^{-\frac{m^2\pi^2 t}{RCl^2}} \cos m\pi\right] \quad . \quad . \quad (7)$$

whence it is apparent that the rate of increase of current at the receiving end of the (unloaded) cable is controlled by the product of its total resistance and total capacity. This led to the practical rule, known as the "Kelvin *KR* law," that speed of signalling could be estimated by dividing a constant by the factor RCl^2.

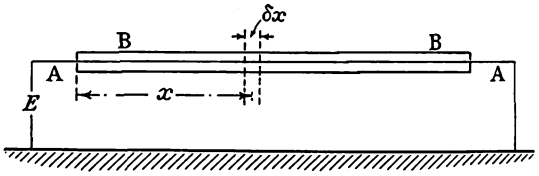

FIG. 1.

Periodic condition.—If the sending voltage is sinusoidal, of the form $E\epsilon^{j\omega t}$, the time differentiator d/dt is replaced by $j\omega$, and equations (1) and (2) become

$$-dV/dx = (R + j\omega L)I. \quad . \quad . \quad . \quad (8)$$

and $$-dI/dx = (G + j\omega C)V \quad . \quad . \quad . \quad (9)$$

whence $$d^2V/dx^2 = (R + j\omega L)(G + j\omega C)V \quad . \quad . \quad (10)$$

and $$d^2I/dx^2 = (R + j\omega L)(G + j\omega C)I \quad . \quad . \quad (11)$$

By the solution of equation (10) or (11) the telegraphic equation for periodic conditions is obtained.†

It is expressed by

$$\left.\begin{aligned} V &= V_s \cosh Px - Z_0 I_s \sinh Px \\ I &= I_s \cosh Px - V_s/Z_0 \sinh Px \end{aligned}\right\} \quad . \quad . \quad (12)$$

where $$P = \surd\left\{(R + j\omega L)\,(G + j\omega C)\right\} \quad . \quad . \quad (13)$$

$$Z_0 = \surd\left\{(R + j\omega L)/(G + j\omega C)\right\} \quad . \quad . \quad (14)$$

where V_s and I_s = voltage and current at sending end, and V and I = voltage and current at distance x from sending end.

The quantity P is known as the "propagation constant," of which the real part is the attenuation constant α and the imaginary part the wavelength constant β; so that

$$P = \alpha + j\beta \quad . \quad . \quad . \quad . \quad . \quad (13a)$$

Z_0 is termed the "characteristic impedance" of the cable.

* O. E. BUCKLEY: *Journal of the American I.E.E.* 1925 vol. 44, p. 821.

* Sir W. THOMSON: "Papers," vol. 2, p. 62 (1884). For complete treatment, see H. W. MALCOLM: "The Theory of the Submarine Telegraph and Telephone Cable," ch. 8 (London, 1917).

† H. W. MALCOLM: *loc. cit.*, ch. 4.

From equation (12) above,

$$V = (V_s - Z_0 I_s)(\epsilon^{Px}/2) + (V_s + Z_0 I_s)(\epsilon^{-Px}/2)$$

and

$$I = \{I_s - (V_s/Z_0)\}(\epsilon^{Px}/2) + \{I_s + (V_s/Z_0)\}(\epsilon^{-Px}/2)$$

When the cable is of infinite length, V and I decrease as x increases, and since V_s, I_s and Z_0 are independent of x, the coefficients of ϵ^{Px} (an increasing function of x) in the above equations must be zero. Hence,

$$V_s = Z_0 I_s \quad . \quad . \quad . \quad . \quad . \quad (12a)$$

and

$$V/V_s = I/I_s = \epsilon^{-Px} \quad . \quad . \quad . \quad (12b)$$

(*b*) *Applicability of Periodic Condition to Speed Estimates.*—Telegraphic signals consist of aperiodic positive, negative and zero impulses, an average of nearly four of which make up a letter. If positive and negative impulses alternated, the fundamental frequency f of the train (two successive impulses in which would make one cycle) would be related to the speed in letters per minute, S, by the equation

$$f = 4S/(60 \times 2) = S/30 \quad . \quad . \quad . \quad (15)$$

Now larger received signals result from aperiodic than from periodic impulses, owing to transient currents, present in the former case and absent, after the first few cycles, in the latter. Thus, in signalling, a letter such as J (— + + +) arrives at greater magnitude than the letter C (+ — + —) sent at the same speed—in fact the chief object of the curbing, or shaping, apparatus at the ends of the cable is to reduce the size of all signals to that of the periodic or quasiperiodic ones, e.g. C, K (+ — +) and R (— + —).

Hence it may be stated that a cable which will transmit a frequency f in sufficient strength (i.e. which will have a sufficiently low attenuation at f cycles per sec.) will permit of a working speed of $30f$ letters per minute.

This applies to all cables, loaded or unloaded, fast or slow, and an approximation to the allowable attenuation may be obtained from the application of the Kelvin KR law to the speeds of unloaded cables. The average value of the Kelvin constant with modern apparatus is 800—i.e. for satisfactory signalling,

$$S = 30f = 800/RCl^2 \quad . \quad . \quad . \quad . \quad (16)$$

Now the attenuation constant of an unloaded cable for alternating current is approximately $\alpha = \sqrt{(\frac{1}{2}\omega RC)}$, leakance and inductance being neglected, and, if αl is the attenuation,

$$\alpha l = \sqrt{(\tfrac{1}{2}\omega RCl^2)} = \sqrt{\{\tfrac{1}{2}\omega \times (800/30f)\}} = 9 \cdot 1 \quad (17)$$

We have now to consider the influence on this approximation, derived from standard practice on unloaded cables, of certain factors peculiar to cables of the loaded type.

(*c*) *Distortion, Interference, and the Practical Standard of Satisfactory Transmission.*—The loaded cable has advantages over the unloaded in that it transmits with less distortion and suffers less from interference.

The attenuation constant of the loaded cable, from equation (13) above, reduces to

$$\alpha = \tfrac{1}{2}R\sqrt{(C/L)} + \tfrac{1}{2}G\sqrt{(L/C)} \quad . \quad . \quad (18)$$

on the valid assumption that ωL and ωC are large in comparison with R and G respectively. Part of the factor R (the d.c. resistance of the conductor) is not dependent, and part (the iron losses, etc.) is dependent on frequency; but in a properly designed loaded cable the dependent part is kept relatively small and, again, the second term of the attenuation, $\frac{1}{2}G\sqrt{(L/C)}$, is small compared with the first, $\frac{1}{2}R\sqrt{(C/L)}$.

The variation of attenuation with frequency, at the frequency for which the cable is designed, is thus less than that of an unloaded cable, for which $\alpha = \sqrt{(\frac{1}{2}\omega RC)}$. This means that distortion is less, and that uniformity in size of signals is obtained with less curbing.

With regard to interference, high-speed loaded cables have up to the present been designed for simplex working only. They are not, therefore, subject to the limitation in speed due, on unloaded cables, to difficulties in maintaining an adequate duplex balance.

Further extraneous interference has been greatly reduced by the introduction of the balanced sea earth.* The usual local receiving earth is replaced by a length of line B (Fig. 2) of the same characteristics as the cable A, terminated by a resistance R. The sea earth extends into water of depth about 100 fathoms, where disturbances, mostly occurring in shallow water, are slight. As the characteristic impedance of the cable does not vary appreciably with frequency within the working range, and is nearly a pure resistance, it can readily be reproduced, with sufficient accuracy, by the resistance R. Thus any disturbance originating at a point C meets with impedances on line and earth equal in the direction of the receiving end, and practically equal in the other (seaward) direction for the critical frequency band. Thus the disturbances to which the receiving apparatus is most sensitive are made ineffective, as they arrive by the two paths in equal strength and opposite directions.

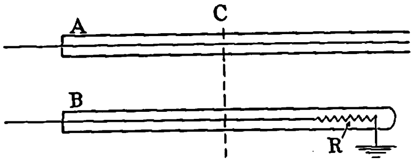

FIG. 2.

From the above considerations of distortion and interference, an increase may be expected in the permissible attenuation figure of 9·1 arrived at in equation (17).

As the result of experience on the first long loaded cable it was stated † that attenuations of 9 for relay working, and 10 for recorder working, were allowable, while for the Pacific Cable Board's continuously-loaded Bamfield (Vancouver)–Fanning Island II (1926) cable the following guarantee was given: "The completed cable when laid and throughout the guarantee period shall be capable of transmitting at the rate of 600 letters per minute simplex; the speed shall be calculated on the basis of a received current of 10 R.M.S. microamperes with receiving apparatus of impedance equal to the characteristic impedance of the cable when sending reversals with 60 volts (d.c.) at the dot frequency, counting 4 centre-holes per letter." This corresponded to an attenuation of approximately 9·3. This figure may be taken as a safe standard for satisfactory recorder working under average conditions, as will be seen in Section (6).

(3) Tests on Cable during Manufacture.

(*a*) *General.*—It is not intended to discuss electrical tests on the raw materials forming cable cores, but mention may be made of an inductance test which is carried out on the loaded conductor, immediately after the annealing, and before the insulating process.* In this test a short part of the moving conductor which has just left the annealing furnace makes sliding contact with two fixed brushes. This part forms one arm of a bridge in which it is approximately balanced by a standard inductance. A Sumpner dynamometer is used as a detector, and deflections due to unbalance in the bridge, consequent on changes in the inductance of the moving conductor along its length, give, on a suitably calibrated scale, a continuous indication of inductance. The bridge is normally supplied with alternating current at a frequency of 50 cycles per sec., and the constants of the conductor are such that the resistance forms only a small part of the total impedance.

The cores of all cables are subjected to tests of d.c. resistance, capacity and insulation by well-known methods, and the effects of pressure and temperature on these constants are determined. In the case of loaded cables, in addition to the usual d.c. tests, each length of core is tested for a.c. resistance and inductance, and selected lengths are tested for leakance and capacity. Determinations are also made of the variation of the primary constants with frequency, current, temperature and pressure.

The importance of these a.c. tests at the present early stage of development of the loaded cable is considerable, as complete data must be available as a basis for the design of future cables and for progressive improvement in materials and factory processes.

For resistance and inductance tests the core, in lengths of about 2 nautical miles, must be wound on drums bifilarly in order to reduce the geometric inductance of the core (as distinct from the inductance added by the loading) to a small and calculable amount—in most cases 0·7 mH per nautical mile. The standard test frequency is that determined by the methods given in Section (2) (*b*); the standard test current is 1 mA (R.M.S.), this being the smallest current at which tests can conveniently be made.

With the bifilar winding used the external magnetic field of the coil is very small, but exact tests have shown that the eddy-current component of the effective resistance is measurably increased if the drum is made of ordinary commercial iron. The increase was found to be of the order of $5 \times f^2 \times 10^{-6}$ ohms for a coil of normal length, this being, in most cases, quite negligible.

It is impracticable to test complete coils for leakance and capacity, for the reasons given in Section (3) (*d*), and the best procedure is to take representative specimens of length about 70 ft. This length gives bridge settings of convenient magnitude and allows of the use of standard air condensers with an equal ratio bridge. The standard test frequency, for convenience in dealing with a large number of specimens, is 1 000 cycles per sec., produced from a thermionic oscillator; the e.m.f. between conductor and earth being 40 to 50 volts. In practice, samples are always immersed in salt water for leakance and capacity tests, as it has been found that if fresh water is used the resistance between earth-plate and core is sufficient to produce an apparent increase in leakance of 5 or 10 per cent.

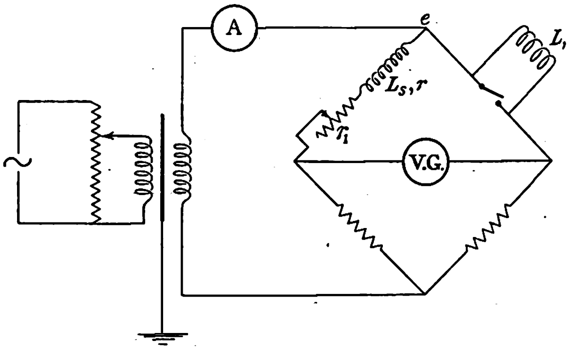

Fig.

(*b*) *Inductance and Effective Resistance.*—Two convenient methods are available for resistance and inductance measurements: (i) the Maxwell* bridge with standard self-inductance, and (ii) the Heaviside-Campbell † bridge with standard mutual inductance. The arrangement of these bridges as used is given in Figs. 3 and 4, the equations for balance being

(i) Maxwell bridge, $L = L_s$, $R = r + r_1$

(ii) Heaviside-Campbell bridge, $L = 2M$, $R = r_1$

with equal ratios in each case.

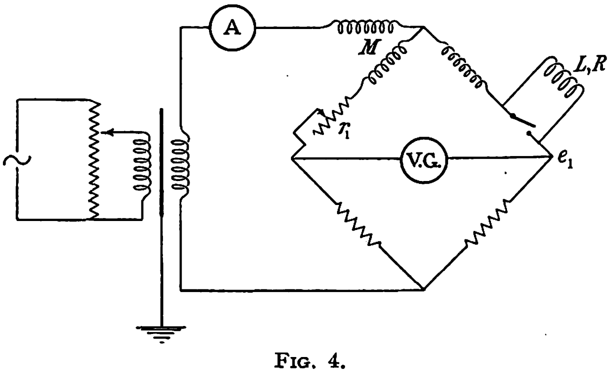

Fig. 4.

The advantages of using equal ratios whenever possible, in order to minimize and check errors due to earth capacities and residuals, is evident. In practice it is advisable to extend the range of the standards, if necessary, rather than to resort to an unequal ratio bridge. Under such conditions, and with the low frequencies used, earth capacity errors are not serious, and may for all practical cases be eliminated by earthing either terminal of the test coil, these being the points having greatest earth capacity. In Fig. 3 the point e is chosen as this connects to earth, in addition, one side of the standard. In Fig. 4 the earth is at e_1, as the alternative point would, if earthed, give the effect of increased impurity in the mutual inductance standard.

* British Patent No. 256680.

* J. C. Maxwell: "A Treatise on Electricity and Magnetism" (1873), 3rd edition, vol. 2, p. 398.

† O. Heaviside: *Philosophical Magazine*, 1887, vol. 23, p. 173; also A. Campbell: *Proceedings of the Physical Society of London*, 1908, vol. 21, p. 69.

Alternating current is supplied to the bridge through a screened transformer, and is measured by a thermal milliammeter A consisting of vacuum thermo-junction and d.c. microammeter. It is regulated by a potentiometer or a series resistance (the former being generally more convenient) placed on the primary, or alternator, side of the transformer. It has been found that with the regulator on the secondary, or bridge, side, balance is more susceptible to capacity errors when testing with very small currents, i.e. when the part of the potentiometer resistance tapped to bridge is small or, with the series regulator, when the resistance is large.

In both bridges a 4-pole change-over switch enables a d.c. source and detector to be substituted for the a.c. supply and vibration galvanometer, so that d.c. and a.c. resistances can be readily compared under the same conditions of test.

Further details with regard to the construction and working of the bridges are as follows:—

Maxwell Bridge.—An accurate standard of self-inductance is required, and for high sensitivity the bridge should have a resistance not greatly in excess of that of the lengths of core to be tested. Such a standard was specially designed and constructed for the purpose. It consists of two tapped coils, one of 100 mH by tens, and the other of 500 mH by hundreds. The resistance of the first coil is 4 ohms, and that of the second 20 ohms. It was anticipated that, by the use of stranded wire, the effective resistance of any section of the coils at a frequency of 200 cycles per sec. would not differ from the d.c. resistance by more than 0·2 per cent, and calibration by means of Hay's bridge,[*] using a standard condenser of known power factor, and comparison with standardized coils, have shown the difference to be within this specification.

The required sections are connected in circuit by means of a plug commutator, which also completely isolates sections not in use, thereby minimizing earth capacity. The coils are not astatic, but are placed at right angles to each other in a common case and have negligible mutual inductance. In practice it has been found that, if the standard is so placed that it is not nearer than 2 ft. to any large mass of metal or any other part of the bridge, no measurable errors are caused by eddy currents or interference produced by the external field.

A specially constructed variable self-inductor of range 10 mH is used in series with these fixed subdivided coils, the combination forming a continuously variable standard from about 1 mH to 600 mH.

Heaviside-Campbell Bridge.—The variable mutual inductance standards available permit of measurements of self-inductance up to 220 mH on an equal ratio bridge. When the test inductance is beyond this value the "known" arm of the bridge is loaded by a fixed standard of self-inductance, the effective resistance of which is exactly balanced out, for convenience in working, by a non-inductive resistance in the "unknown" arm.

In order to determine the effect of impurity in the mutual inductance[*] on effective resistance measurements, a series of standardized coils was tested on the equal ratio Heaviside bridge at a range of frequencies up to 200 cycles per sec. The impurity coefficient, σ, is given by $R_t - R_a = 2\sigma$, where R_t is the true, and R_a the apparent, effective resistance of the coil. The results of these impurity tests are given in Fig. 5. The coefficient was found to vary substantially as the square of the frequency up to 200 cycles per sec. In most practical cases the correction is negligible.

Of the two bridges, the Maxwell bridge has been found somewhat easier to work, as accuracy of setting is slightly greater than with the other. In both cases, however, it is possible to detect unbalances of 0·02 per cent in inductance, and 0·25 per cent in effective resistance, between 20 and 100 cycles per sec. with 1 mA testing current on coils of average length.

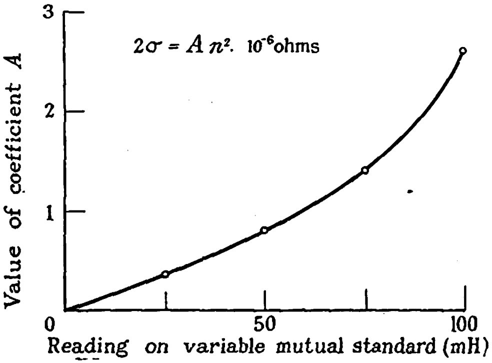

FIG. 5.

(*c*) *Leakance and Capacity.*—For leakance and capacity testing, the Wien series resistance bridge[†] with Wagner earth connection,[‡] and the Wien parallel resistance bridge[†] with direct earthing, are suitable. The series resistance arrangement has been extensively used in the past for testing short lengths of cable.[§] The arrangement is shown in Fig. 6, and with equal ratios the balance equations are

$$C = C_s/(1 + \omega^2 C_s^2 R^2)$$

$$G = 1/r = (\omega^2 C_s^2 R)/(1 + \omega^2 C_s^2 R^2)$$

In all practical cases $\omega^2 C_s^2 R^2$ is negligible compared with unity, so that $C = C_s$ and $G = \omega^2 C_s^2 R$.

For this test it is necessary that the tank of water containing the specimens of cable should be insulated from earth, although the insulation need not be of a very high order. The bridge components are electrostatically screened, the screens being connected as shown to the points at earth potential. The possible points of connection of the screens of R and C_s are shown in Fig. 7, and are all theoretically imperfect.

In case (*a*), as used, the screen of C_s is not at exactly the same potential as either set of condenser plates, and a small fraction of the effective capacity (as calibrated with moving plates connected to screen) is not in series with the resistance.

[*] S. BUTTERWORTH: *Proceedings of the Physical Society of London*, 1921, vol. 33, p. 312.

[†] MAX WIEN: *Annalen der Physik*, 1891, vol. 44, p. 697.

[‡] K. W. WAGNER: *Elektrotechnische Zeitschrift*, 1911, vol. 32, p. 1001.

[§] A. ROSEN: *Proceedings of the Physical Society of London*, 1923, vol. 35, p. 235

The errors introduced thereby, however, are calculable for a given setting of R and are negligible in practice.

The other cases are inadmissible, as in (*b*) there is a capacity to earth within the arm for which the Wagner earth does not correct, in (*c*) both screens are not at earth potential, and in (*d*) the capacity between the resistance R and its screen is added to that of C_s.

The series resistance bridge has been found to give accurate results at 1 000 cycles per sec. for specimens of average capacity (0·003 μF), but it suffers from the following disadvantages: (i) the containing tank must be insulated if the Wagner earth is used, (ii) the time taken in calculating results from bridge readings is appreciable when testing is carried out on a commercial scale, and (iii) the series resistance corresponding to a given power factor varies inversely as the frequency, and for low frequencies (e.g. 50 cycles per sec.) is impracticably large. For general convenience the author has found it preferable to use a parallel resistance arrangement, adapted as a substitution method, as shown in Fig. 8.*

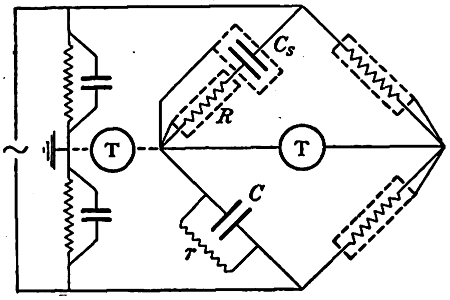

FIG. 6.

The initial balance of this bridge is taken with standard air condensers C_s and mica condenser C_1 (of capacities slightly higher than that of the test specimen) and resistances R, R_1, of 100 000 ohms each. The test core is then put in parallel with C_s and R, and these standards are adjusted to values C_s' and R' for balance.

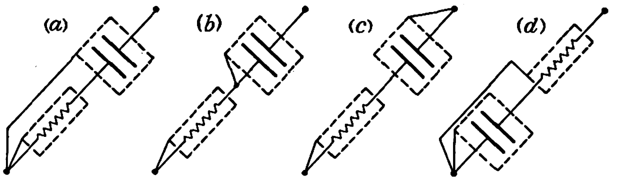

FIG. 7.

Then, $(1/R) + j\omega C_s = (1/R') + j\omega C_s' + (1/r) + j\omega C$

Hence $C = C_s - C_s'$

$$G = 1/r = (1/R) - (1/R') = (R' - R)/RR'$$

The auxiliary condenser C_s and resistance r_s are introduced to enable zero balance to be obtained with C_s set at a convenient value and with R = 100 000 ohms.

In practice the adjustment to R is made on the last few hundred ohms, so that RR' may usually be taken as 10^{10}, and calculations are thus simplified. It is evident that an accurate setting of R is necessary, but with a supply voltage of 40 or 50 volts it is possible to set the resistance to one or two ohms and obtain the leakance of the average sample to within 1 per cent at 1 000 cycles per sec. For low frequencies, a step-down transformer between bridge and detector (in this case a vibration galvanometer) enables the sensitivity to be kept up so that results within a few per cent are obtainable.

Owing to the high impedance of the bridge it is essential that the insulation of leads from the source of supply should be high and constant. Given this condition, and reliable high resistances, the bridge is very convenient to work, and the fact that the method of procedure is direct substitution, with a direct earth, avoids errors which would otherwise be introduced by residuals and earth capacities.

The accuracy of the bridge is checked from time to time by comparison with the series resistance bridge and by tests on an air condenser and standard 2-megohm leak.

Power Factor of Standard Condensers.—In most routine tests this may be neglected, but in some cases, where it is not small compared with that of the specimen measured, it may be approximately determined on the parallel resistance bridge as follows:—The bridge is balanced with a variable condenser, part of capacity C_s (Fig. 8), set at its maximum reading. A second variable air condenser, set at a low reading, is then connected in parallel with it, and the bridge rebalanced by reducing the capacity of the first condenser and by adjusting R. The power factor of the second condenser is thus obtained, the assumption being made that the power factor of the first varies with the reading, i.e. that the leakance is the same for all settings. This instrument is then available as a standard for determining the power factor of others in a similar manner.

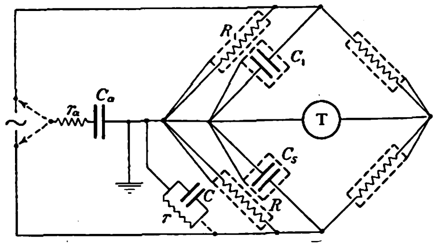

FIG. 8.

Condition of Specimens for Leakance Determination.—It is important that specimens of core should be soaked in water for some days previous to testing, although a good approximation may be obtained after the first few hours if the average behaviour of the material with time of immersion is known. Leakance of gutta-percha and allied gums has been found to increase during the first three or four days of immersion, this being due to the absorption of a small quantity of water. After about the sixth day this action ceases, and a very slow improvement with time sets in. The measured leakance, however, is greatly influenced by the condition of the few inches of core immediately above the surface of the water, and it is essential that this core surface be quite dry. If it

* F. W. GROVER: *Scientific Papers of the Bu eau of Standards*, 1907, No. 64, p. 393.

is damp, the leakance measured is increased more than in direct proportion to the small extra surface thus in partial contact with the water, and errors of as much as 10 per cent may result. This effect is independent of the surface insulation between the exposed copper ends and the surface of the water or the film of moisture on the core near the surface. It is explained by the following considerations.

The condition of the end is as indicated in Fig. 9, and the equivalent circuit diagram in Fig. 9A. Here G and C represent the leakance and capacity of the core in water, δG and δC the small additional leakance and capacity introduced by the extra damp length. It is assumed that the film will have a somewhat high resistance, the mean value of which is represented by R, to the surface of the water.

Let ΔG and ΔC be the apparent additional leakance and capacity introduced by the film of moisture, i.e. the admittance of branch a′b′.

Then $\quad 1/(\Delta G + j\omega\Delta C) = R + 1/(\delta G + j\omega\delta C)$

whence $\quad \Delta G + j\omega\Delta C = \dfrac{\delta G + j\omega\delta C}{1 + R(\delta G + j\omega\delta C)}$

and, by separation of real and imaginary parts,

$$\Delta G = \frac{\delta G + R(\delta G^2 + w^2\delta C^2)}{1 + 2R\delta G + R^2(\delta G^2 + \omega^2\delta C^2)}$$

and $\quad \Delta C = \delta C/\left\{1 + 2R\delta G + R^2(\delta G^2 + \omega^2\delta C^2)\right\}$

From the above it will be seen that, as R is decreased from ∞ to zero, ΔC is increased from 0 to δC; while ΔG is increased from zero to a value greatly in excess of δG, to which it descends as R approaches zero. For example, if, at 1 000 cycles per sec., $R = 2$ megohms, $\delta C = 30\ \mu\mu$F, $\delta G = 0{\cdot}001\ \mu$mho, ΔG becomes approximately $0{\cdot}07\ \mu$mho, an amount usually appreciable compared with the leakance of the whole specimen.

In consequence of the fact that wax is not "wetted" by water, the ends of all specimens are coated with paraffin, so that there is no unwaxed surface at the water line. By this means the damp-surface error just described may be avoided.

(*d*) *Corrections arising from Length of Test Coils.*—The methods previously described measure the closed- and open-circuit impedances of the core, and these impedances may be taken as equal to $R + j\omega L$ and $G + j\omega C$, respectively, if the length is sufficiently short. In any cable having distributed constants R/l, L/l, G/l and C/l per unit length, however, we have, for the closed-circuit impedance,

$$Z_c = Z_0 \tanh Pl, \quad \text{where} \quad Z_0 = \sqrt{\left(\frac{R + j\omega L}{G + j\omega C}\right)}$$

and $\quad Pl = \sqrt{\left\{(R + j\omega L)(G + j\omega C)\right\}}$

The expansion of tanh Pl gives

$$\begin{aligned} Z_c &= \sqrt{\left(\frac{R + j\omega L}{G + j\omega C}\right)}\left\{Pl - \tfrac{1}{3}(Pl)^3 + \tfrac{2}{15}(Pl)^5 - \ldots\right\} \\ &= \frac{(R + j\omega L)^{\frac{1}{2}}}{(G + j\omega C)^{\frac{1}{2}}}\left\{(R + j\omega L)^{\frac{1}{2}}(G + j\omega C)^{\frac{1}{2}} - \tfrac{1}{3}(R + j\omega L)^{\frac{3}{2}}(G + j\omega C)^{\frac{3}{2}} + \ldots\right\} \\ &= (R + j\omega L)\left\{1 - \tfrac{1}{3}(R + j\omega L)\ (G + j\omega C) + \tfrac{2}{15}(R + j\omega L)^2(G + j\omega C)^2 - \ldots\right\} \\ &= (R + j\omega L) + \left\{\tfrac{2}{3}RLC\omega^2 + \tfrac{1}{3}GL^2\omega^2 + \tfrac{2}{5}RL^2C^2\omega^4 \ldots + j\omega(\tfrac{1}{3}L^2C\omega^2 - \tfrac{1}{3}R^2C + \tfrac{2}{15}L^3C^2\omega^4 \ldots)\right\} \end{aligned}$$

That is to say, the measured value of R must be reduced by

$$\tfrac{2}{3}RLC\omega^2 + \tfrac{1}{3}GL^2\omega^2 + \tfrac{2}{5}RL^2C^2\omega^4 \ldots$$

and that of L by

$$\tfrac{1}{3}L^2C\omega^2 - \tfrac{1}{3}R^2C + \tfrac{2}{15}L^3C^2\omega^4 \ldots$$

For all practical purposes it is sufficient to use the first terms of these corrections. Thus readings of R are reduced by $(\frac{2}{3}RLC\omega^2)$, and those for L by $(\frac{1}{3}L^2C\omega^2)$. It will be seen that in both cases the percentage correction varies as the square of the length of the coil.

The value for C is evidently the capacity of one limb of the bifilar wound coil to the other. If the coil were in water this would be one-quarter of the capacity to earth of the whole coil; but as the test is usually carried out in air, the wire-to-wire capacity of the loop under these conditions must be known.

For example, if for a coil of length 2 nautical miles $C = 0{\cdot}1\ \mu$F, and the apparent values of R and L are $3{\cdot}5$ ohms and 200 mH, for $f = 100$ ($\omega = 628$), the true value of R is then $3{\cdot}50 - 0{\cdot}02 = 3{\cdot}48$ ohms, and of $L = 200 - 0{\cdot}5 = 199{\cdot}5$ mH, to a sufficient degree of accuracy. Such corrections are usually inappreciable for frequencies below 50 cycles per sec.

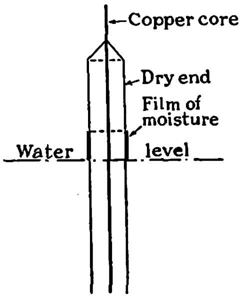

FIG. 9.

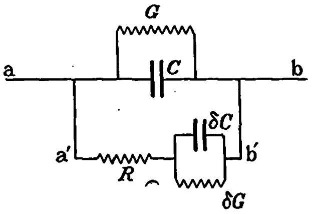

FIG. 9A.

The corrections for leakance and capacity are determined in a similar way by expanding coth Pl, for $Z = Z_0 \coth Pl$. They indicate that, to a first approximation, the apparent values of G and C are too high by $\frac{1}{3}\omega^2C(CR + 2GL)$, and by $\frac{1}{3}(\omega^2C^2L - 2RGC)$, respectively. In practice, the correction to G on a full length of core would be high enough seriously to prejudice the accuracy of the final result, and it is partly for this reason that leakance and capacity tests are taken only on short samples for which the corrections are negligible.

(*e*) *Tests under Pressure and at Low Temperature.*—The average depth to which a long submarine cable is submerged is between 2 500 and 3 000 fathoms, and at these depths pressures of 3 to $3\frac{1}{2}$ tons per sq. in., and a temperature of about 36° F., are experienced.

In order to ensure that pressure shall be transmitted uniformly to the strain-sensitive loading material, and shall not cause mechanical distortion, a layer of viscous compound is placed as a cushion between loaded conductor and insulator, the former being run through a bath of compound immediately before being covered with the latter. Pressure tests taken in the factory are of two classes:—(i) observations of inductance on lengths of a few yards to detect fall in permeability due to mechanical damage to the loading wire, and (ii) tests on longer coils to determine the variation of the primary constants with pressure and temperature.

While in the latter case the individual effects of the two independent variables are found to be additive, in the former this may not be so. For example, with a defective compound, inductance may be independent of pressure at normal temperatures, or of change of temperature at atmospheric pressure, but may vary considerably with pressure at 36° F. owing to changes in the viscosity of the compound with temperature. It is therefore necessary to bring the test specimens down to the low temperature before pressure is applied, the straight cylindrical tube in which they are placed being water-jacketed for this purpose. Normal procedure is to apply hydrostatic pressure in five or six equal increments from zero up to 3 tons per sq. in., and to observe the inductance at each increment. A drop of inductance will indicate that the compound is not sufficiently fluid, or has been irregularly applied; in the latter case there is usually a gradual recovery with time back to the normal value as the compound distributes itself more or less evenly under pressure; in the former case recovery may be slow, or may not take place at all. Normally, no change of inductance greater than 1 or 2 per cent is observed with pressure up to 4 tons per sq. in.

For the second class of tests, coils of about 100 yards in length are subjected to hydrostatic pressure in a small water-jacketed cylinder. With regard to inductance, with decreasing temperature there is a slight proportional decrease amounting to 2 per cent for a change of temperature from 75° to 35° F.; with pressure, the absence of variation observed on the shorter lengths is verified.

(*f*) *Variations of the Primary Constants with Frequency, Current, Temperature and Pressure. Experimental data.*— The tests described in Section (4) were taken on the Pacific Cable Board's Bamfield (Vancouver)–Fanning Island II (1926) cable,* and factory tests on the core for this cable will therefore be primarily considered. Tests on other cores of different dimensions are introduced in order to verify and amplify deductions made in particular cases.

Results throughout this paper will be referred to a length of 1 nautical mile, unless otherwise stated.

The conductor of the Bamfield–Fanning II cable consists of a round copper wire closely surrounded by 6 thin copper tapes, the whole being of diameter 0·185 in. and weighing 608 lb. per nautical mile. The loading is of high-permeability alloy known as "mumetal No. 6," in the form of a wire of average diameter 0·0108 in. This is applied to the conductor in one close continuous spiral, the weight of which is 114 lb. per nautical mile of conductor. The dielectric is of gutta-percha of radial thickness 0·130 in., weighing 370 lb. per nautical mile, and the layer of compound between conductor and dielectric is of radial thickness approximately 0·010 in.

From the above dimensions the following preliminary estimates may be made (for 1 nautical mile of core), using well-known formulæ:—

(i) D.C. resistance = 1·96 ohms at 75° F. for copper of 100 per cent standard conductivity, including an allowance of 1 per cent for the particular (taped) composition of the conductor.

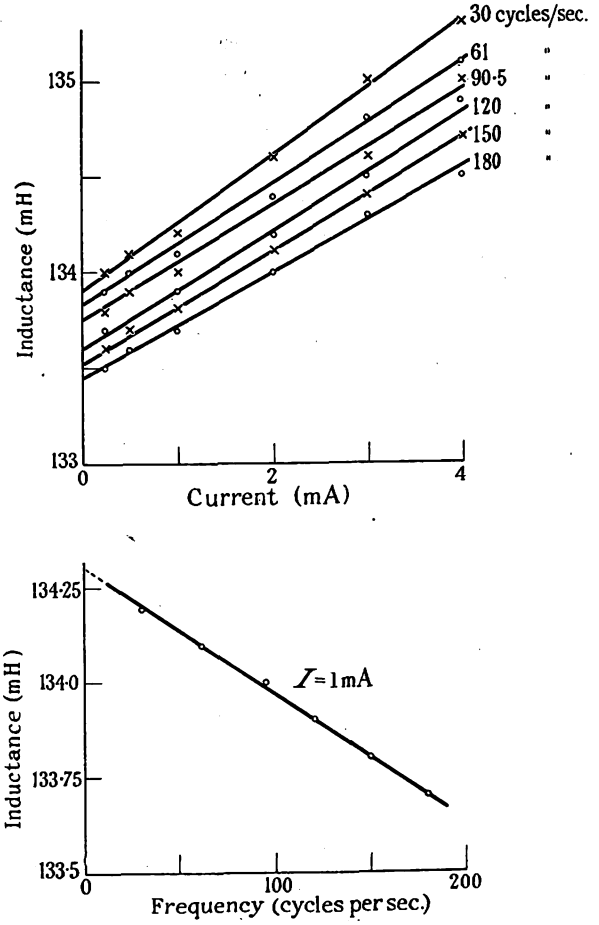

FIG. 10.

(ii) Capacity = 0·39 μF, taking the specific inductive capacity of gutta-percha and compound as 3·2.

(iii) Inductance (millihenrys) added by loading $(L_1) = 0\cdot0318\mu$, where μ = effective permeability of loading.

(iv) Geometric, or natural, inductance of core, when wound bifilar, $(L_g) = 0\cdot7$ mH.

(v) Added resistance due to eddy currents

$$(R_{ec}) = 8\cdot3\,\mu^2 f^2 10^{-12} \text{ ohms},$$

taking specific resistance of loading material as 45 microhms per cm^3.

The formulæ used in estimates (iii) and (v) do not take into account small corrections—inappreciable in this case—for variation with frequency due to eddy-current reactions and to the angle ϕ between the loading helix and a line through it parallel to the axis of the conductor.

The correction factors are given as

$(1 - \frac{1}{30}m^4d^4)\sin^2\phi$ for inductance, and
$\left\{1 - (17/420)m^4d^4\right\}\sin^2\phi$ for eddy-current resistance,[*]

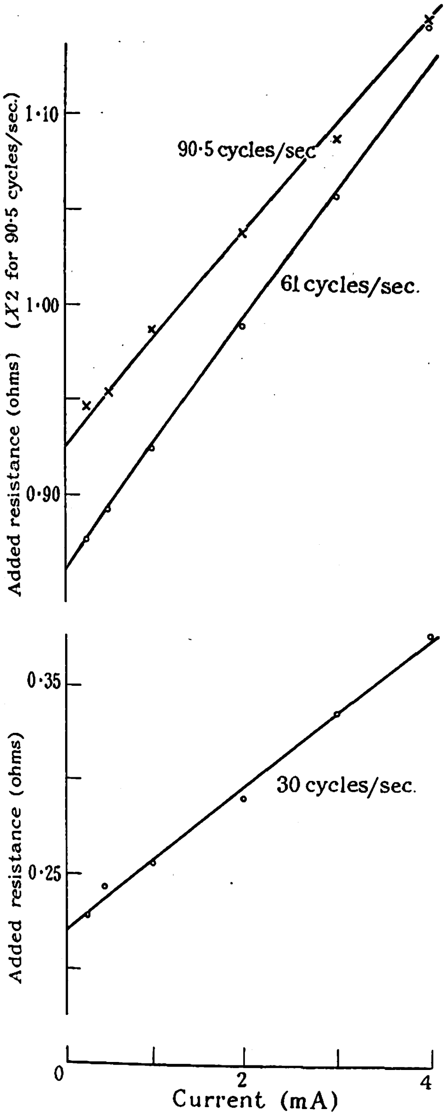

FIG. 11.

where $m = \sqrt{(2\pi\mu\omega/\rho)}$,
μ = permeability of loading material,
ρ = resistivity of loading material, and
d = diameter of loading wire.

It may be noted, however, that in practice the correction for inductance appears to depend on the first power, and not on the square, of the frequency. Fig. 10 shows a typical case.

The most important a.c. tests are those determining the variation of inductance (L) and added resistance (R_{ad}) (i.e. a.c. resistance—d.c. resistance) with current and frequency, as these largely determine the speed of the cable.

Variation of Inductance and Added Resistance with Current and Frequency.

(i) *For Light Currents, from Zero to about 5 mA.*—The variation with currents has in both cases been found to be linear, typical results being given for a sample marked X. 2989 in Figs. 10 to 13. It has generally been accepted that the added-resistance curves start parallel to the current axis, i.e. that there is no variation with currents near zero, but the author has found that accurate tests consistently give the linear variation. This characteristic has been noted by Jordan[†] from tests on iron-cored coils.

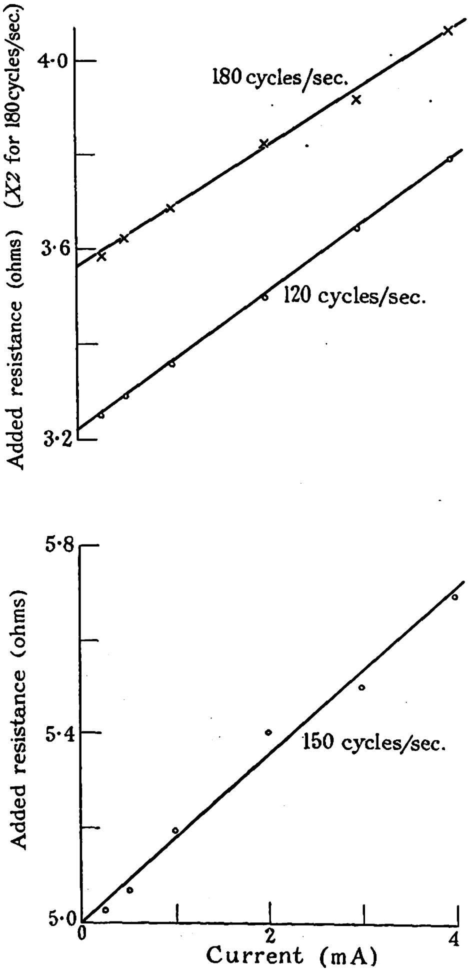

FIG. 12.

By repeating these tests at different frequencies, a combined current-frequency variation law may be determined.

In Fig. 13, values of R_{ad}/f are plotted against f, giving straight lines. The added resistances for zero currents (obtained by extrapolation from the current curves) when divided by f and plotted against f, show that an added resistance, varying linearly with f, exists

[†] H. JORDAN: *Elektrische Nachrichten-Technik*, 1924, vol. 1, p. 7.

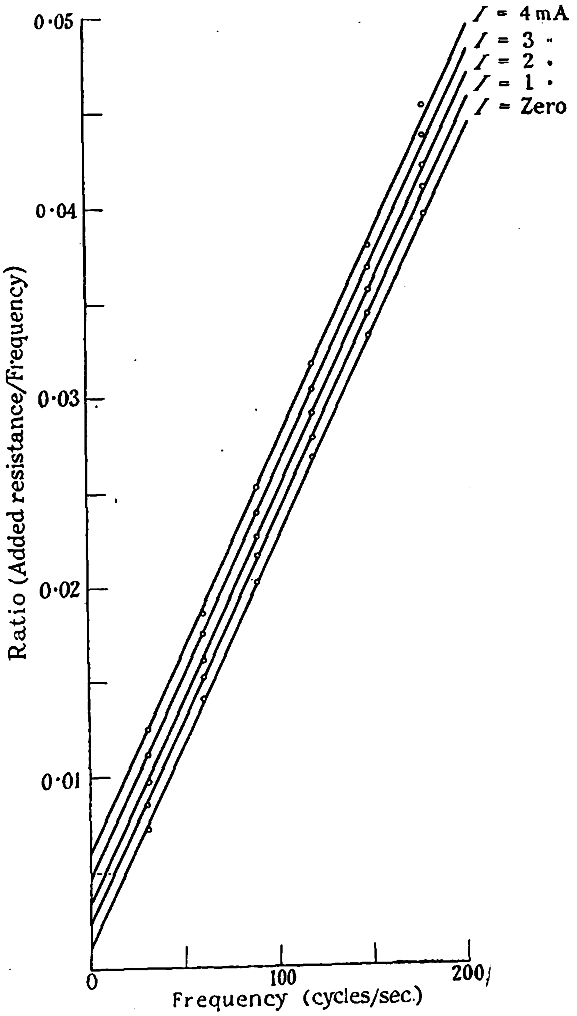

FIG. 13.

at zero current. This may also be obtained by extrapolation to zero of the curve connecting the coefficient of f with current (Fig. 13A). Hence we may write, for small currents,

$$R_{ad} = af(1 + cI) + bf^2$$

and

$$L = L_0 + dI,$$

where a, b, c and d are constants, I is the current and f the frequency. That part of the added resistance which varies as f^2 is due to eddy currents; of the part which varies as f, that remaining at zero current has been termed by Jordan "after-effect"; the other part, also varying with f, is due to hysteresis.

Allowance for after-effect in loaded cables does not appear to have been made hitherto, it having been assumed that there is no iron loss for currents near zero other than that due to eddy currents.*

The separate components of the added resistance for a given inductance (i.e. a given permeability of loading material) may be written thus:—

$$\left.\begin{aligned} R_{ae}\ (\text{after-effect}) &= af \\ R_h\ (\text{hysteresis}) &= acfI \\ R_{ec}\ (\text{eddy current}) &= bf^2 \end{aligned}\right\}\text{for small currents,}$$

and the following deductions may be made:—

$$\mu = \mu_0 + eI, \quad \text{and} \quad H = \text{magnetizing force} = kI,$$

where e and k are constants.

Flux, $B = \mu H = \mu_0 kI + ekI^2 \doteqdot \mu_0 kI$, or $I = (B/\mu_0 k)$.

Hysteresis loss $= R_h I^2 = acfI^3 = (acfB^3/\mu_0^3 k^3)$; that is, hysteresis loss varies as B^3. Similarly after-effect and eddy-current losses vary as B^2.

In the example given (Figs. 10 to 13) the laws of variation of inductance and added resistance for small currents are

$$L = 134 \cdot 3 - 0 \cdot 0033f + 0 \cdot 3I$$

$$R_{ad} = 0 \cdot 001f(1 + 1 \cdot 3I) + 213f^2 10^{-6}$$

I being expressed in milliamperes.

* O. E. BUCKLEY: *loc. cit.*; also J. J. GILBERT: *Electrician* 1927, vol. 99, p. 191.

The relation between added resistance and permeability, at a current of 1 mA, is shown by the tests on specimens of different inductances set out in Table 1.

It will be seen that the coefficient of *n* varies approximately as the square of the permeability, discrepancies being attributed to differences in mechanical or thermal treatment. The coefficient of f^2 varies closely as μ^2, but the added resistance due to eddy currents is $R_{ec} = 12\cdot0\mu^2 f^2 10^{-12}$ ohms instead of the theoretical $8\cdot3\mu^2 f^2 10^{-6}$ ohms, i.e. the realized R_{ec} is 1·45 times the calculated value. This increase has been found to be dependent on the diameters of conductor and loading wires, and is probably due to the flux density over the cross-section of the loading wire not being uniform, as assumed in the theoretical consideration.

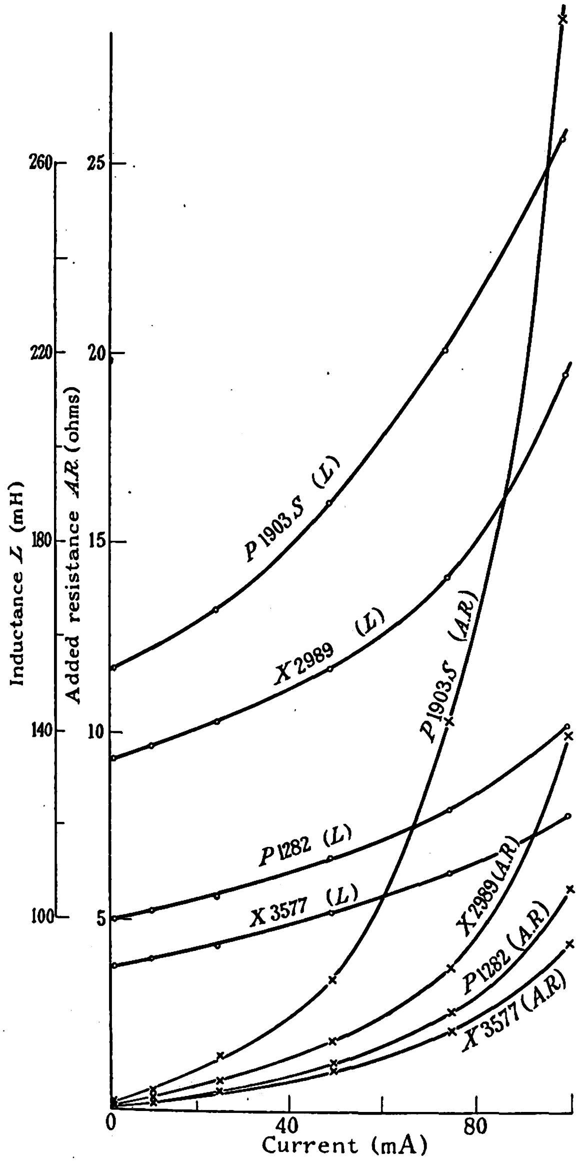

FIG. 14.

(ii) *For Currents up to* 100 *mA*.—As the normal sending current in a loaded cable is about 100 mA, the current tests must be extended up to that value. Typical results on four specimens of different initial inductance at 20 cycles per sec. are given in Fig. 14. Tests on one specimen at 20, 30 and 40 cycles per sec. are shown in Fig. 15.

It must here be noted that the tests determine the performance of the cable on alternating current of sinusoidal wave-form. Owing to non-linear variation of inductance with currents greater than a few milliamperes, the flux is not of sinusoidal wave-form, but, as the bridge detector is tuned to the fundamental frequency, the inductance and resistance measured are those due to the effective sine-wave component alone.

The inductance-current curves may be termed the magnetization curves of the cable and, while the maximum inductance usually occurs for a current above 100 mA, this may not always be the case. For a particular specimen marked X. 3446 the maximum is at approximately 100 mA, as will be seen from Fig. 16. In this case the mean diameter of the loading spiral, composed of 0·0108-in. wire as in the other cases, is 0·130 in. The shape of the magnetization curves depends on the composition of the alloy and its history, particularly with regard to thermal treatment, and these conditions for the best (i.e. the flattest) curve for any required initial inductance must be found by experiment. To a first approximation, however, with optimum conditions the rate of variation of inductance with current is a function of the square of the initial inductance.

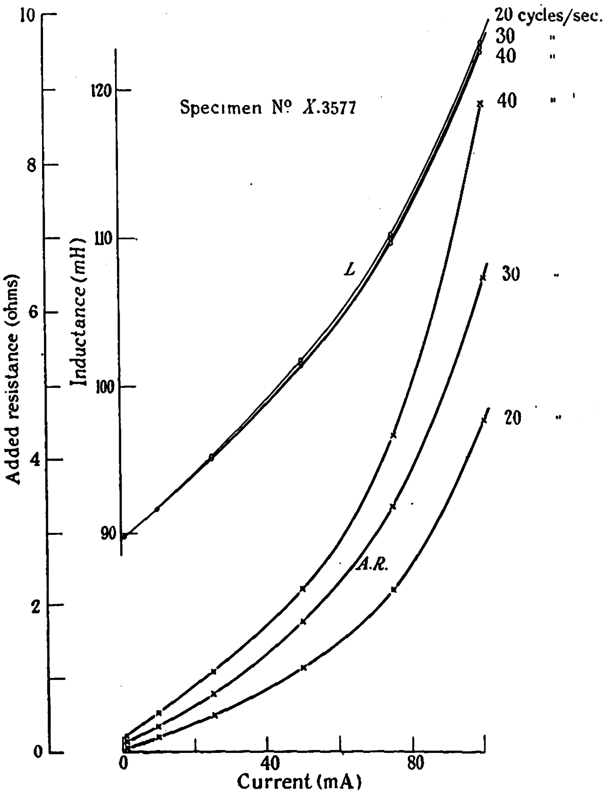

FIG. 15.

An examination of the tests illustrated in Figs. 14 to 16 enables an expression for hysteresis loss to be obtained in terms of inductance, and yields an approximation of the "after-effect" resistance (R_{ae}), given the eddy-current resistance (R_{ec}). The testing current is first converted into effective magnetizing force H, by the relation $H = (2I/10r)$ where r = mean radius of loading spiral in cm and I = current in amperes, R.M.S. values having been used in these computations. In the case of all samples except X. 3446, $2r = 0{\cdot}196$ in. and $H = 0{\cdot}80I$, while for X. 3446, $H = 1{\cdot}20I$. The effective permeability corresponding to each inductance is calculated from the dimensions of the core, and from this and H an effective value of flux density B is obtained for each current.

The added resistances less R_{ec} are then tabulated, R_{ec} being found by test or estimate at 1 mA and calculated for other currents. From these resistances is subtracted an estimated value for R_{ae}, this being, of course, invariable with current.

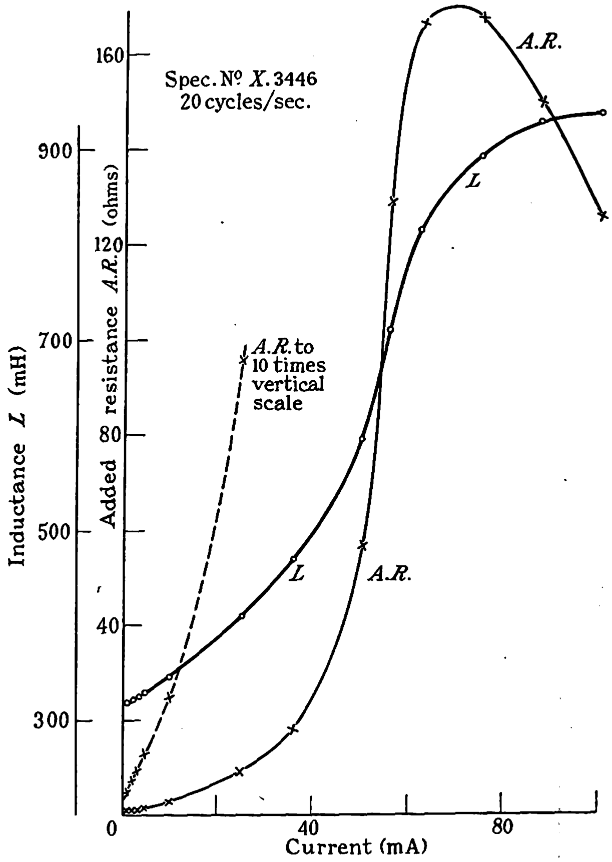

FIG. 16.

Thus the current test is reduced to three series of corresponding values: (i) currents, (ii) effective magnetizing forces and (iii) hysteresis resistances estimated by the method of taking differences just described. Series (iii) is then multiplied by the square of series (i) and plotted against series (ii)—that is, I^2R_h is compared with B. It is found that, with logarithmic scales, the variation gives a straight line, with possibly slight deviation for currents below a few milliamperes. This deviation may be eliminated by adjusting the original estimate of R_{ae}, which is an appreciable proportion of $(R_h + R_{ae})$ only for the lower currents. Thus R_{ae} is determined as that constant deduction from $(R_h + R_{ae})$, which allows a definite relation between hysteresis loss and flux density to be established.

The results of this analysis on the current tests plotted in Figs. 14 to 16 are shown in Fig. 17, from which it is seen that the dependence of hysteresis loss on the cube of the flux density holds for higher currents as well as for those of a few milliamperes. The curve for X. 3446 is not taken beyond I = 56 mA, above which current it departs from the straight line and shows that the exponent of B decreases as the saturation shown in Fig. 16 is approached. All other curves include the normal testing range up to I = 100 mA.

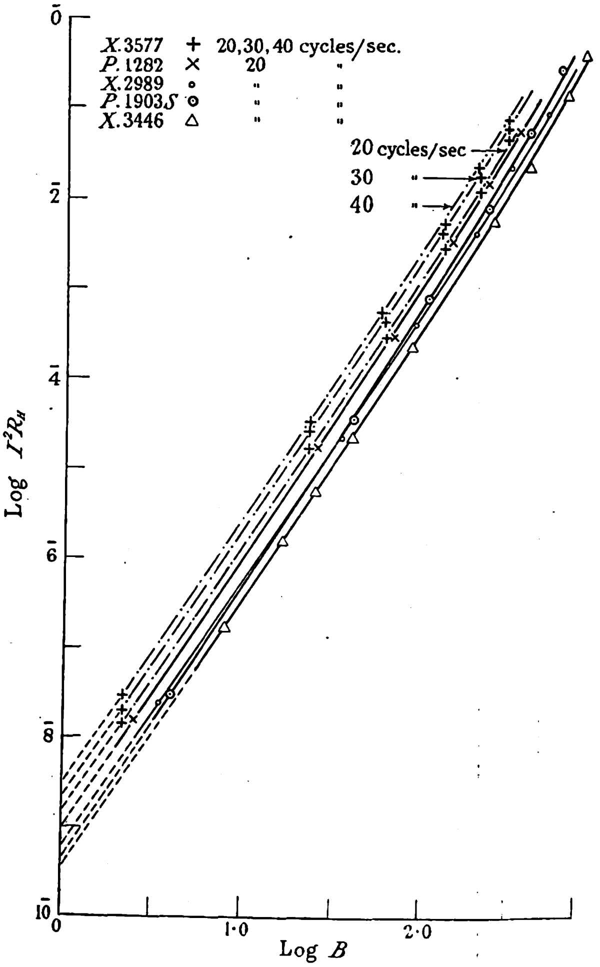

FIG. 17.

Table 2 gives values of R_{ae} and hysteresis loss determined from Fig. 17.

In the case of X. 2989, R_{ae} was also determined as shown in Figs. 13 and 13A. The correction to X. 3446 converts the results for mean diameter of loading spiral from 0·130 in. to 0·196 in.

These results enable the hysteresis loss of a length of loaded cable to be calculated, from the magnetization curve, for any current and frequency within the range covered, and show that with different specimens hysteresis loss may be expressed as $0\cdot 5 \times 10^{-3} f B^3/\mu_0^2$.

For a current of 1 mA ($H = 0\cdot 0008$), $B = \mu_0 H$ practically, and, at 20 cycles per sec.,

$$I^2 R_h = 0\cdot 01 \mu_0 H^3, \quad \text{and} \quad R_h = 5\cdot 1 \times 10^{-6} \mu_0.$$

TABLE 3.

Pressure	Temperature	G
tons per sq. in.	° F.	
0	36	$0\cdot 0054 f^{1\cdot 32}$
0·95	36	$0\cdot 0078 f^{1\cdot 28}$
2·1	36	$0\cdot 014 f^{1\cdot 21}$
3·0	36	$0\cdot 016 f^{1\cdot 20}$

The standard test at 1 mA and 20 cycles per sec. on all coils of core for the Bamfield–Fanning II (1926) cable gave the mean inductance as 118·3 mH, including the geometric, or natural, inductance of 0·7 mH. The corresponding permeability is 3 700. Hence the mean added resistance, from the data above, should be as follows:—

$$R_h = 5\cdot 1 \times 10^{-6}\mu_0 = 0\cdot 02 \text{ ohm}$$
$$R_{ae} = 0\cdot 065 \times 10^{-12}\mu_0^{3\cdot 2} = 0\cdot 02 \text{ ohm}$$
$$R_{ec} = 12\cdot 0 \times \mu^2 f^2 10^{-6} = 0\cdot 065 \text{ ohm}$$
$$\text{Total } R_{ad} = 0\cdot 002 f + 165 f^2 10^{-6} = 0\cdot 105 \text{ ohm}$$

The standard test gave the mean R_{ad} as 0·107 ohm at 65° F. The mean d.c. resistance of the cable at 75° F. was 1·967 ohms.

Variation of Leakance and Capacity with Frequency, Temperature and Pressure.—The following preliminary operations are necessary in testing:—

(i) The specimen is put under a pressure of 2 or 3 tons per sq. in. for a short time before zero pressure measurements are taken. As previously noted, this has the effect of smoothing out any irregular distribution of the compound—a condition which appears to result in increased leakance. If the precaution is omitted, the variation with pressure may not be consistent, and original zero pressure readings cannot be repeated. Although pressure normally increases the leakance, the application of the first step to an unprepared specimen may result in a slight drop, owing to the reduction resulting from even compound distribution being greater than the increase due to pressure.

(ii) The leakance of the standard condenser must be determined for all the test frequencies. The value of this condenser is usually 0·015 μF or more, owing to the length of cable necessary to obtain sufficient sensitivity, and for part of this a mica condenser of 0·010 μF has been used. The power factor of the 0·010 μF mica, plus that of the air condensers to make up 0·015 μF, has been found to increase largely with reduction in frequency. The combination used had a power factor

TABLE 3A.

Pressure	Temperature	G
tons per sq. in.	° F.	
0	75	$0\cdot 00077 f^{1\cdot 4}$
0	55	$0\cdot 0011 f^{1\cdot 5}$
0	36	$0\cdot 0061 f^{1\cdot 32}$
3·0	75	$0\cdot 00093 f^{1\cdot 5}$
3·0	55	$0\cdot 0065 f^{1\cdot 3}$
3·0	36	$0\cdot 025 f^{1\cdot 1}$

of 0·0004 at 1 000, of 0·0006 at 66, and of 0·0011 at 20 cycles per sec., the corresponding leakances being 0·03, 0·003, and 0·0017 μmho. As these corrections change with temperature and humidity, they must be frequently checked, and their application is essential if consistent results are to be obtained.

Variation of leakance and capacity of a typical specimen with pressure is shown in Fig. 18. The value of the leakance-frequency variation is shown in Fig. 19, from which the laws given in Table 3 are deduced.

Further tests on a specimen of different dimensions are given in Figs. 20 and 21, which include variation due to temperature. The results are set out in Table 3A.

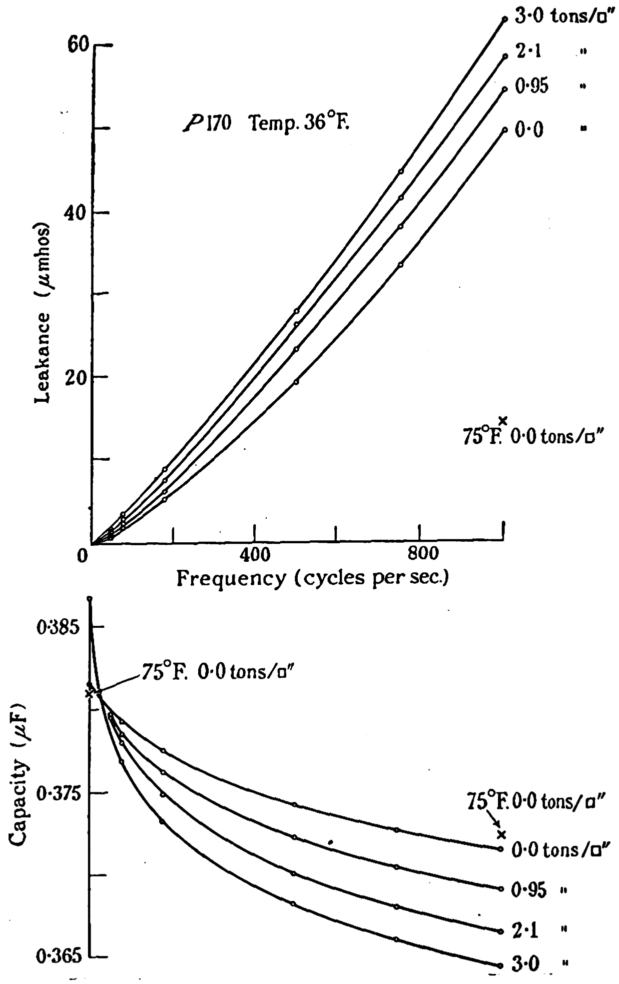

FIG. 18.

From extended tests it has been found that the changes shown in these tables are permanent, i.e. there is no tendency to recover with time while the test conditions of temperature and pressure are maintained.

It will be seen that the effects of increasing pressure and of reducing temperature are similar, i.e. leakance, and the rate of increase of capacity with the reduction of frequency, are increased.

In general, the tests follow Schweidler's * theory, except that the exponent of frequency is greater than unity.

No variation of leakance or capacity with voltage up to 60 volts has been found.

The standard test at 1 000 cycles per sec., 75° F. and atmospheric pressure gave the mean leakance of the cable as 14·4 μmho and the mean capacity as 0·382 μF.

The mean d.c. capacity was 0·393 μF at 75° F. and atmospheric pressure.

Leakance and capacity at 36° F. and 3 tons per sq. in. may thus be taken from Fig. 18, making allowance for the capacity of the specimen (P. 170) being 3 per cent lower than the mean under the same conditions of temperature and pressure.

(*g*) *Prediction of Attenuation and Head-End Loss from Factory Tests.*—It is convenient to divide the attenuation of a loaded cable into two parts: (i) attenuation for currents at which resistance and inductance may be considered invariable, and (ii) extra attenuation, termed "head-end loss," due to increase of resistance (chiefly hysteresis) and inductance with currents up to the normal sending value of about 100 mA. In order to estimate both these parts, assumptions must be made with regard to the influence on the constants of mechanical handling during laying. This will not appreciably affect leakance or capacity, but will reduce the permeability of the strain-sensitive loading material and consequently affect inductance and resistance. A reduction in initial permeability of 15 per cent will be assumed, this figure being indicated by strain tests in the factory. Added resistance will be correspondingly reduced by the laws determined in the last section of this paper, but an increase of eddy-current resistance must be allowed for,

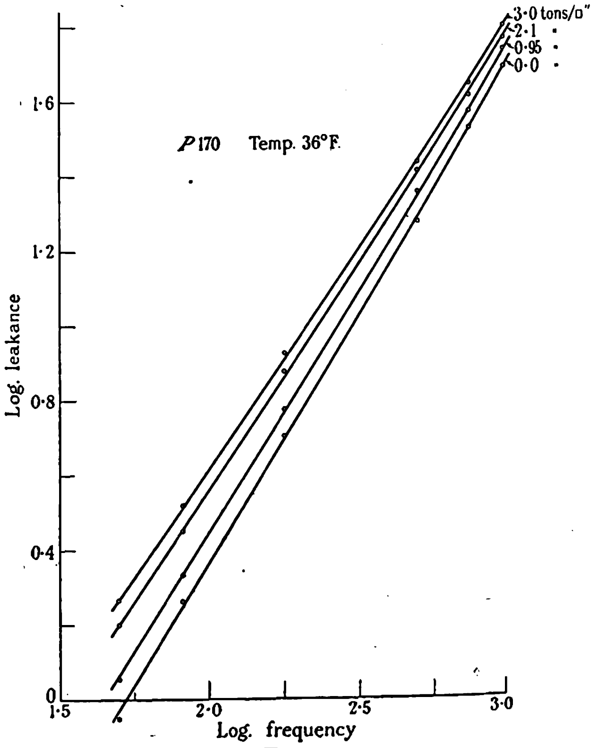

FIG. 19.

---

* SCHWEIDLER: *Annalen der Physik*, 1907, vol. 24, p. 742; also L. HARTSHORN: *Journal I.E.E.*, 1926, vol. 64, p. 1152.

owing to a decrease in the specific resistance of the loaded material with temperature.

For mumetal No. 6 the temperature coefficient is 0·0008 per deg. F., giving an increase in R_{ec} from 65° F. to 36° F. (estimated sea-bottom temperature) of 2·5 per cent. At the latter temperature the d.c. resistance may be expected (from the mean at 75° F.) to be 1·80 ohms. It is now necessary to allow for additional resistance and inductance due to the fact that the return circuit consists of a concentric ring of armouring and sea-water outside the insulator of the cable. The values shown in Fig. 22, calculated from formulæ deduced from tests on an unloaded cable,* are provisionally used. The average sea-bottom pressure is estimated from chart soundings as 3 tons per sq. in., using the relation 1 000 fathoms depth = 1·19 tons per sq. in. pressure. The estimate of primary constants for currents near zero is given in Table 4.

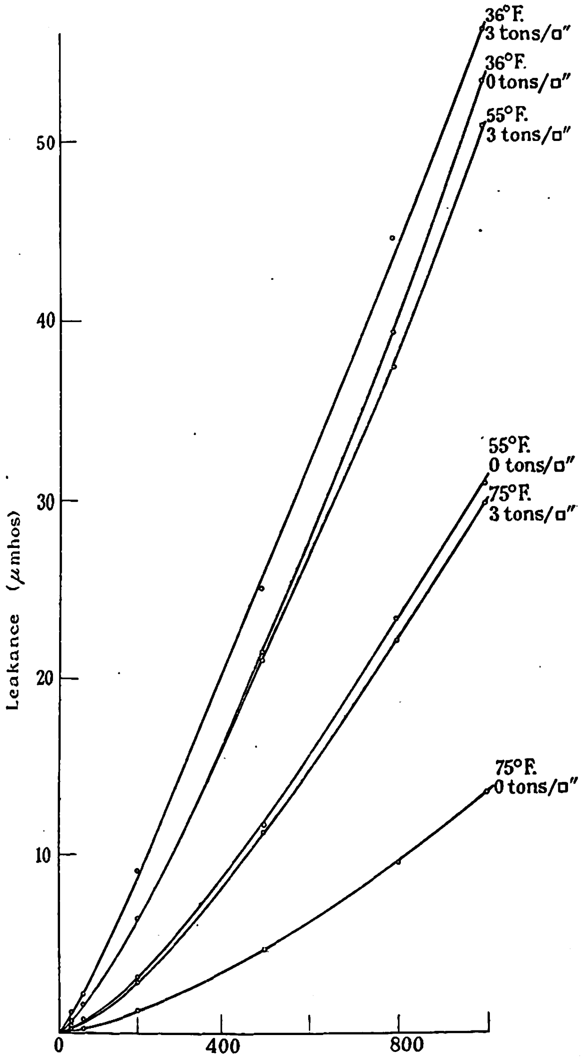

FIG. 20.

Head-end loss is calculated from tests determining variation of inductance and effective resistance with current. In certain magnetic alloys of relatively low initial permeability (about 1 000) these variations can be expressed as definite functions of current, and the transmission formulæ modified accordingly. Thus Salinger * has assumed variations of the form

$$L = L_0\epsilon^{kI}, \quad \text{and} \quad R = R_0\epsilon^{\frac{1}{2}kI},$$

while Meyer † has taken the linear variation,

$$L = L_0(1 + \lambda I) \quad \text{and} \quad R = R_0 + rI,$$

and in both cases formulæ have been derived for the calculation of head-end loss.

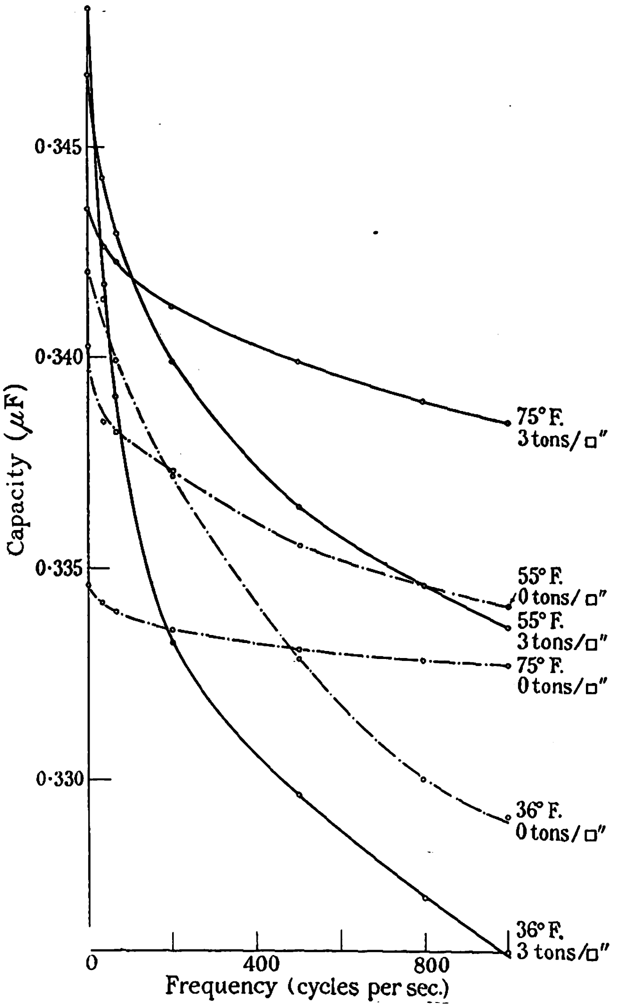

FIG. 21.

In the case of the higher-permeability alloys used for loading telegraph cables, however, no simple consistent relations exist between current, inductance and resistance, and the estimate has to be made by summing the attenuations of cable sections of such length that the current in them may be considered constant—the current in the next section being determined by the attenuation of the section so considered. In a previous description of this method ‡ the calculation has been commenced at an assumed sending current of 100 mA and carried down in steps to a current of 1 mA, below which value "zero attenuation" (i.e. attenuation at zero current) has been used. The author considers it better to start with the lowest current and to work upwards, as this enables the variation of head-end loss with current to be predicted. Further, a current below 1 mA should be worked to, as "zero attenuation" in most cases differs materially from attenuation at 1 mA. Preferably the calculation should start at 0·2 mA. The basis of the calculations are the current tests shown in Figs. 14 and 15.

Curves B:—Tests on local earth.
Curve C:—Final estimate of R_{ad}.

FIG. 22.

After the application of suitable corrections to allow for sea-bottom conditions, these test values were used to obtain curves of the *increase* (due to the preponderating effect of hysteresis loss) of attenuation with current. The excess attenuation, due to current in excess of 0·2 mA, was calculated for the head-end of the cable, section by section. Results obtained are shown in Fig. 23. As it was considered that the inductance of the head-end of the cable when laid would approximate to that of specimen X. 3577, a head-end loss at 20 cycles per sec. of about 0·6 could be anticipated for a sine-wave current of R.M.S. value 100 mA.

(4) TESTS ON CABLE AFTER LAYING.

(*a*) *General.*—Before a.c. testing is detailed it is necessary to note (i) the final laid length of the cable and earth lines, and the distribution of inductance, (ii) tests of resistance by direct current, and (iii) the equipment used in obtaining a.c. power.

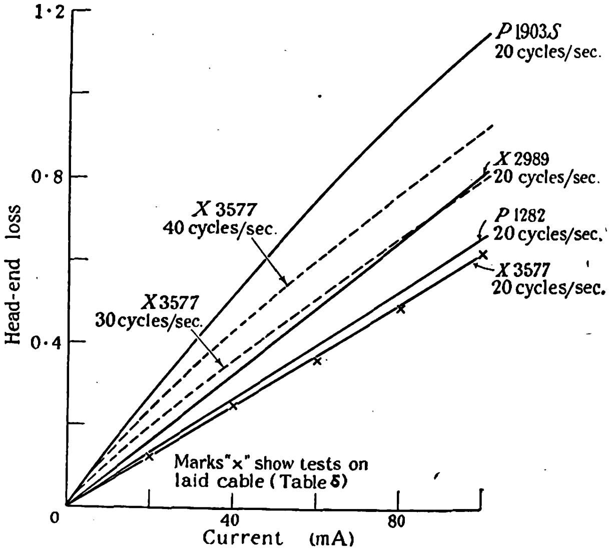

FIG. 23.

(i) The laid length of the Bamfield–Fanning II (1926) cable was 3 467 nautical miles. The Bamfield shore end consisted of 3 cores enclosed within the same sheathing,

* D.C. resistance = 1·80 ohms.

viz. the main (loaded) core; the sea-earth (loaded) core, terminated at a distance of 53·0 nautical miles by a resistance of 470 ohms; and the local-earth (unloaded) core, terminated at 3·92 nautical miles by direct connection to the sheathing. The inductance of the main core was graduated, as evenly as possible from the factory tests, in sections of approximately 250 nautical miles, the mean inductance of sections rising from 95 mH at the shore ends to 144 mH in the centre. The inductance of the sea-earth core was matched as nearly as possible with that of the main core running with it. The conductor weight of the unloaded local-earth core was 700 lb. per nautica mile, while that of the other two cores, as already noted, was 608 lb.

(ii) The d.c. resistance of cable and sea earths was measured by the "false zero" method, ordinary laboratory methods being inapplicable owing to interference from earth currents. Cable and earth are connected to an ordinary Wheatstone bridge, and the deflection of the galvanometer is noted with a resistance equal to that of the battery substituted for the battery itself. This is the "false zero," and when the battery is replaced the standard resistance is adjusted till this deflection is obtained. The initial condition is then restored in order to check possible variation of earth currents during the test, which must be repeated if the "false zero" has changed. If a time is chosen when earth currents are constant the test can be repeated without variation of result and an accuracy of 0·2 or 0·3 per cent is obtainable.

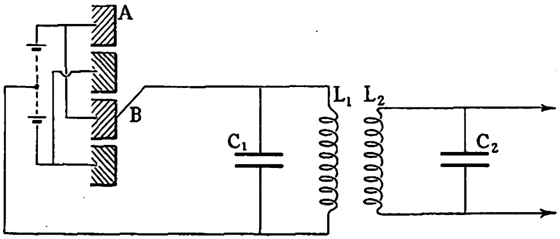

FIG. 24.

The results of the test were as follows:—

Main cable, 6 204 ohms = 1·789 ohms per nautical mile.
Resistance-terminated sea-earth, 569·5 ohms.
Local earth, 6·25 ohms = 1·59 ohms per nautical mile.

(iii) The equipment used in obtaining a.c. power consisted of a d.c.–a.c. motor-alternator, the speed of the alternator being controlled by shunt and series regulators on the d.c. motor and a variable gear-ratio between the two machines. The frequency was determined by a speed indicator on the alternator shaft. This was used for transmitting in attenuation measurements, and for impedance testing with currents up to the normal sending value of 100 mA. For impedance testing at 1 mA, and for the small voltage required for calibration in attenuation measurements (to be described later) a supply of sine-wave current was obtained by filtering reversals of direct current. Alternate segments of a 10-segment commutator, part of which is indicated at A in Fig. 24, were connected through slip-rings to the positive and negative poles of a battery. Connections from the centre of the battery and the brush B were taken to a condenser C_1 and inductance L_1 in parallel. A second inductance L_2 with parallel condenser C_2 was loosely coupled to L_1. Both inductances were flat "ironless" coils of inductance 1 henry, having resistances of about 30 ohms. With the condensers set for resonance at the frequency of the reversals, a small output of very nearly sinusoidal wave-form was obtained from the coupled circuit L_2C_2, with a battery of 8 or 10 volts. As the commutator was directly geared to a phonic motor driven by a vibrating tuning-fork, a constant and accurate frequency was obtained, this feature being the chief advantage of the arrangement. With the particular fork and motor available the commutator could be run at speeds giving frequencies up to 100 cycles per sec. For frequencies above this the filter was tuned to the third harmonic of the reversal, condenser C_1 being placed in series with primary coil L_1 instead of in parallel. With the low battery voltage used sparking at the commutator was not excessive, and the wave-form remained practically sinusoidal as long as the load was substantially non-inductive and of resistance not less than about 500 ohms.

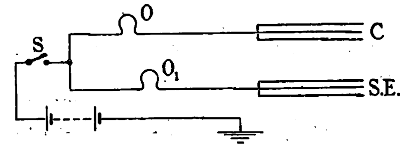

FIG. 25.

(b) *Measurement of Impedance.*—A series of impedance tests on a laid cable is of use—other than for the obvious purpose of applying Ohm's law to sending voltage and current—in indicating the inductance near the sending end (capacity being assumed), the position and extent of irregularities in the loading, and the degree to which the resistance-terminated sea-earth balances the cable for the object described on page 449.

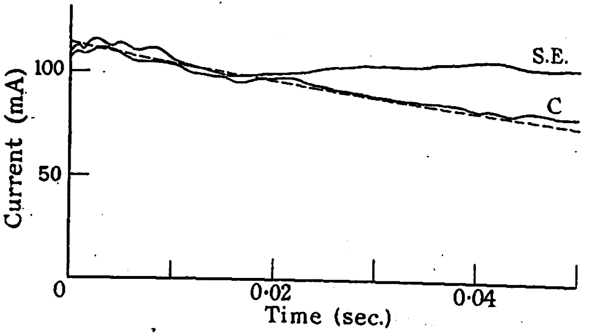

FIG. 26.

Before impedance determination by bridge methods is described, a more general and less direct test will be dealt with, i.e. the recording of current entering cable and sea earth. For this purpose the circuit shown in Fig. 25 was used, current from a battery being applied by the closing of switch S to cable C and sea earth SE simultaneously, through separate vibrators of an oscillograph, O and O_1. The vibrators recorded on the same paper, starting from the same zero line, the paper being time-marked by the control of a beam of light by a vibrating tuning-fork. Results obtained are shown, referred to the current and time calibrations of the apparatus, in Fig. 26, which is about 0·7 times the size of the original record. The far end of the cable was earthed for the test, and the applied voltage was 60·0 volts.

The oscillograph vibrators were of resistance 5 ohms, so that the sending impedance was small compared with the cable impedance.

It will be seen that the currents entering cable and sea earth (and hence their impedances) begin to deviate appreciably after about 0·02 sec., but it may be said that the resistance-terminated sea earth simulates the cable, for the purpose required, closely for disturbances of frequency above 50, and approximately for frequencies down to about 20 cycles per sec.

The currents in the cable and sea earth ultimately approach the steady values $V_s/6\,204 = 9\cdot7$ mA and $V_s/569\cdot5 = 105$ mA respectively. Deviations from smoothness are due to irregularities in loading.

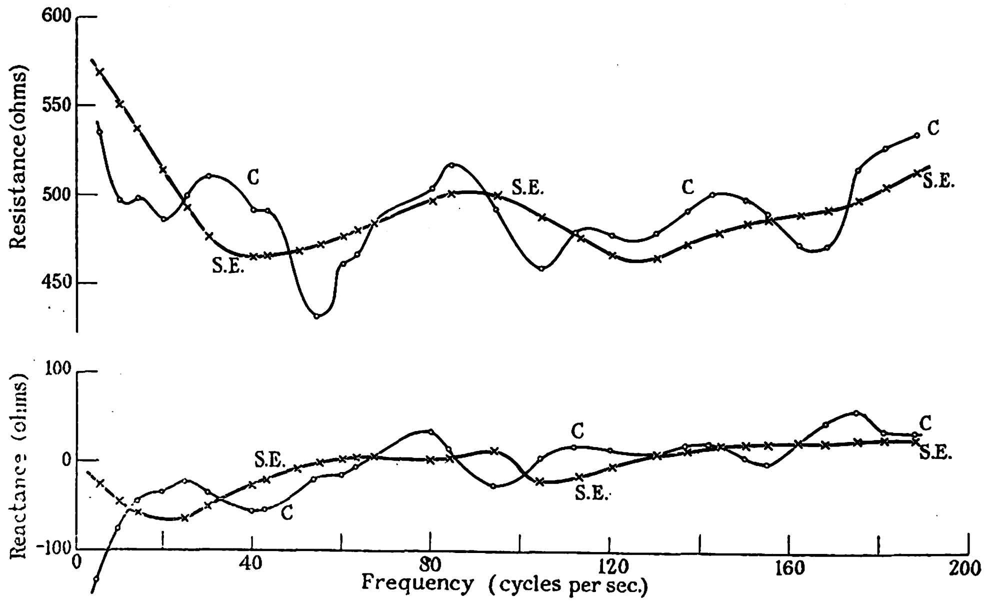

FIG. 28.

The current in the cable is theoretically *

$$I_s = E\sqrt{\left(\frac{C}{L}\right)}\epsilon^{-at}I_0(at)$$

$$= E\sqrt{\left(\frac{C}{L}\right)}\left[1 - at + \frac{1.3}{(2!)^2}(at)^2 - \frac{1.3.5}{(3!)^2}(at)^3 + \dots\right]$$

where $a = R/2L$ and $I_0(at)$ is the " zero-th "o rder non-oscillating Bessel function.

Values of capacity are taken from factory tests already given, including variation with frequency, as shown in Table 5.

If an inductance of 100 mH is assumed, the dotted curve in Fig. 26 is obtained from the above formula, taking R as the measured value 1·79 ohms. The close agreement between this and the experimental record indicates that the effective inductance to a direct current of 110 mA at the end of the cable is 100 mH.

For bridge measurements of characteristic impedance the arrangement shown in Fig. 27 was used.

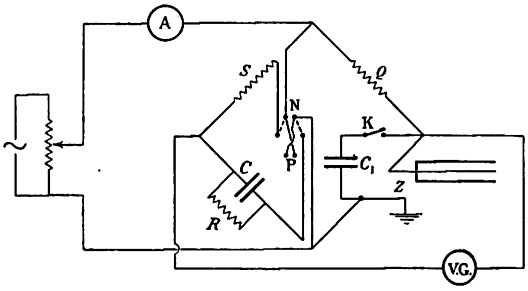

FIG. 27.

With the change-over switch in the position N (as shown dotted) the arrangement is a Wien bridge for use when the angle of Z is negative, in which case $1/Z = (1/R) + j\omega C$, with $Q = S$. With the switch in position P—Maxwell bridge *—balance may be obtained when Z has a positive angle, the equation being $Z = SQ\{(1/R) + j\omega C\}$. Although the angle of the

* H. W. MALCOLM: *loc. cit.*, p. 298.

* J. MAXWELL: *loc. cit.*, p. 425.

characteristic impedance of the cable is theoretically negative at all frequencies, it actually may become positive owing to reflections consequent on irregularities of loading. As an alternative to using the Maxwell bridge in such cases a condenser, capacity C_1, may be paralleled with the cable by closing the key K, and balance may be obtained with the Wien arrangement. This obviates a change in the operation of working out results (an appreciable advantage if many tests are taken), but the current to line is no longer one-half the total current recorded by the meter A. The difference, however, does not exceed 0·5 per cent in any case here recorded, and the standard method has been the Wien bridge (change-over switch in position N) for both negative and positive angles.

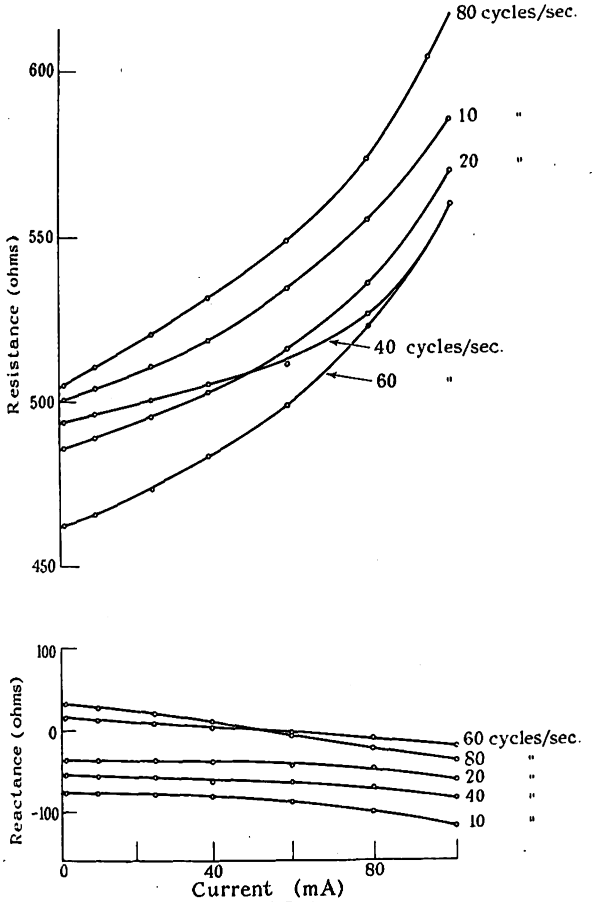

FIG. 29.

The variation of impedance (Z_0, ϕ) of cable and sea earth with frequency at 1 mA is shown in Fig. 28, in which results are expressed in terms of resistance ($Z_0 \cos \phi$) and reactance ($Z_0 \sin \phi$).

The impedance of the cable varies about a mean value of approximately 490 ohms, and if an average capacity of 0·38 μF is assumed the inductance, derived from the relation $\sqrt{(L/C)} = 490$, is 91 mH total, or about 89 mH added by the loading. The irregular shape of the curve is the result of the superposition of several regular variations, each due to one particular reflection, and the position of these reflections may be obtained by dividing the velocity of propagation by twice the frequency interval between successive maxima.* Thus in the "cable" curve of resistance, primary maxima occur at 30, 85 and 144 cycles per sec., or at average intervals of 57 cycles per sec. Secondary maxima appear at intervals of approximately 30 cycles per sec., starting at 14. The average velocity of propagation near the end ($L = 91$, $C = 0 \cdot 38$) being 5 400 nautical miles per sec., the main reflection is located at a distance of 47 nautical miles and a secondary reflection at about 90 nautical miles from the end.

The "sea earth" curve indicates a variation of periodicity about 85 cycles per sec.—i.e. an irregularity 32 nautical miles from the end. The length of the earth line to the terminating resistance was 53 nautical miles, and disturbance from this point would result in successive maxima at intervals of about 51 cycles. The absence of these is further evidence of the closeness of simulation of the cable impedance by the terminating resistance.

Variation of impedance of cable with current is shown in Fig. 29, similar curves being obtained for the sea earth. The fact that the slopes of the curves are irregular with respect to frequency shows that the location of irregularities changes with current and that they are therefore due to inductance, and not to capacity. The average impedance at 100 mA is 580 ohms, giving an inductance of 127 mH total, or 125 mH added. The average slope thus compares fairly well with that of the inductance of X. 3577 tested in the factory (Fig. 15).

The impedance of the local earth was measured by the Anderson bridge † as shown in Fig. 30.

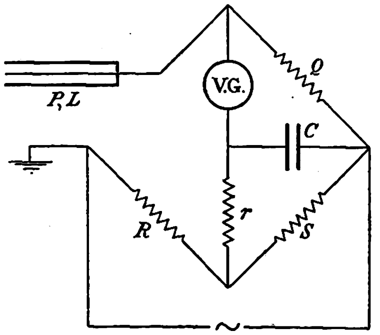

FIG. 30.

This core being unloaded and of relatively short length, the impedance gave resistance (P) and inductance (L) direct from the bridge equations $P = QR/S$, and $L = CQ[r(1 + R/S) + R]$.

Results are shown in Fig. 22, the d.c. resistance of the core having been subtracted. The sheathing up to the end of the local earth was composed, for the most part, of 23 No. 1 iron wires, while that of the main cable was chiefly 20 No. 14 steel wires. Differences in permeability, specific resistance and thickness of sheathing may be expected to have considerable influence on the resistance and inductance of the return path, and the results are

* WEINBACH: "Principles of Transmission in Telephony," ch. 16 (New York, 1924).

† E. B. ROSA and F. W. GROVER: *Bulletin of the Bureau of Standards*, 1905, vol. 1, p. 291.

therefore not applicable to the main cable, as will be shown experimentally in Section (4) (*e*).

(*c*) *Measurement of Attenuation and Head-End Loss.*—The attenuation of a long submarine cable is determined for any frequency by measuring the received current or voltage when a periodic e.m.f. of the required frequency and of known voltage is applied at the sending end. The applied e.m.f. need not be sinusoidal as long as the value of the fundamental is known, as, owing to the increase of attenuation with frequency, only the fundamental arrives (practically speaking) at the receiving end, the harmonics having been attenuated to negligible magnitude in transmission.

It is desirable to test attenuation with sending voltages down to 2 or 3 volts, and as the ratio of received to sent voltage (or current) of a cable with a total attenuation of 9, when terminated by its characteristic impedance, Z_0, is about 1/10 000, the quantities to be measured are very small. Three methods of test will be described.

(i) The Sumpner dynamometer is of sufficient sensitivity, and may be used as shown in Fig. 31. With the change-over switch on T (test) as shown, current from the cable passes through condenser C' in series with the moving coil, M, of the instrument. In parallel with this combination is the resistance R. R and C' are preferably adjusted so that the receiving impedance is equal to the characteristic impedance, Z_0, of the cable, i.e. $(1/R) + j\omega C' = 1/Z_0$, the impedance of the moving coil being small enough to be omitted from the calculation. The field coils, F, are excited from a local a.c. source of frequency differing from that transmitted through the cable by about 1 cycle per minute. The moving coil thus deflects periodically on either side of zero in 1-minute beats, a time of about this length being necessary in order that deflections shall not be affected by the damping of the moving coil. A series of extreme deflections, which occur when the currents in M and F are in phase or 180° out of phase, is noted, and the switch is then moved to C (calibrate). Steady deflections of required values can then be obtained by varying r, reversal of direction being obtained by reversal of the moving-coil connections.

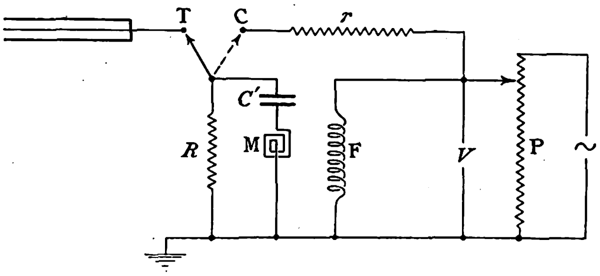

FIG. 31.

Let the impedance of the field coils F be $A\underline{/90^\circ - \theta}$, and that of the moving coil M and condenser C′ be $B\overline{\backslash 90^\circ - \theta_1}$. The currents in F and M are then out of phase, for the same applied voltage, by $180^\circ - (\theta + \theta_1)$. The steady deflections to be obtained are therefore the extreme deflections of the beat corrected for this deficiency $(\theta + \theta_1)$, i.e. multiplied by $\cos(\theta + \theta_1)$. This correction is small but not always negligible. In a particular instrument used the impedance of F at 40 cycles per sec. was $13{\cdot}4\underline{/83^\circ\,8'}$ ohms. The resistance of M was 40 ohms, and the impedance of moving coil and condenser was $3\,980\overline{\backslash 89^\circ\,25'}$ ohms, the capacity of the latter being 1 μF. The correcting factor was thus $\cos(6^\circ\,52' + 0^\circ\,35') = 0{\cdot}99$.

The potentiometer P regulates the sensitivity of the apparatus by controlling the voltage, V, across the field coils, which is also (conveniently) the calibrating voltage. The resistance r must be high compared with the impedances of V, P, and F.

The total impedance of the calibrating circuit is $r + Z_0\overline{\backslash\phi} = (r + Z_0)\overline{\backslash\text{zero}}$, nearly. The voltage across the series combination C′ and M is thus $(VZ_0\overline{\backslash\phi}/(r + Z_0)$, and the component of this voltage in phase with V is $(VZ_0 \cos\phi)/(r + Z_0)$ or $(VR\cos^2\phi)/(r + Z_0)$. This is equal to the voltage drop Vr across Z_0 due to the current from the cable, and the attenuation is determined from the relation:—

$$Vr = \frac{V_s}{\cosh Pl + (Z_0/Z_r)\sinh Pl} = \frac{2V_s\epsilon^{-Pl}}{1 + (Z_0/Z_r)} = V_s\epsilon^{-Pl}$$

for a long cable when $Z_r = Z_0$.

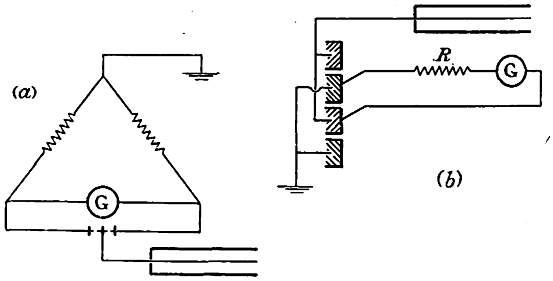

FIG. 32.

(ii) *Measurement by Rectification.*—A method has been described * in which the incoming sinusoidal current is rectified by means of a synchronously running relay, and measured on a d.c. galvanometer. The circuit diagram is given in Fig. 32 (*a*).

The author uses a modification of this arrangement in which, in place of a relay, a 10-segment commutator having 2 brushes spaced an odd number of segments apart is used [Fig. 32 (*b*)]. With this is used a single receiving circuit, consisting of resistance, R, in series with d.c. galvanometer, G, instead of the bridge necessary in the other case. The commutator is run at nearly the same reversal-speed as the frequency of the incoming current so that maximum deflections occur periodically, as in the case of the Sumpner dynamometer test. The galvanometer indicates the average value of the half sine-waves, i.e. the value $(1/\pi)\int_0^\pi \sin x\,dx = 2/\pi$, and the ratio of this to the R.M.S. value is $2\sqrt{2}/\pi = 0{\cdot}90$.

If I_r is the galvanometer current, then for a long cable

$$I_r = \frac{V_r}{Z_r} = \frac{2V_s\epsilon^{-Pl}}{Z_r + Z_0},$$

and

$$\epsilon^{Pl} = \frac{2V_s \times 0{\cdot}90}{I_r(Z_r + Z_0)} = \frac{1{\cdot}80\,V_s}{I_r(Z_r + Z_0)}$$

---

* E. S. HEURTLEY: *loc. cit.*

This test has the great advantage of utilizing the high sensitivity obtainable with d.c. reflecting galvanometers. The resistance R should be made high so that the impedance of the galvanometer may be taken as its d.c. resistance without the introduction of appreciable error.

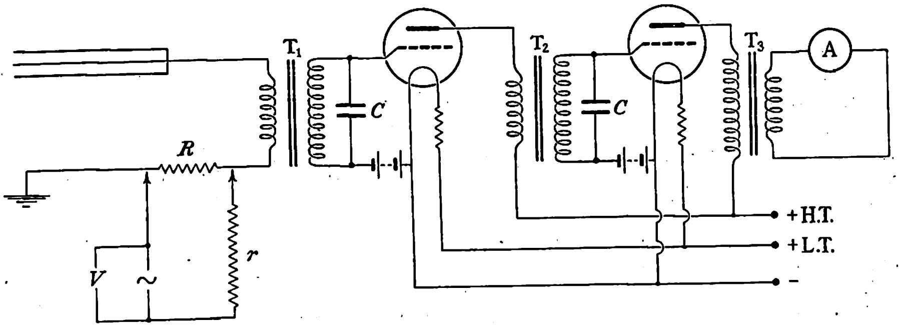

FIG. 33.

For the higher voltages at low frequencies the received current is frequently large enough to give sufficiently accurate readings on a direct-reading microammeter. This method is not subject to disturbance from earth currents, which are commutated into ineffective reversals.

(iii) *Measurement by Substitution and Amplification.*—In both the methods just described, the requirement that the period of the deflection shall be not less than about 1 minute makes each test comparatively long, as several complete swings must be observed and the necessarily close frequency adjustment takes some time. In addition, method (i) suffers from the disadvantage that corrections must be applied and the result is not given in simple terms of the variables employed, and method (ii) tends to give high results at the higher frequencies owing to imperfect commutation. The characteristic impedance of the cable must be known in both cases.

In the third method results are quickly obtained and worked out, and the impedance of the cable need not be known. The circuit is shown in Fig. 33.

Current from the cable passes to earth through the primary of a transformer T_1 and a variable resistance R, and is amplified by a 2-stage transformer-coupled amplifier as shown, the output being applied through a step-down transformer T_3 to a thermal milliammeter A. A local calibrating circuit consisting of a low-voltage a.c. supply with a thermal voltmeter and series high resistance r adjustable up to 10 000 ohms, can be switched across resistance R. The secondaries of transformers T_1 and T_2 are tuned by condensers C. The test procedure is as follows:—

The distant station transmits continuously and the ratios of the transformers are adjusted so that a convenient deflection is obtained on A. The secondaries of T_1 and T_2 are tuned by adjusting the condensers for maximum output. The local supply is then switched across R and the beat of the two frequencies is observed by the periodic change of the deflection of A. If this shows that the frequencies are in sufficiently close agreement (within 0·2 per cent) a prearranged series of voltages is applied to the far end, each voltage for three 1-minute periods with 1-minute intervals between. During the transmission periods the deflection on A is noted with the local circuit off, and when the distant station is not sending the local circuit is switched on, and R is adjusted until the same deflection is obtained. Thus for each voltage 3 tests and 3 calibrations are taken, the cable being left in circuit the whole time.

It is convenient to work with a calibrating voltage of about 1·5 volts, as the thermal voltmeter is then readily checked by a single primary cell standardized by a d.c. voltmeter.

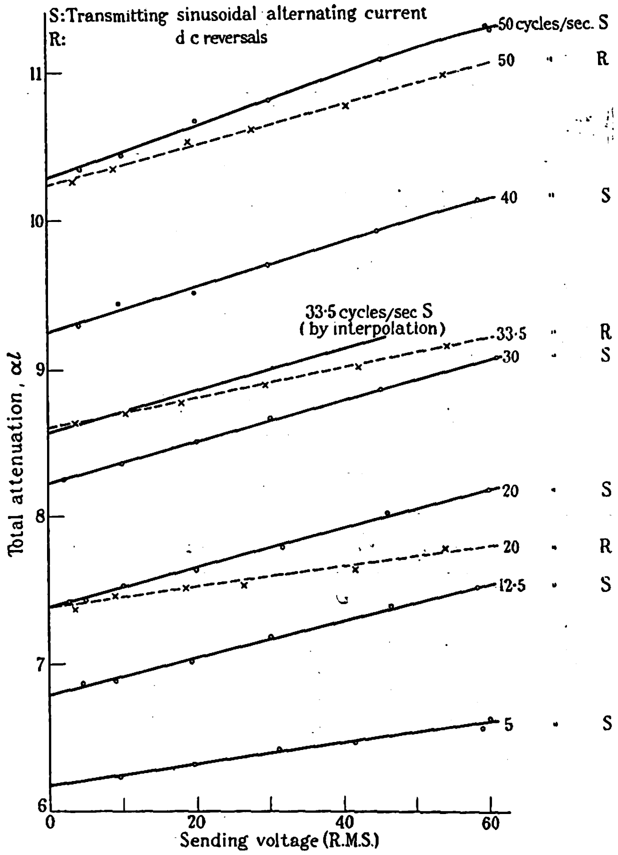

FIG. 34.

If I_r is the current in the primary of T_1 resulting in the deflections for test and calibration thus adjusted to equality, and if the impedance of the receiving circuit is Z_r, for test, $I_r = (2V_s\epsilon^{-Pl})/(Z_r + Z_0)$, for a long cable, and for calibration, $I_r = \{VR/(r + R)\}\{1/(Z_r + Z_0)\}$.

Hence $VR/(r+R) = 2V_s\epsilon^{-Pl}$ = received voltage for open-circuited receiving end. In practice the value of r is conveniently between 3 000 and 10 000 ohms, while that of R varies up to about 300 ohms.

The voltage V must of course be read with the calibrating circuit on. It is adjusted by changing the coupling of the coils L_1 and L_2 in Fig. 24. An advantage of the method is that interference from earth currents is minimized by the double tuning of the circuit, and is the same for both test and calibration.

The results of attenuation tests, which were all taken by this method, are shown in Fig. 34, tests at 20 cycles per sec. being verified by method (ii). The extrapolation of the curves to zero voltage, and division by the length, give the initial attenuation constant, a_0. The variation with frequency of a_0, and head-end loss for $V_s = 60$ volts, are given in Fig. 36.

The results obtained are, from the equations above, voltage attenuations, and the relation between voltage and current head-end loss must here be noted.

Let the former be written h_1 and the latter h_2.

If the effective impedance of the cable with sending voltage V_s is Z_e, then the attenuation of current is given by

$$I_r = I_s\epsilon^{-(a_0l+h_2)} = \frac{V_s}{Z_e}\epsilon^{-(a_0l+h_2)},$$

where a_0 = attenuation constant for currents near zero.

Also, attenuation of voltage is

$$V_r = V_s\epsilon^{-(a_0l+h_1)}, \quad \text{whence} \quad I_r = \frac{V_s}{Z_0}\epsilon^{-(a_0l+h_1)}$$

where Z_0 is the initial value of Z_e.

$$\text{Thus} \quad \frac{\epsilon^{-h_1}}{Z_0} = \frac{\epsilon^{-h_2}}{Z_e}, \quad \text{and} \quad h_2 = h_1 - \frac{\log(Z_e/Z_0)}{\log\epsilon}$$

In Table 6 the voltage head-end loss at 20 cycles per sec. from Fig. 34 is converted into current head-end loss by the use of the 20-cycle per sec. impedance-current test ($Z_0 = 487$). Variation of h_2 with I_s is plotted with the factory estimates in Fig. 23.

TABLE 6.

I_s	Z_e	$V_s(=I_sZ_e)$	h_1	h_2
mA				
20	494	9·9	0·14	0·12
40	504	20·2	0·28	0·25
60	517	31·0	0·42	0·36
80	537	42·9	0·59	0·49
100	572	57·2	0·78	0·62

Attenuation tests were also taken with d.c. reversals transmitted by the commutator at 20, 35·5 and 50 cycles per sec. In Fig. 34 the attenuations are plotted against the R.M.S. voltage of the fundamental frequency, i.e. d.c. voltage × 0·90. Comparison of these with results for sine-wave transmission shows that attenuations for zero voltage agree within 0·5 per cent. Head-end losses are lower, as shown in Table 7, the reduction being attributed to the suppression of part of the hysteresis loss of the fundamental by the harmonics of the reversals —this effect decreasing as frequency increases and length of line over which harmonics are effective decreases.

TABLE 7.

50	1·02	0·85	0·83

(*d*) *Measurement of Propagation Time.*—The wavelength constant of the loaded cable, from equation (13), reduces to

$$\beta = \left[\left\{\tfrac{1}{2}R\sqrt{(C/L)} - \tfrac{1}{2}G\sqrt{(L/C)}\right\}^2 + \omega^2CL\right]^{\frac{1}{2}}$$

on the same assumptions that lead to the short formula for a [equation (18)].

In the present case, from Table 4, at 30 cycles per sec.,

$$\left\{\tfrac{1}{2}R\sqrt{(C/L)} - \tfrac{1}{2}G\sqrt{(L/C)}\right\}^2 = 3\cdot6 \times 10^{-6},$$

while $\omega^2CL = 1\cdot35 \times 10^{-3}$.

Hence, at 30 cycles per sec., $\beta = \omega\sqrt{(CL)}$ to within 0·2 per cent, and the time of propagation $T = \beta l/\omega = l\sqrt{(CL)}$ practically.

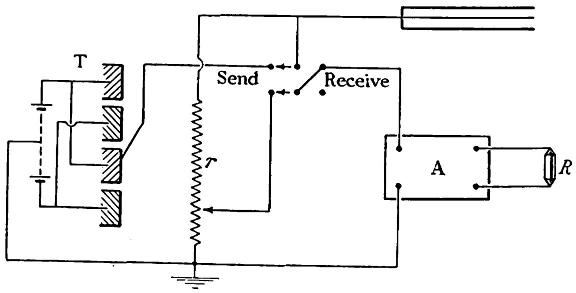

FIG. 35.

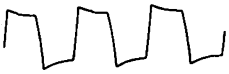
The method of measurement is to transmit a signal from station A to station B, and as soon as possible a reply from B to A. Then if at A the time between sending the signal and receiving the answer is t_1, and at B the time between receiving and answering is t_2, $T = \frac{1}{2}(t_1 - t_2)$. Circuits for recording both signals and the timing impulses to enable t_1 and t_2 to be evaluated, have been given by Gilbert * and Salinger.†

In the latter case, sent impulses operate a recorder connected directly between cable and earth, but received signals pass through a condenser mesh and an amplifier before being recorded. A correction must therefore be applied to allow for the resultant phase displacement of these signals. The former arrangement eliminates this error, both sent and received signals being recorded *after* amplification. The amplifier is sensibly distortionless, and records the sent signals (square-topped reversals through a condenser) as distorted reversals, thus—

---

* J. J. GILBERT: *Electrician*, 1927, vol. 99, p. 249.

† H. SALINGER: *Elektrische Nachrichten-Technik*, 1928, vol. 5, p. 130.



The necessity of measuring to zero phase of the fundamental, which occurs somewhat earlier than zero phase of these signals, is pointed out.

The author uses the circuit shown in Fig. 35. T and A are the commutator and the 2-stage (tuned) transformer-coupled amplifier previously referred to in connection with attenuation measurements. R is a recorder, and *r* a resistance of about 10 000 ohms. The transmitter T runs continuously, and while the double-pole change-over switch is on "send," reversals are transmitted to line and are applied to the amplifier by a tapping across a small part of *r*. Owing to the tuned couplings of the amplifier the record is of sinusoidal form, and the zero phase time-difference between the distorted reversals and the fundamental is thus corrected for. After a few reversals (conveniently 10) have been transmitted, the switch is moved to "receive," when the answering signal is amplified and recorded, having received the same phase displacement in the amplifier as effected the record of the sent signal. The timing impulse is taken from a contact on the tuning-fork driving the transmitter motor, and is preferably marked by a separate recorder alongside the sent and received impulses. It is checked up with the impulse at the other end of the cable by observing beats between the two sources as in attenuation testing, and must be accurate to a few parts in 10 000. The number of reversals transmitted is controlled by a rotary make-and-break contact driven by the transmitter motor through reduction gearing at such a speed as to close the battery circuit of the transmitter, for the time of 10 reversals, at conveniently short intervals of about 2 seconds. The send-receive switch, operated by hand, is put to "send" only for a sufficient time to allow 1 complete operation of the contact to send the 10 reversals to line. The time-intervals at both stations are counted from the same point in the train of reversals, this being generally the start of the 8th reversal. Specimen records are shown in Fig. 37.

The propagation time of the Bamfield–Fanning II cable was found to be 0·67 sec. at 30 cycles per sec., no difference being found (within the experimental error of 0·005 sec.) with voltages of 15, 30 and 60 volts.

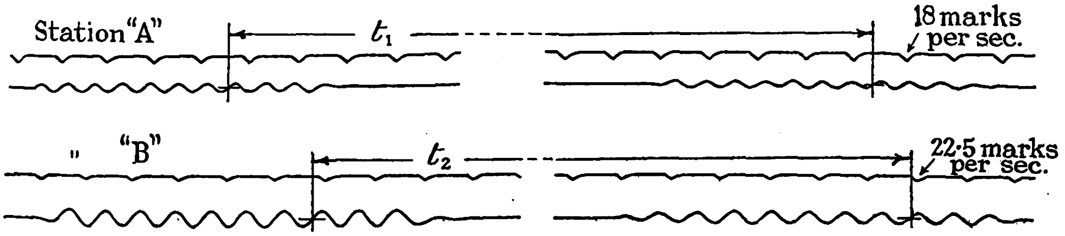


FIG. 37.

(*e*) *Method of Determining Constants.*—From the attenuation tests taken on the laid cable, recorded in Section (4) (*c*), the values per nautical mile at zero voltage obtained (Fig. 36) are as set out in Table 8, col. 2.

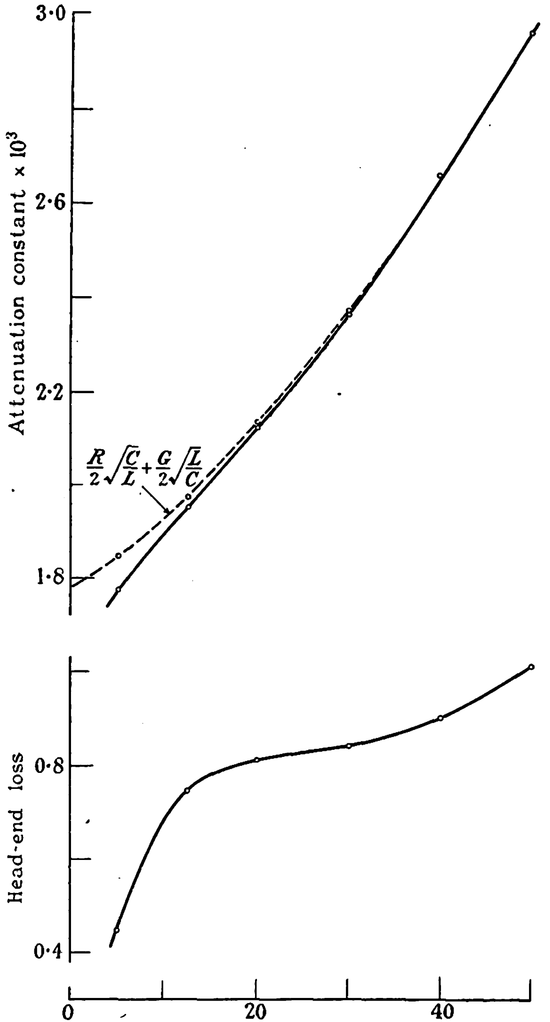

FIG. 36.

Numerical values of the primary constants *R*, *L*, *G* and *C*, are required which will give these attenuations and be consistent with the propagation time at 30 cycles per sec.—viz. 0·67 sec. The method of determining these is as follows:—

A series of values of the expression

$$\tfrac{1}{2}R\sqrt{(C/L)} + \tfrac{1}{2}G\sqrt{(L/C)} = a_1$$

is found from the estimated constants in Table 4. The difference between these and the attenuation, calculated by equation (13), decreases as frequency increases (and ωL and ωC become greater in comparison with R and G) as shown in Table 8, col. 3.

TABLE 8.

Frequency	$a_0 \times 10^3$	$(a_1 - a_0) \times 10^3$
cycles/sec.		
5	1·78	0·07
12·5	1·96	0·02
20	2·13	0·01
30	2·375	0·005
40	2·67	0·00
50	2·97	0·00

For a series of constants near those in Table 4 these differences will be the same. Therefore, if they are added to the attenuations found by test and the curve extrapolated to zero frequency, a value for

$$\tfrac{1}{2}R\sqrt{(C/L)} + \tfrac{1}{2}G\sqrt{(L/C)}$$

at zero frequency may be found. In the present case this is $1{\cdot}78 \times 10^{-3}$ (Fig. 36).

But, for this condition, R = d.c. resistance = 1·79 ohms, and $\tfrac{1}{2}G\sqrt{(L/C)}$ = zero, so that, at zero frequency, $\sqrt{(C/L)} = 1{\cdot}99 \times 10^{-3}$. Now from the propagation time test, $\sqrt{(CL)} = 1{\cdot}93 \times 10^{-3}$ at 30 cycles per sec., or, applying a correction for variation of capacity with frequency from Fig. 18, at zero frequency

$$\sqrt{(CL)} = 1{\cdot}95 \times 10^{-3}.$$

From these values of $\sqrt{(C/L)}$ and $\sqrt{(CL)}$, $L = 98{\cdot}0$ mH, and $C = 0{\cdot}388$ μF. Table 4 may now be amended as shown in Table 9 to give a second approximation of the constants of the laid cable.

The differences between the resultant attenuations and the results of tests may be reduced by altering original assumptions of either added resistance or leakance, but the change will be made in the sea-return resistance as there is less experimental data on this factor than on the others. The use of the trial curve C (Fig. 22) results in the final estimate given in Table 10.

† D.C. resistance = 1·79 ohms.

The constants of the laid cable thus compare with factory tests and estimates as follows:—

Resistance.—Measurements and estimates of d.c. resistance are summarized as follows:—

(i) Original estimate, from actual weight of conductor, with 1 per cent allowance for composite (taped) structure, 1·96 ohms at 75° F.

(ii) Realized from factory tests, 1·967 ohms at 75° F.

(iii) Estimate for laid cable from (ii), using coefficient 0·00238 per deg. F., 1·80 ohms at 36° F.

(iv) Realized from tests on laid cable, 1·79 ohms.

The difference between (iii) and (iv) is not likely to be due to an inaccurate estimate of sea-bottom temperature, as the cable follows the route of the Bamfield–Fanning (1902) unloaded line, for which the temperature is given by soundings and by final resistance tests as 36° F. It is probably connected with the allowance referred to in (i). This assumes partial contact between tapes and centre wire, which was probably not realized to the degree anticipated, owing to the penetration of the liquid compound beneath the tapes. This would account for the difference between (i) and (ii). It is probable, however, that the contact improved under pressure at sea-bottom. Hence (iv) is consistent with (i) rather than with (ii). This effect has also been noticed with other loaded cables.

With regard to added resistance, it has already been shown that no alteration in the estimates made from factory tests was necessary, as discrepancies could be eliminated by a small change in the assumed values of sea-return resistance.

Inductance.—The mean inductance added by the loading fell from 117·6 mH demagnetized (factory) to 95·2 mH (laid), a decrease of 19 per cent. Table 9 shows curve B (Fig. 22) for sea-return inductance to be inapplicable, as it would result in inductance due to loading increasing substantially with frequency.

Leakance.—No alteration in factory estimates was required.

Capacity.—Practically no alteration required. Tests on the laid cable do not necessarily check the assumed variation of capacity with frequency, but there is no reason to suppose any departure from the factory tests, as specimens were kept under observation for possible change with age over the period of time between factory and final tests.

(5) ARRIVAL CURVES.

For an ideal heavily-loaded cable having constants invariable with frequency and current, and with negligible leakance, no current arrives at the receiving end until a time $T = \sqrt{(CL)}l$ after the commencement of the transmitted impulse. The signal head then rises abruptly to the value

$$I_r = 2E\sqrt{(C/L)}\epsilon^{-(R/2)\sqrt{(C/L)}}$$

(in the case where the terminating impedance is zero); after which the received current increases with time until the sent impulse is discontinued or the limiting value $I_r = E/Rl$ is reached.

In the practical case the dependence of the constants on frequency and current prevents the initial abrupt rise from being realized. Records of arrival curves are of use in estimating whether the deviation of the signal head from a vertical straight line is due to head-end loss (i.e. to variations of the constants with current) or to the change in the characteristics of the cable with frequency. Further, the possibility of constructing message signals from a given arrival curve, and the effect of the impedance of the end apparatus, may be tested.

Arrival curves for an ideal cable for the case where the sending impedance is zero, and the receiving impedance a non-reactive resistance r, were calculated, using the following constants:—

$$R = 1{\cdot}79 \text{ ohms} \qquad = 3\,467 \text{ nautical miles}$$
$$L = 98{\cdot}0 \text{ mH} \qquad \sqrt{(L/C)} = 505 \text{ ohms}$$
$$C = 0{\cdot}384\ \mu\text{F} \qquad \sqrt{(CL)}l = 0{\cdot}67 \text{ sec.}$$

For $G = 0$, and a steady sending voltage E, the sum of the original and first reflected waves is given by Heaviside * as

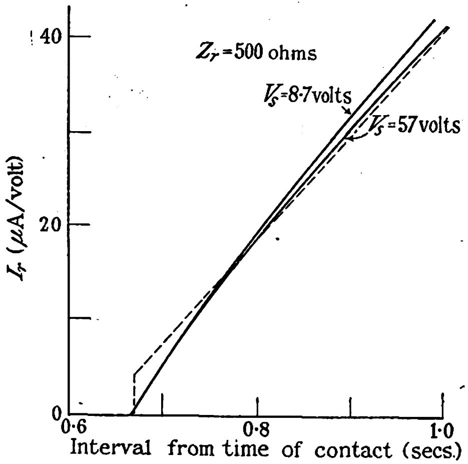

FIG. 38.

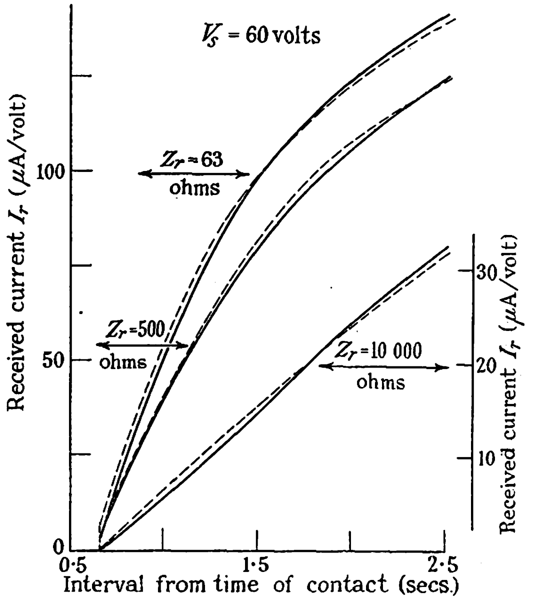

FIG. 39.

$$I_r = E\sqrt{(C/L)}\epsilon^{-at}\Big[(1 + c)I_0(z) + (1 - c^2)\Big\{(w/z)I_1(z) - (cw^2/z^2)I_2(z) + \dots\Big\}\Big]$$

where

$$a = R/2L, \quad c = \Big\{\sqrt{(L/C)} - r\Big\}/\Big\{\sqrt{(L/C)} + r\Big\}$$
$$w = a\Big\{t - \sqrt{(CL)}l\Big\}, \quad z = a(t^2 - CLl^2)^{\frac{1}{2}}$$

and $I_m(z)$ is the mth order non-oscillating Bessel function.

---

* O. HEAVISIDE: "Electromagnetic Theory," vol. 2, p. 389 (1899).

In special cases the following simplifications occur:—

If $r = 0$, $c = 1$

$$I_r = 2E\sqrt{(C/L)}\epsilon^{-at}I_0(z)$$

If $r = \sqrt{(L/C)}$, $c = 0$

$$I_r = E\sqrt{(C/L)}\epsilon^{-at}\left[I_0(z) + (w/z)I_1(z)\right]$$

If r is large, c approaches -1.

Writing $k = 1 + \sqrt{(L/C)}/r$

$$I_r = (E\epsilon^{-at}/r)\Big[(2/k)I_0(z) + (4/k^2)\Big\{w/zI_1(z) - (cw^2/z^2)I_2(z) + \dots\Big\}\Big]$$

As the propagation time $\sqrt{(CL)}l$ is 0·67 sec., these expressions should be exact to $t = 2\cdot01$ secs. when the second reflected wave arrives at the receiving end. As a check, the arrival curve for $r = 0$ was also evaluated from the formula *

$$I_r = \frac{E}{Rl}\left[1 - \epsilon^{-2at} + 4\epsilon^{at}\sum_{m=1}^{m=\infty}\frac{\cos m\pi \sinh at\sqrt{\left(1 - \frac{4m^2\pi^2L}{CR^2l^2}\right)}}{\sqrt{\left(1 - \frac{4m^2\pi^2L}{CR^2l^2}\right)}}\right]$$

The calculated curves for $r = 63$, 505, and 10 000 ohms are shown by the dotted lines in Figs. 38 and 39.

The experimental curves in these diagrams were obtained by means of an oscillograph, the received signal being first amplified by a substantially distortionless thermionic amplifier. The cable was earthed through a non-inductive resistance of the required value, r, and the voltage across an adjustable part of this was applied to the amplifier. Calibration was afterwards performed by applying known voltages across r (with cable disconnected) and observing the resultant deflections of the oscillograph vibrator.

The chief experimental difficulty was interference from earth currents, which, being of similar nature to the currents to be recorded, could not be eliminated.

The inflection of the curve for $r = 10\ 000$ megohms (Fig. 39) is attributed to this cause.

In general, the test curves follow the theoretical ones after the first 0·1 sec. In the most important region (the first 0·05 sec.) there is marked deviation. As shown in Fig. 38, no difference was found in the initial shape for sending voltages of 57 and 8·7 volts. That is, the influence of head-end loss (which in the first case was 6 times as great as in the second) on the shape of the head of the signal was not discernible. The shape of the signal head must, therefore, be attributed to the variation of attenuation with frequency.

Records were also taken of the signal " understand " (marking 50 per cent) without sending apparatus [Fig. 40 (A)], and with a sending condenser of 5 μF [Fig. 40 (B)]. The dotted line in the first case is the signal built up from the arrival curve in Fig. 38. It consists of the algebraic sum of a number of these arrival curves, all continued to the end of the signal, a new one commencing with each change of sent impulse, and corresponding in sign to the direction of the change.

Thus on the original positive curve are superimposed, at corresponding time-intervals, positive curves representing impulses c, e, h, and j [Fig. 40 (C)], and negative curves representing impulses b, d, f, g and k.

The similarity of the original and the built-up curve indicates the possibility of predicting the shape of a signal from the arrival curve by the method used.

The starting time of all arrival curves is taken as 0·67 sec. from the result of the propagation-time test.

(6) TRANSMISSION CAPACITY OF THE CABLE.

The transmission of signals was tested over a range of speeds from 1 600 to 6 000 centre-holes, or elements, per minute. At the sending end a suitable shaping mesh * was interposed between the transmitter and the cable. At the receiving end the cable was earthed through a shunted condenser in series with a resistance, variable up to 1 000 ohms. The voltage-drop across the resistance was applied to the input circuit of a thermionic amplifier, the output circuit of which actuated a high-speed siphon recorder.

Test messages were sent by means of punched tape in an automatic transmitter driven by a phonic motor, and the shaping meshes were adjusted by trial for optimum shape, and uniformity in size, of signals.

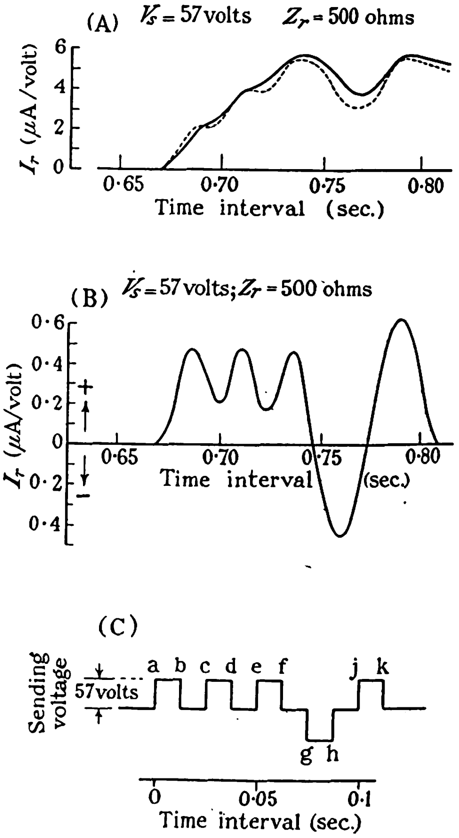

FIG. 40.

* O. HEAVISIDE: *loc. cit.*, p. 381; and H. W. MALCOLM: *loc. cit.*, pp. 498 and 512.

* E. S. HEURTLEY: *loc. cit.*

For the purpose of verifying the assumption made in Section (2) (*c*) with regard to permissible attenuation for satisfactory working, three tests will be considered, the results of which are shown in Fig. 41.

The records are of signals (the letters of the alphabet) received at speeds of (*a*) 4 000, (*b*) 4 800 and (*c*) 5 200 centre-holes per minute. The sending voltage was 60 volts, and block signalling (in which successive impulses in the same direction are run together and there is no earthing interval) was used in all cases.

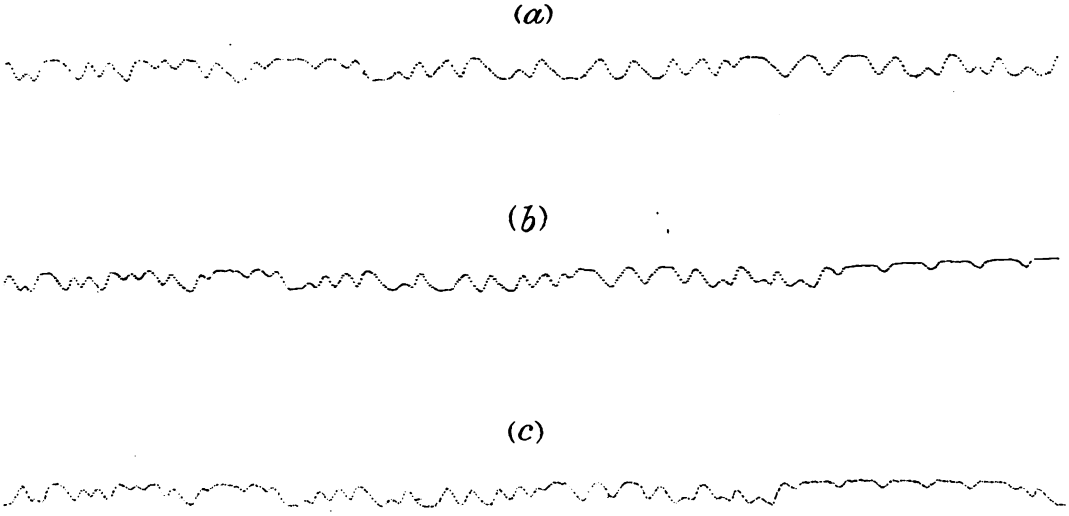

FIG. 41.

The overall attenuations of the cable for the fundamental reversal frequencies corresponding to the transmission speeds are computed as shown in Table 11.

TABLE 11.

Record	Speed	Reversal frequency	Corresponding attenuation		
			$a_0 l$ from Fig. 36	Head-end loss	Total
	centre-holes/min.				
(*a*)	4 000	33·5	8·60	0·64	9·24
(*b*)	4 800	40·0	9·25	0·72	9·97
(*c*)	5 200	43·5	9·60	0·77	10·37

The head-end loss was taken (by interpolation) from Table 7 for reversals at 60 volts.

By inspection of Fig. 41, conditions sufficiently favourable for recorder working with code messages are indicated by (*b*), and those suitable for the transmission of plain language by (*c*). That is, for recorder working, an attenuation of 10 is allowable and the attenuation of 9·3 implied in the guarantee (page 450) is amply safe.

Record (*a*) shows signals suitable for relay operation, for which the assumed criterion (attenuation = 9) is justified.

The author understands that relay working at 4 000 centre-holes per minute was successfully carried out at the far end of the cable at Fanning Island.

(7) CONCLUSIONS.

The chief processes of this investigation may be summarized as follows:—

(i) Theoretical and practical considerations show the transmission speed of a loaded telegraph cable to be limited by its attenuation, and hence allow its performance to be determined in terms of its alternating-current characteristics.

(ii) An inquiry into the nature of the required tests, and the different conditions under which they must be performed, is made. Test methods are examined and the precautions necessary for consistent results are stated. From test data obtained during the process of manufacture, the effective characteristics of the laid cable are predicted.

(iii) These characteristics are then determined by attenuation and propagation-time tests, and small discrepancies between them and the predictions are accounted for. The results of impedance tests, and records of departure and arrival curves, are shown to be consistent with these determinations.

(iv) Finally, the procedure is justified by the realization of a transmission speed in accordance with the criteria adopted.

It has been shown that the limiting reversal frequency is that for which the total attenuation is 9, or 10, according to the method of working. The attenuation has been treated as the sum of two parts, (i) the value for currents near zero, and (ii) extra attenuation at the head end due to the increase of losses in the loading with current. It has been shown that both these factors may be closely estimated from factory tests, and the importance of the tests discussed in Section (3) (*f*), and their generalization for use in designing other cables, is thus apparent.

The least certain of the predictions made is that of the inductance of the laid cable. It is difficult in the factory to simulate, even approximately, the mechanical stresses to which the cable is subjected in the process of laying, and, owing to variable influences such as weather conditions and depth of sea-bottom, the stresses in no two cases are exactly alike. It may be stated, however, that the drop of inductance due to mechanical handling will be between 10 and 20 per cent, and that an average estimate of 15 per cent will not be greatly in error. It has been shown that a considerable range of values of the effective permeability of the loading material is obtainable, and in any particular case the optimum for the laid cable must be calculated and the required factory value thus obtained.

The great importance of resistance measurements is shown in these calculations, for which the added resistance must be known in terms of frequency, current and initial permeability. If attenuations are then calculated for several assumed (increasing) values of initial permeability, it will be found that an optimum attenuation is reached, above which the increase of added resistance preponderates adversely over the increase of initial permeability.

Thus added resistance controls the performance of a loaded cable by limiting the inductance which may be usefully employed.

The influence of leakance on attenuation, expressed by the factor of $\frac{1}{2}G\sqrt{(L/C)}$, is similar to that of added resistance, but to a smaller degree. If, however, future improvements enable substantial reduction of added resistance to be obtained, leakance may become the predominating limiting factor unless produced *pro rata*.

With the dielectric at present used, changes in capacity with frequency, temperature, pressure and age are relatively small and affect the final attenuation in a minor degree only. If, however, the variations which do occur are established, the capacity of the laid cable may be predicted with considerable accuracy and a sound basis for the estimates of the other constants may thus be obtained.

In the design of cables a factor of safety must necessarily be introduced, but by the use of accumulated test data such as have been incorporated herein a close approximation to predicted results should be realized.

The author wishes to express his thanks to the management of the Telegraph Construction and Maintenance Co., Ltd., for permission to make use of the matter incorporated in this paper.

A METHOD OF MEASURING THE OVERALL PERFORMANCE OF RADIO RECEIVERS.

By H. A. Thomas, M.Sc., Associate Member.

[From the National Physical Laboratory: communicated by permission of the Radio Research Board.]

(*Paper first received* 20*th June*, 1929, *and in final form* 13*th March*, 1930; *read before the* Wireless Section 15*th January*, 1930.)

Summary.

The paper describes researches which have been carried out at the National Physical Laboratory for the Radio Research Board. An improved method of measuring the amplification of a radio receiver is described, together with the manner in which this method can be applied to practical cases, particularly at short wavelengths. The apparatus covers a wavelength range of from 15 to 30 000 metres, and is capable of dealing with inputs of from 0·25 to 1 000 mV over this range. After describing in detail the construction and operation of the apparatus in Section (1), the results of tests on four receivers of widely different types are given in Section (2), and some general deductions are obtained from the properties of these receivers. In conclusion, suggestions are made in Section (3) for a possible means of classifying receivers for different purposes.

Table of Contents.

Section (1).—Method of measurement.
- (*a*) Introduction.
- (*b*) The construction of the screened cabin for the oscillator.
- (*c*) The construction of the screened input resistance.
- (*d*) The input oscillator.
- (*e*) The measurement of the output voltage.
- (*f*) The complete circuit arrangements.

Section (2).—Examples of measurements upon various types of receivers.
- (*a*) Introduction.
- (*b*) A 4-valve receiver (200–16 000 m).
- (*c*) A commercial short-wave receiver (15–60 m).
- (*d*) A screened short-wave receiver (15–80 m).
- (*e*) A supersonic-heterodyne receiver with frame aerial (50–500 m).

Section (3).—Suggestions for specifying the performance of receivers.

Section (1).—Method of Measurement.

(*a*) *Introduction.*—The aim of all measurements of the constituent parts of a radio receiver is ultimately to obtain a characteristic relationship between the input supplied to the receiver and the output voltage given by the receiver, together with an analysis of the behaviour of the individual portions of the apparatus. Such a measurement is the most important of all those that can be obtained, and at the same time is the most difficult. The difficulty lies in the fact that the output quantities are in general very large compared with the input quantities, so that the slightest form of accidental coupling between the input and the output circuits introduced by the measuring apparatus may completely modify the behaviour of the receiver. Another difficulty lies in the fact that the input and output frequencies are dissimilar.

Most of the early attempts to obtain the overall characteristics of a receiver were based on an assumption that the overall performance could be represented in terms of the product of the performances of the separate components. If this assumption were valid, the problem would be simple, but, unfortunately, the effects due to the input impedance of an amplifying stage, together with the various forms of retroaction, render this assumption unjustifiable in all but the very simplest cases.

Due to the difference in frequency between the input and output, the large magnitude of the step-up ratio, and the retroaction effects, substitution, bridge and comparison methods are difficult to employ. The input must be supplied by means of an artificially generated signal, the form of which must be such that the results obtained can be readily applied to the actual conditions met with in practice.

The relatively large output must also be measured by a method which in no way disturbs the normal operation of the receiver.

An overall performance measurement implies the inclusion of the input tuned circuit, the antenna or frame-coil, whichever is used in practice with the receiver. The problem of applying a known e.m.f. to this tuned circuit may be solved in one of the following three ways:—

- (i) By inducing the e.m.f. into the main tuning inductance by means of a known mutual inductance, the current in the primary of which is known.
- (ii) By passing a known current through a condenser of known value which forms part of the tuning capacity.
- (iii) By inserting in series with the tuned circuit a small non-inductive resistance or a small inductance carrying a known current.

The first method has been used,* but it involves the measurement of a mutual inductance of large ratio at radio frequencies. It is difficult to make such measurements with any accuracy, and also the tuning circuit of the receiver must always include, or consist of, this secondary circuit of the calibrated mutual inductance, which must always be carefully screened from the rest of the receiver. The method is therefore inapplicable as a general method of testing receivers in which the tuned circuit forms part of the complete arrangement.

---

* T. A. Smith and G. Rodwin: "Notes on Radio Receiver Measurement," *Proceedings of the Institute of Radio Engineers*, 1927, vol. 15, p. 387.

In the second method, since the value of the tuning condenser is specified by the wavelength range, the e.m.f. which can be applied can only be controlled by the current passed through this condenser and supplied by the main oscillator. Consequently the possible range of the input e.m.f. is very limited. For the smallest measurable radio-frequency current, the value of this condenser must be very large if the e.m.f. across it is to be of the right order.

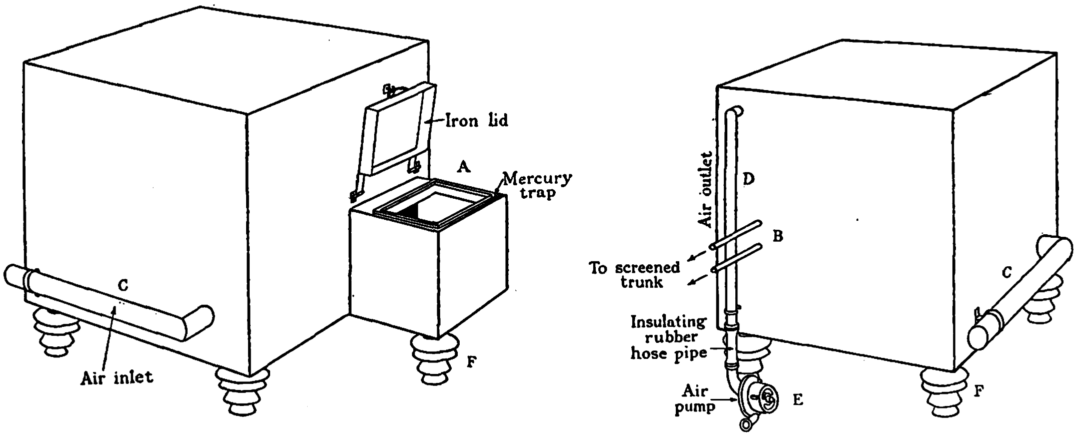

FIG. 1.—Screened oscillator cabin.

The third method has been adopted to a greater extent than the previous methods,* owing to its more general application and its comparative independence of frequency. Small non-inductive resistances can be made within fairly wide limits and, with a reasonable range of current, can be used for a wide range of input voltage. A radio-frequency oscillation, modulated to a known extent at an audio frequency, supplies current to these resistances. The prevention of direct magnetic and electric induction from the oscillators and leads to the resistance demands the most elaborate screening of these components. This is effected by enclosing the oscillators in a completely screened metal room and screening the leads to the resistance. The amplifier, too, must be housed in a screened room to prevent induction from external sources. Refinement in measurement is dependent upon the efficacy of these screens, and practically nothing except complete shielding is permissible.

The screened resistance takes the form of a straight resistance wire with a concentric return, by which means complete shielding is effected. If the resistance wire is tapped at various points, e.m.f.'s of known magnitudes are obtained. At very high radio frequencies it is important that the current through the wire should be measured at a point as near to the tapping as possible. If the filament of the amplifier is connected to the joint between the resistance wire and the concentric return, the batteries will be connected to the amplifier screen which is at earth potential, which condition is required for the imitation of the normal operation of the receiver. It is important that this battery earthing connection be adhered to, otherwise the capacities to the screen may modify the measured performance. If the amplification is very large, the resistance wire becomes very short and at very high frequencies its inductance becomes important. This inductance is too small to measure and must be calculated from the known dimensions of the wire.

In practice, the only factors limiting the accuracy of the measurement are:—

(i) The impossibility of measuring the effective impedance of the screened input resistance, and the consequent dependence of this value upon the calculated value of the inductance of the wire. The possibilities of error, however, are small.

(ii) The difficulty of measuring the current in the resistance at very high radio frequencies. At present a non-contact thermo-junction ammeter is used, and the assumption is made that its d.c. calibration is valid at all frequencies.

This limitation is, however, imposed on many other measurements at high radio frequencies at the present time. A better method of measuring very high radio-frequency currents would naturally improve the accuracy of the measurements at such frequencies.

(*b*) *The Construction of the Screened Cabin for the Oscillator.*—A perspective view of the completed oscillator cabin is shown in Fig. 1. The screened cabin is a 6½ ft. cube and consists of a wooden skeleton covered with No. 22 S.W.G. tinned iron sheet. Great care was taken to solder over every joint, and the completed box was hermetically airtight. Previous experience with screened doors had shown the difficulty of making them sufficiently effective, and consequently a mercury-sealed trap door (shown at A) was adopted.* The seal consists of a welded angle-iron frame dipping into a channel-shaped iron frame containing mercury. This door has been tested and found to be entirely satisfactory, but it has been found important to maintain the portion of the iron frame immersed in the mercury in a thoroughly clean condition. The output current leads are taken through seamless steel tubing (shown at B).

OAKLEY: "Quantitative Determination of Radio Receiver Performance," *Journal of the American I.E.E.*, 1927, vol. 46, p. 498.

* R. L. SMITH-ROSE: "On the Electromagnetic Screening of a Triode Oscillator" *Proceedings of the Physical Society of London*, 1922, vol. 34, p. 127.

The ventilation of such a box presents some difficulty, the method here adopted making use of two long copper pipes C and D, provided with three copper-gauze baffles which give adequate screening while permitting a sufficient passage for air. Pipe D is connected by an insulating rubber hose-pipe to a centrifugal pump E, and pipe C is the inlet. The diameter of pipe D is much smaller than that of C, so that the air pressure inside the box is only slightly lower than that of the outer atmosphere. The complete box is insulated from earth by means of the five large insulators F.

The output pipes B are insulated from the connecting trunk G, Fig. 2 (*a*), by a method, shown in detail in Fig. 2 (*b*), which gives good insulation and at the same time effective screening. Tests made with the completed box have shown that it is sufficiently screened for the purposes required.

(*c*) *The Construction of the Screened Input Resistance.*—Since the radio-frequency current is taken through the trunks to cabin A containing the amplifier, the radio-frequency resistance needs to be very efficiently screened.

For short-wave work, usually below 40 m, the inductance of the resistance wire is not negligible and consequently it was decided to use a screened straight wire in which the inductance was calculable. Such an arrangement would take the form shown in Fig. 3 (*a*), the current passing through the central wire and back through the screening cylindrical tube. The external field would be negligible, and if a certain length of wire l_1 were used the potential difference across this length could be applied to the amplifier.

The input lead B would have a length l_2 equal to the radius of the cylinder in the magnetic field due to the inner wire, and an e.m.f. could be induced in this wire. The construction Fig. 3 (*b*) is better, since the length of unscreened lead B is now materially reduced. However, the distance *d* must be reduced to a minimum if the capacity between the wire and the screen is to be negligible, such capacity acting as a shunt to the resistance, but this distance *d* also affects the capacity of the tapping lead to the screen; a compromise is therefore necessary which gives a new minimum capacity shunt effect. Since one lead A of the potentiometer is connected to the screen, it follows that this lead is effectively earthed and is connected to the main screen of cabin A. In all tests this lead is connected to the filament of the amplifier, thus "earthing" all batteries, which condition is normal. Therefore lead Y, Fig. 2, is connected to the screen and need not really be used, but in certain special cases, such as the input to a push-pull stage, no earth is required, and then the lead Y can be disconnected from the screen by the switch and the lead brought out of the screen.

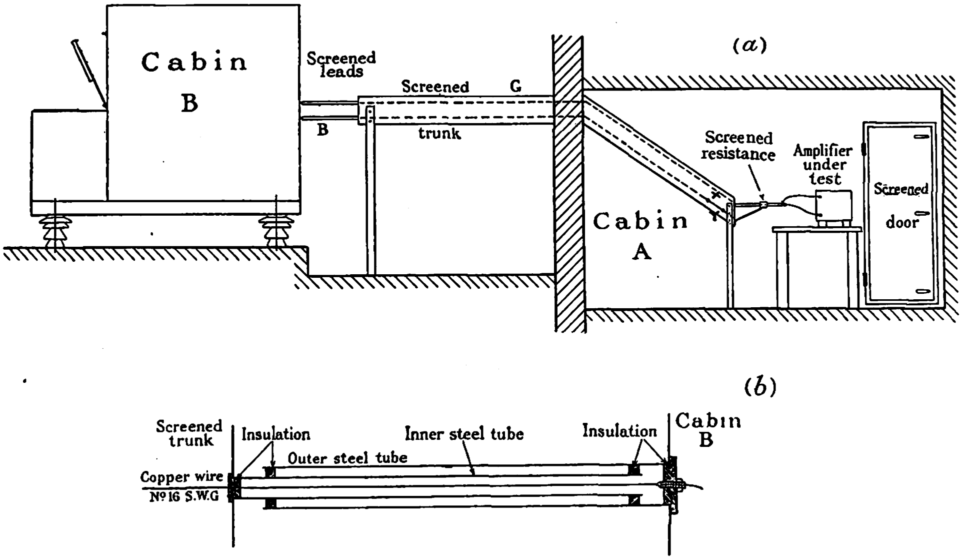

FIG. 2.

The final arrangement adopted for the input resistance is shown in Fig. 3 (*c*). No. 47 S.W.G. eureka wire is used as the resistance, and No. 40 S.W.G. copper wire is used to connect to the wire X, Fig. 2. The details of the insulation and screening are clearly shown in the diagram. Six such resistances have been made, having values of 0, 0·76, 0·96, 5·139, 11·23 and 27·86 ohms respectively. The resistance was measured by a potentiometer, this obviously being more satisfactory than a bridge resistance measurement, owing to the unknown electrical nature of the soldered joints. The inductance of the six wires was calculated and was found to be 0, $1 \cdot 39 \times 10^{-3}$, $3 \cdot 39 \times 10^{-3}$, $25 \cdot 98 \times 10^{-3}$, $60 \cdot 45 \times 10^{-3}$ and $176 \cdot 5 \times 10^{-3}$ μH respectively, these figures being obtained from the lengths of the eureka resistance wire measured by a travelling microscope.

The screened resistance can be plugged into a bayonet socket adjacent to the screened vacuum junction, as shown in Fig. 3 (*d*). This junction is of the non-contact type and measures the current within a few inches of where it passes through the resistance wire; this point is of importance since, at very high frequencies, the current varies along the trunk leads.

resistance, but lead B is connected to the screen end of the wire. This resistance is used to ascertain whether any electric or magnetic induction effects are present. Using this resistance, no output should be given if there are no induction effects.

FIG. 3.—Details of screened resistance for supplying known potential differences to a wireless receiver.

The two input leads are screened up to the terminals of the amplifier, the capacity of these leads being insufficient to alter appreciably the impedance of the resistance even at frequencies corresponding to wavelengths [in the neighbourhood of 30 m (10 megacycles per sec.). The zero-resistance wire has a construction identical with that of the 0·76-ohm screened

The inductive reactance of the resistances is negligible at frequencies below 10 megacycles, and at frequencies above this value the reactance can easily be calculated. These resistances appear to be quite satisfactory and have been used on wavelengths of 15 m (20 megacycles per sec.).

(*d*) *The Input Oscillator.*—Various types of radio-frequency oscillator have been tried, the push-pull type being used for the preliminary work. It has been found, however, that the series-fed Hartley oscillator with grid condenser and leak gives the best results, as this oscillator will work satisfactorily with a 2-volt low-impedance valve and a high-tension supply of 20 volts. Using this circuit arrangement, an oscillator has been built which will cover all wavelengths down to 5 m (60 megacycles per sec.).

In the early work, capacitative coupling to the input screened leads and resistance was adopted, a variable condenser connected between the free potential lead and one end of the oscillating coil being used, while the earthed lead was connected to the centre tapping. The adjustment of this condenser provided a very simple means of varying the current, but unfortunately this type of coupling exaggerates the harmonics and, since the thermo-junction measures the R.M.S. value of the current in the resistance, has been abandoned. The present arrangement employs a tuned circuit inductively coupled to the oscillator, the screened resistance being in series with this circuit. Although not so simple to operate, the purity of wave-form obtained by this method compensates for the increased practical difficulties.

The audio-frequency oscillator consists of a push-pull arrangement with a tuned output circuit in series with the anode feed to the radio-frequency oscillator. The wave-form obtained with this arrangement is sufficiently good for most measurement purposes. The modulation percentage was originally measured by means of an electrostatic voltmeter, but this instrument has now been replaced by a valve voltmeter owing to the sluggishness of the electrostatic instrument. The complete oscillator unit is carefully screened and consists of the audio-frequency oscillator, a modulator unit, the modulation measuring voltmeter, the radio-frequency oscillator and the coupling unit. The complete circuit arrangements are dealt with later in sub-section (*f*).

(*e*) *The Measurement of the Output Voltage.*—Most types of receiver give an output at an audio frequency, and in the early work a vibration galvanometer was used to measure this output. Such an instrument is eminently suitable for the measurement of very small outputs such as those given in telephones but, with more modern receivers, outputs of loud-speaker intensity are more common and the potential on the grid of the power stage is of the order of several volts.

Since the power stage must always be looked upon as a converting mechanism, the amplification must be expressed in terms of the voltage output delivered to the grid of the power stage with respect to some input voltage. To measure reasonably large outputs it is usual to use a valve voltmeter connected across the grid and filament of this stage, but difficulties have been encountered with the use of a valve voltmeter connected in this manner, owing to the large shunt load imposed by this instrument. This effect is illustrated by the results given in Fig. 4, the output as measured by a valve voltmeter being plotted against the input supplied to a 2-stage resistance-capacity amplifier. In curve A, the valve voltmeter was connected directly across the input of the power valve and it is seen that, as the input is increased, the output appears to reach a saturation value due to the load of the voltmeter. If, however, the voltmeter is connected across a 100-ohm resistance inserted in the anode circuit of the power valve, the characteristic is given by curve B, which shows a linear relationship between the input and the output. This low anode-circuit resistance is negligible in comparison with the loud-speaker impedance and consequently its effect, considered as a modifying element in the circuit arrangement, is negligible. The amplification will appear to be higher than that obtained when the voltmeter is connected directly across the input of the power stage when very small outputs are being obtained, as shown by the tangent drawn to the lower part of curve A. Since the modulation percentage never exceeded 15, the only important harmonic produced due to rectification is the second, and this can never produce an error greater than 3 per cent in the output measurement.* In all measurements, therefore, the voltmeter was connected across a low non-inductive resistance in the anode circuit, and the power stage was calibrated by supplying an audio-frequency oscillation directly to the grid and filament by means of a high-resistance potentiometer. By this means the actual voltage on the grid of the power valve can be obtained by noting the deflection of the valve voltmeter connected in the anode circuit.

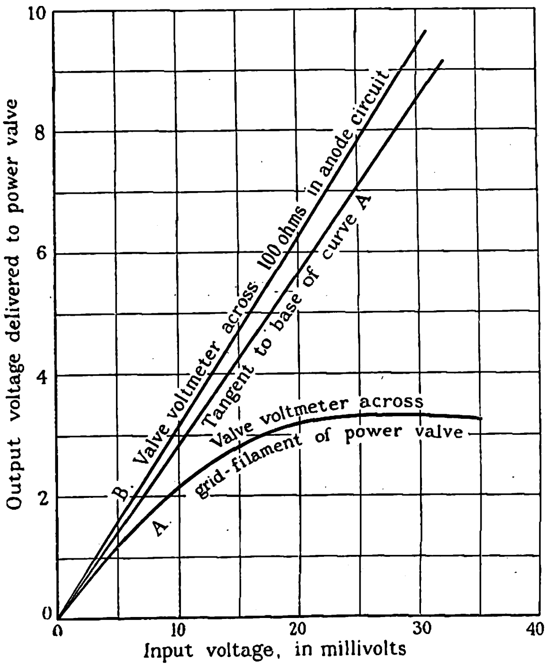

Fig. 4.

(*f*) *The Complete Circuit Arrangements.*—Fig. 5 shows the completed arrangement of the apparatus. The radio-frequency oscillation is modulated by means of the screened audio-frequency oscillator and the modulator. By means of a variable coupling between the audio-frequency tuned coupling circuit and the oscillator, and also by shunts across the output transformer of the modulator valve, the modulation percentage may be varied.

* W. B. Medlam and V. A. Oschwald: "The Performance of Valve Detectors," *Journal of the Institute of Wireless Technology*, 1928, vol. 1, p. 147.

It has been found that the output current given by the radio-frequency oscillator is sensibly proportional to $(V - K)$, where V is the high-tension d.c. voltage and K is an experimental constant. If the R.M.S. voltage of the modulator output is E, then the modulation percentage is given by

$$\frac{\sqrt{2}\,E}{V-K} \times 100 \text{ per cent}$$

An inductively-coupled tuned system supplies the screened resistance, the current in which is measured by the non-contact thermo-junction Q. A second junction P is inserted inside the oscillator cabin so that the operator can tune the circuits, but no measurements of current are taken on this instrument. With the switches in cabin A at position (1), the input is normally applied to the amplifier and the negative filament leg is connected to the screens and may be earthed if required; at position (2) the power stage is calibrated with an audio-frequency input by means of a high resistance. The milliammeter in the anode circuit of the power stage is used as an indicator to obtain the same grid bias under both conditions, the bias voltage being controlled by a potentiometer as shown in the diagram.

FIG. 6.—Circuit diagram of receiver, showing method of measurement.

The apparatus is capable of giving an input range of 0·25–1 000 mV at any wavelength from 5–30 000 m (20–0·01 megacycles per sec.), and an output range of 20–6 000 mV at any audio frequency.

SECTION (2).—EXAMPLES OF MEASUREMENTS UPON VARIOUS TYPES OF RECEIVERS.

(*a*) *Introduction.*—Having described the principal features of the measuring apparatus, some results of tests performed upon various types of receivers will now be given. The object of these tests was essentially to demonstrate the utility and range of the apparatus, and, although the results show the properties of the different receivers tested, no mathematical analysis of them has been attempted. For the purpose of analytical work, special amplifiers would need to be built and their constants would require exact measurement. The results, however, demonstrate the types of overall characteristic likely to be obtained from receivers of a similar type to those employed.

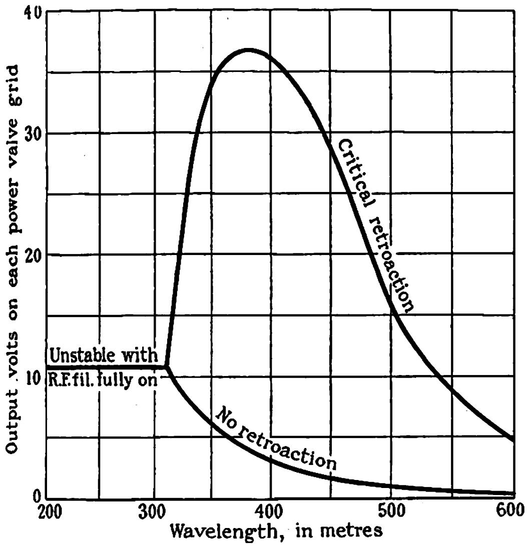

FIG. 7.

The receivers used for the tests were deliberately selected to cover several usual types, and, since the apparatus has been proved satisfactory for measuring the performance of these essentially different types, such measurements constitute a reasonable ground for believing that the apparatus can be employed to examine practically any type of receiver.

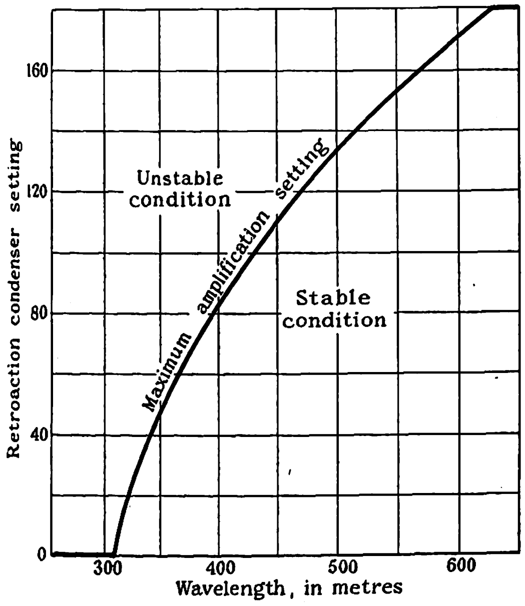

FIG. 8.

(*b*) *A 4-valve Receiver* (200–16 000 *m*).—A typical modern 4-valve receiver was examined. The particular receiver chosen had one radio-frequency stage, an anode-current rectifier with resistance-capacity coupling to the first audio-frequency stage, a transformer-coupled audio-frequency stage, and finally a push-pull output stage. The circuit arrangement is shown in Fig. 6. The radio-frequency stage is neutrodyned and a tapped secondary winding on the radio-frequency transformer provides the retroaction. The rectifier has a choke in series with the anode resistance, and the normal aerial and earth connections are shown by the dotted lines. For the purposes of the test the normal earth connection was taken to the screen, which was effectively earthed, and the known input voltage was applied to the tuned circuit as shown.

The valve voltmeter was connected across a 100-ohm resistance in series with the loud-speaker. To calibrate the push-pull output valves, the tapped secondary was removed and a tapped non-inductive resistance was substituted, the middle point being earthed. The audio-frequency oscillator fed this resistance and gave the output on the valve voltmeter.

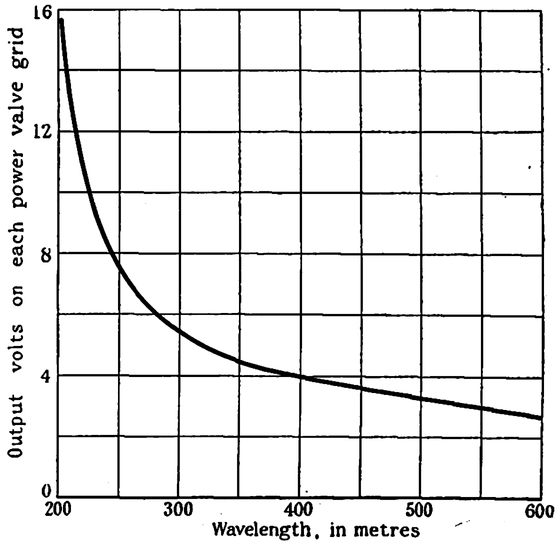

FIG. 9.

An earthed screen is used to prevent retroaction between the two radio-frequency circuits. The current in the filament of the radio-frequency valve is adjustable by means of a rheostat, this being used as a volume control and also as a stabilizer at certain wavelengths where the neutrodyne arrangement is not satisfactory.

A constant input of 5 mV modulated 15 per cent at 1 000 cycles per sec. was applied to the tuned circuit at various frequencies, and the R.M.S. output voltage delivered to either grid of the push-pull output valves was measured with the filament current of the radio-frequency valve at maximum and with the retroaction condenser at zero. This characteristic is shown in Fig. 7. At a wavelength of 310 m the receiver became unstable, and at any wavelength below this the radio-frequency valve filament-current had to be reduced to maintain stability. The amplification at these lower wavelengths could not be raised above the value given at 310 m. At wavelengths above 310 m the retroaction condenser was now adjusted to the threshold of oscillation and the output was measured. It will be seen from Fig. 7 that the maximum amplification occurred at a wavelength of 380 m. Any point lying between the two curves represents a possible stable condition depending upon the setting of the retroaction condenser. The actual settings of this condenser are shown in Fig. 8. Below 310 m the receiver is unstable with maximum filament current in the radio-frequency valve, even with the retroaction condenser at zero, whereas above 625 m the receiver is stable when all the extra retroaction is inserted. All points lying below the curve represent a condition of stability, and all points above the curve one of instability.

The next test was made at the constant wavelength of 370 m with a constant modulation of 10 per cent but with variable input. The relationship between the output and the input was found to be very nearly that of a square law. This test was made at different wavelengths and always gave a similar relationship, from which we deduce that this characteristic represents the property of the rectifier, since the radio-frequency and audio-frequency portions of the receiver sensibly obey a linear law.

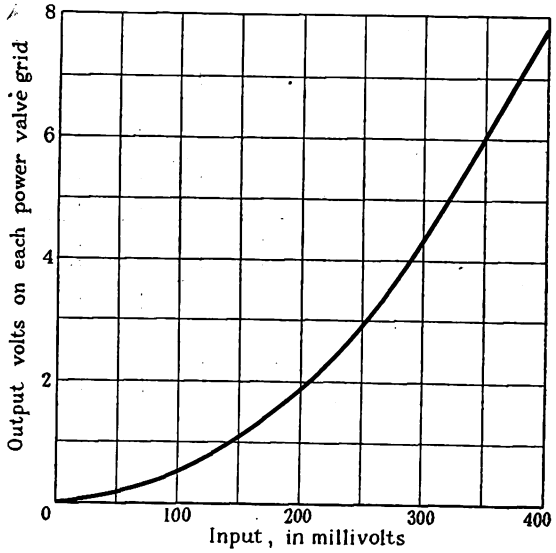

FIG. 10.

It was found that if the output exceeds about 4 volts on each power-valve grid, the relationship between the output and the modulation percentage departs from a linear law. This has been found to be generally true, irrespective of wavelength, and is clearly due to some saturation effect.

A constant input of 70 mV was now applied directly to the radio-frequency stage and the circuit was tuned to give the maximum amplification with no extra retroaction and with the full filament current at each wavelength. The output is plotted in Fig. 9 and it is seen that the radio-frequency stage is stable down to a wavelength of 200 m. The rectifier characteristic obtained by applying the known e.m.f. to the rectifier grid is shown in Fig. 10, the input being applied directly to the rectifier. The relationship between the input and output voltages for a definite modulation percentage is a perfect square law. From these two characteristics, Figs. 9 and 10, the amplification of the radio-frequency stage can be obtained and is plotted in Fig. 11. An examination of this figure shows that the amplification of the radio-frequency stage rises from about 3·2 at 600 m to nearly 9 at 200 m. The receiver is unstable at this wavelength if an input circuit is connected before the radio-frequency stage, but the figure represents the stable condition with no input circuit. Since the voltage factor of the radio-frequency valve is 13, this amplification figure is very low. Tests on other radio-frequency amplifiers have given similar low values, and, where high values are obtained approaching the valve voltage-factor, retroaction is usually responsible for such values.

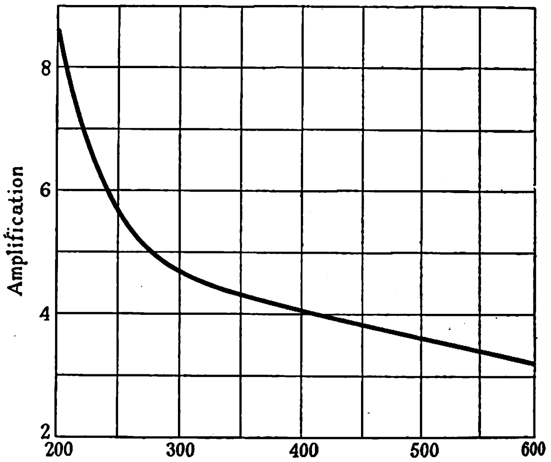

FIG. 11.

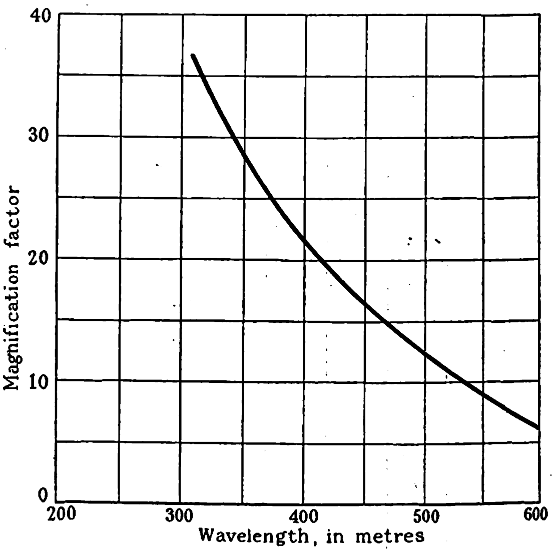

FIG. 12.

By combining the overall performance characteristic obtained by supplying the tuned input circuit with a known signal, and the radio-frequency valve characteristic, we can obtain a figure for the magnification factor or coil factor of the tuned input circuit; this is shown in Fig. 12. In the absence of all loading and retroaction effects, this characteristic should be given by $\omega L/R$, where L and R are respectively the inductance and radio-frequency resistance of the input tuned circuit.

An attempt was made to reconcile the experimental figures for the amplification of the radio-frequency stage and the magnification factor of the input circuit with the theoretical figures obtained by a cursory examination of the circuit. The radio-frequency resistance of the input circuit and the radio-frequency stage load circuit was obtained by measurement, together with the inductance and self-capacity of the coils used in these circuits. The simplest examination of these figures revealed the serious discrepancy between the experimental results and the results obtained by any simple theoretical calculation which neglects the effects due to retroaction and input impedance: not only are both experimental figures far lower than the predicted figures obtained by such a simple analysis, but the form of the curves is different. The departure in form shows that a proportionately higher figure is obtained as the frequency is raised, which is undoubtedly due to retroaction effects at the higher frequencies. It is clear that the input impedance and retroaction effects are very serious and no useful results would be obtained by a closer examination of the characteristics, as the receiver is one in which no special precautions have been taken to prevent stray retroaction. The results given are of considerable interest, in that they demonstrate the general properties obtained with a typical receiver, but a closer examination would be impossible on account of the numerous unknown quantities involved.

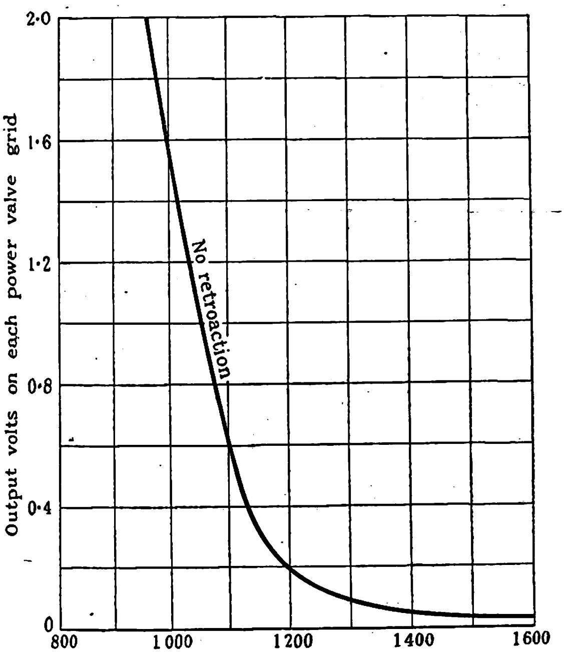

FIG. 13.

The properties of the receiver on long waves, using two different coils, are shown in Figs. 13, 14 and 15. In Fig. 13 the overall performance characteristic is given with no extra retroaction, while Fig. 14 shows the effect of retroaction. In this case a much greater increase of amplification is possible by the use of retroaction, but the best performance is only slightly better than in the medium wavelength case. This effect is due, no doubt, to the much smaller inherent retroaction at the longer wavelengths, the curves for "no retroaction" showing a much reduced amplification. Again, the rapid rise in amplification at the lower wavelength end and the instability coupled with it are to be noted. The critical retroaction setting is shown in Fig. 15, from which it will be noticed that the receiver can be rendered unstable at all wavelengths with a smaller

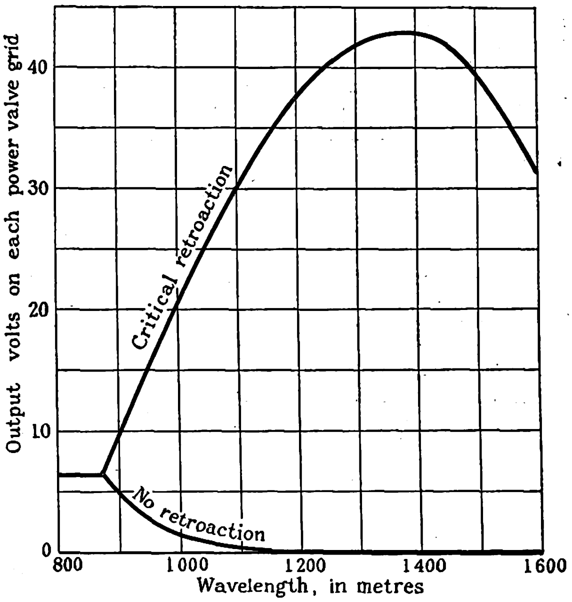

FIG. 14.

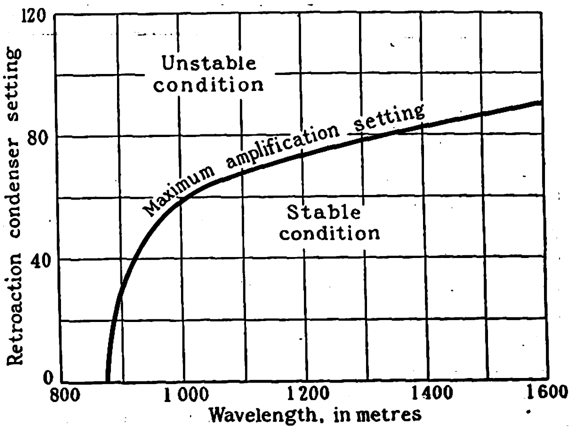

FIG. 15.

retroaction setting than in the previous medium-wave case, but, as before, it is unstable below a critical wavelength. In both cases the neutrodyne condenser was set to give balance by the usual audibility method, but no guarantee can be given that this setting was absolutely exact.

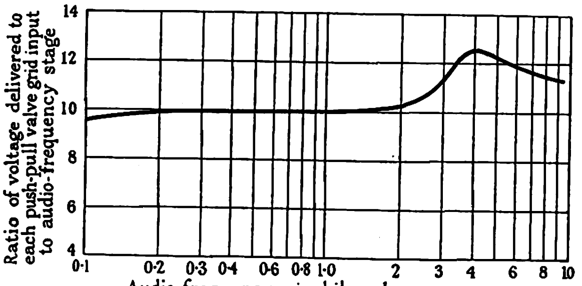

FIG. 16.

It is to be noticed that several characteristics show output voltages of 40 or so. It is to be realized that, where such points occur, they are obtained by calculation only. For instance, if a characteristic is being obtained on the basis of a constant input of 5 mV and an output of 2 volts is obtained at a certain wavelength, another wavelength may require only 1 mV to give the same output. Making use of the known overall properties, the output is then computed in terms of a 5-mV signal. Such computation is permissible and renders the curves more useful, but at no time during the tests did the output exceed the limit of linearity of the output stage characteristic.

The last test performed upon this receiver consisted in maintaining a constant input and modulation while varying the modulation frequency. In this way the audio-frequency characteristic of the amplifier stage preceding the output valves was obtained and is shown in Fig. 16.

(*c*) *A Commercial Short-Wave Receiver* (15–60 *m*).—To examine the utility of the apparatus at short waves, an examination of a standard short-wave receiver employing one stage of radio-frequency amplification was undertaken.

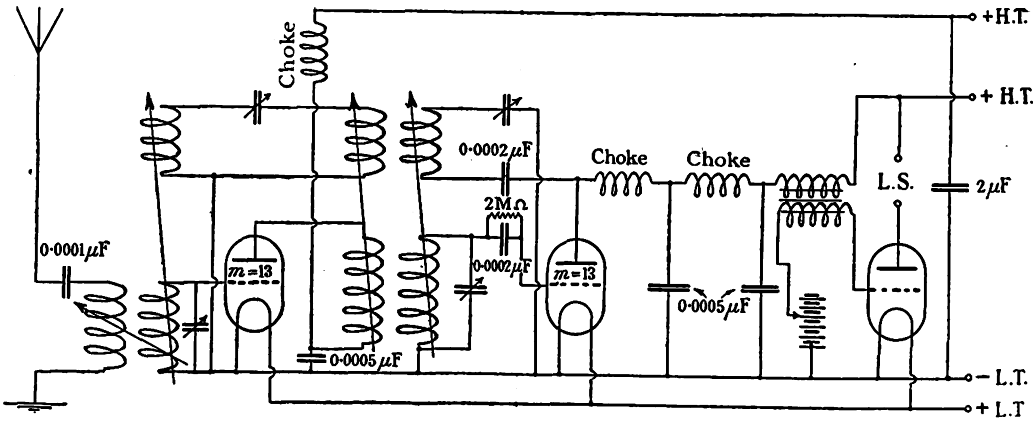

FIG. 17.—Circuit diagram of commercial short-wave receiver (15–60 metres).

The receiver circuit diagram is given in Fig. 17. There is one stage of radio-frequency amplification, the valve used having a voltage factor of 13 with an internal resistance of 30 000 ohms, followed by a rectifier valve with the same voltage factor and internal resistance, and lastly any normal output valve. Since the receiver is designed for use with weak telephonic outputs, the valve voltmeter was connected directly across the telephones and the power stage was calibrated with this connection. The known input voltage was supplied to either the input tuned circuit, the grid of the radio-frequency valve or the rectifier grid, by which means the performance of each part of the receiver could be analysed. Two tests were carried out at all wavelengths, namely, one with a variable modulation at a definite input, and the other with a variation of the input at a definite modulation. The modulation frequency was 1 000 cycles per sec. throughout, representative of an average audio-frequency in telephones with heterodyne reception of continuous waves.

The rectifier was calibrated at 30 and 60 m and found to be sensibly independent of frequency and to obey approximately a square-law relationship. By the use of this characteristic, together with those obtained by supplying the input tuned circuit or the radio-frequency stage, an analysis of the radio-frequency circuits was rendered possible. It is only possible to separate the coil and radio-frequency stage factors for the no-retroaction condition, since the amplification

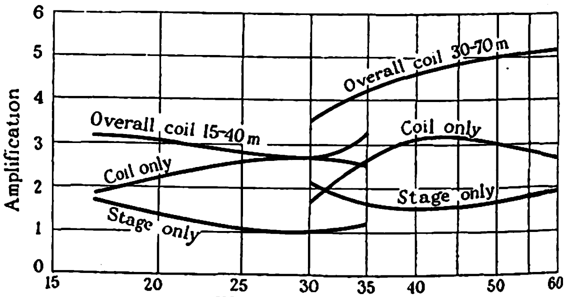

FIG. 18.

given when considerable retroaction is present is produced by the product of the two augmented values of both the coil factor and the radio-frequency stage factor. It is impossible to separate these two under critical conditions, owing to the modifying effect of the input resistance upon the circuits.

Within the limits of experimental accuracy, the output was found to obey a linear relationship with respect to the modulation percentage for constant input. With outputs greater than 0·3 volt on the power-valve grid the departures from this law were never greater than 5 per cent, and in the cases when the output was of the order of 0·1 volt they were much less.

It was found that the form of the input-output characteristic with constant modulation was independent of the frequency. For output voltages exceeding 0·1 this relationship was linear, but below this output voltage the characteristic was curved in a similar manner to the lower bend of a rectifier characteristic. The test made on the rectifier gave a somewhat similar curve, but the difference between the two was sufficient to suggest that a small amount of rectification was taking place in the radio-frequency stage. With critical retroaction the form of this input-output characteristic becomes saturated. This is due to the more critical retroaction setting possible with the weaker inputs, the larger inputs tending to throw the receiver more readily into oscillation. If the retroaction condenser had been adjusted for stability with a large input and left unaltered for the weak signals, this effect would have disappeared, but in the curves giving critical retroaction conditions the retroaction was adjusted for each measurement to give the greatest possible amplification. Owing to the difficulty of obtaining a critical setting, these characteristics have an accuracy of not more than 10 per cent.

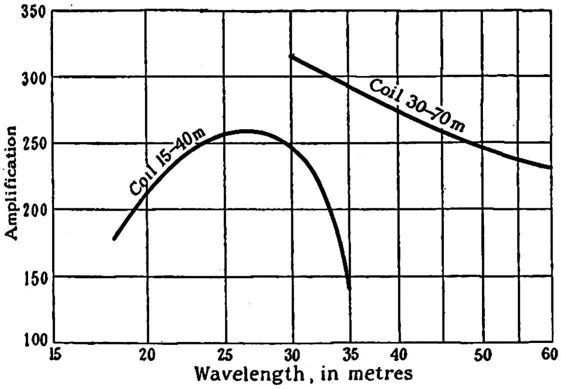

FIG. 19.

The receiver is provided with two sets of coils to cover the wavelength band of 17–60 m. The overall radio-frequency amplification obtained by the input tuned circuit and the stage of amplification before the detector is shown in Fig. 18 with no retroaction, and the critical retroaction case is given in Fig. 19. In the former figure the overall amplification has been resolved into its two components, namely, the coil factor and the audio-frequency stage factor.

The general properties to be noticed by an examination of these results are that, owing to capacity shunting effects, the sensitivity falls as the frequency rises in the no-retroaction case; this is clearly shown in the case of the coil having the range 30–60 m (Fig. 18). The other effect of raising the frequency is to increase the retroaction, resulting in greater amplification. This is particularly noticeable below 30 m where the sensitivity is maintained. This characteristic agrees with the results obtained on the previous amplifier. In the critical retroaction case, where the input voltage is 1 mV the sensitivity increases as the wavelength is reduced, owing to the greater retroaction effect on the shorter waves, but it appears that at wavelengths below 25 m the retroaction condenser cannot be set so critically and a loss of sensitivity takes place.

In the critical retroaction case the measured performance given in Fig. 19 is valid only for inputs not exceeding 1 mV, for with greater inputs the amplification is found to be materially reduced. It would appear at first sight that this behaviour is due to amplitude distortion, but on examination it is found to be due to the inability of obtaining so critical an adjustment of the retroaction condenser for the higher inputs. The results obtained on larger inputs suggest that the amplification with very weak inputs may be greater than that shown for an input of 1 mV in Fig. 19. The most striking feature of the results is the very poor amplification of the radio-frequency stage. This gives an amplification which never exceeds 2·1 and is only 1 at a wavelength of 28·5 m. It is interesting to note that the maximum coil factor is obtained at the same wavelength as the minimum radio-frequency stage factor for both ranges, and also that the maximum amplification obtained by the use of critical retroaction is obtained at the wavelength corresponding to the minimum radio-frequency stage factor. Since the use of retroaction is responsible for such a large increase in amplification, and since the radio-frequency stage appears to help to such a small extent, one arrives at the conclusion that methods of critical retroaction adjustment are more important than amplification at the high radio frequency by separate stages. Later experiments have confirmed this view. To illustrate

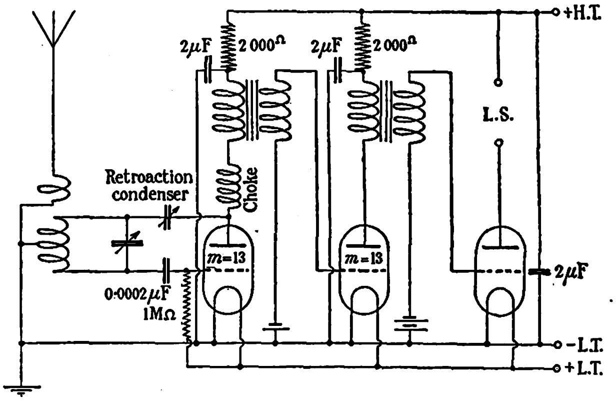

FIG. 20.—Circuit diagram of screened short-wave receiver (15–80 metres).

this point more fully, the next test was made upon a short-wave receiver covering the same wavelength range but employing no radio-frequency amplification.

(*d*) *A Screened Short-Wave Receiver* (15–80 *m*).—The circuit arrangement of this receiver is shown in Fig. 20. Each stage was screened, and the coils used were made with bare copper wire well spaced, and with merely a skeleton frame to support them, so that the losses were reduced to a minimum. Two coils are required to cover the wavelength range from 15 to 80 m. It was found that this type of circuit was more easily adjusted than the previous one, largely owing to there being only two condensers, one of which controls the retroaction, whereas the previous circuit had three condensers, two of which were tuning controls.

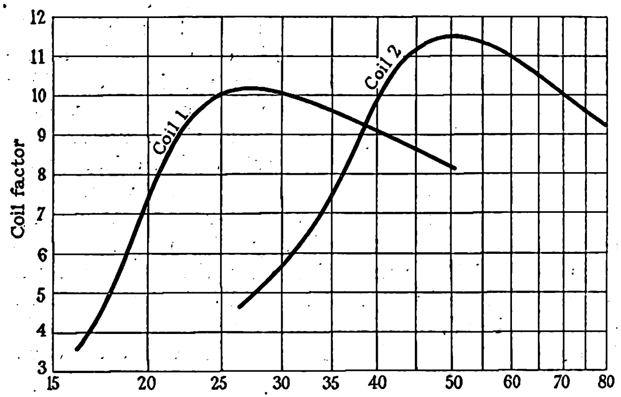

FIG. 21.

By comparing these results with those of the previous receiver, Figs. 18 and 19, it is seen that a similar overall performance can be obtained by the use of a retroactive rectifier circuit, and that the predominant factor is the retroaction.

The radio-frequency stage in the previous amplifier was contributing but slightly to the overall result, and there appears to be little justification for the greater complexity of the controls and circuit involved by the use of a radio-frequency stage when a simple retroactive system can give the same performance.

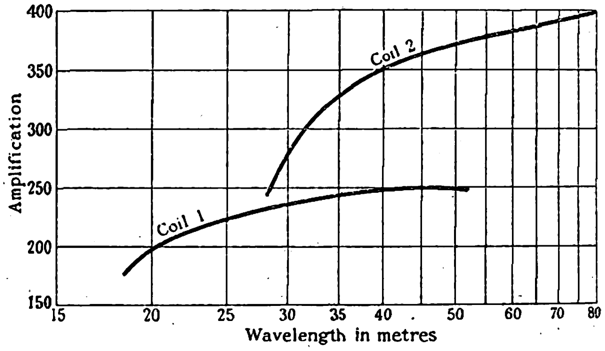

FIG. 22.

(*e*) *A Supersonic-Heterodyne Receiver with Frame Aerial* (50–500 m).—Finally, a complete examination of the properties of a supersonic-heterodyne receiver was made, and the results are expressed in such a manner as to be of direct application to the practical use of such receivers.

The receiver used was partly built up from commercial components, but was somewhat modified to suit the needs of a portable direction-finding receiver. The circuit arrangement is shown in Fig. 23. There is a separate oscillator having various coils to cover the required ranges, a 3-stage intermediate-frequency amplifier inductively coupled to the first rectifier, a second rectifier and an output stage. The voltage factors and internal resistances of the various valves are shown in Fig. 23.

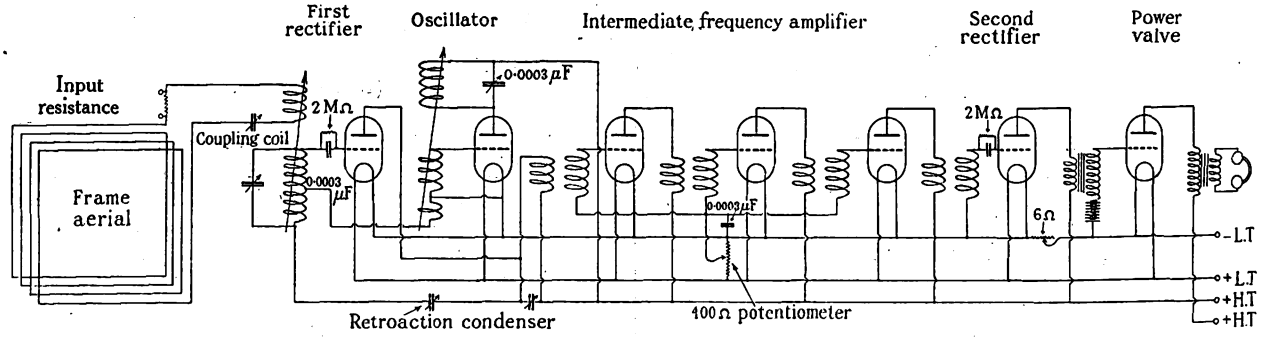

FIG. 23.—Circuit diagram of supersonic heterodyne receiver (50–5 000 metres).

By applying the known e.m.f. to the input tuned circuit and obtaining the audio-frequency output, and then by applying the e.m.f. directly to the rectifier, the coil factor can be obtained without deliberate retroaction. This characteristic is shown in Fig. 21, from which it will be noticed that the step-up due to the coil alone is much superior to that obtained in the previous case. This is largely due to the superior coils and also to the smaller load thrown upon the input circuit by the impedance of the rectifier valve circuit. By the use of retroaction, a greatly improved performance is possible, as shown in Fig. 22, the performance being similar with the two coils, namely, a fall in amplification with rise in radio frequency.

The first characteristic to be obtained was the amplification of the three stages comprising the intermediate-frequency amplifier. This is given in Fig. 24, the potentiometer control of the grid bias to the second valve being so adjusted that the system was just stable and giving its maximum amplification. For this test the input resistance was connected directly to the grid of the first intermediate-frequency stage, and the characteristic shown in Fig. 24 represents the ratio of the voltage delivered to the second rectifier to the input voltage applied to the first intermediate-frequency stage. The type of characteristic obtained is a very general one for an intermediate-frequency amplifier and many similar characteristics have been obtained previously.* Owing to the inductive coupling between the first intermediate-frequency stage and the first rectifier, this latter characteristic does not represent the true selectivity of the intermediate-frequency section. To obtain this selectivity we must include the coupling between the first rectifier and the first intermediate-frequency stage. The input at the intermediate frequency was now applied to the first rectifier and a characteristic obtained between the voltage delivered to the second rectifier and the voltage applied to the first rectifier. Since the frequency of the applied voltage was that corresponding to the intermediate-frequency amplifier, such a test does not truly represent the conditions existing on the first rectifier, but it does give the true selectivity of the intermediate-frequency stages. This characteristic is shown in Fig. 25 and can be used to calculate the selectivity of the input circuit at any desired frequency.

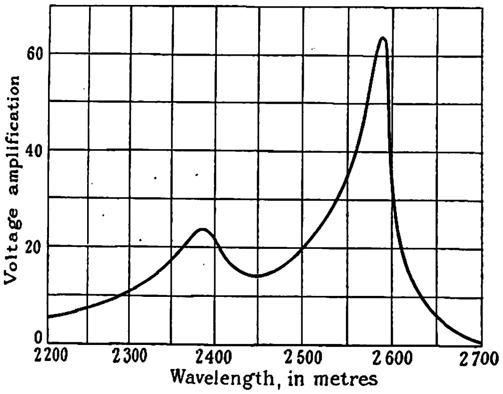

FIG. 24.

Using this characteristic, the selectivity of the receiver has been calculated for the particular wavelength of 325·7 m and is plotted in Fig. 26. By applying the known modulated e.m.f. to the frame-aerial circuit, an experimental selectivity characteristic was obtained and is plotted alongside the theoretical curve for comparison. The agreement between the two curves is considered to be good enough for most general purposes.

The overall characteristic was now obtained. Tests were made to find the relation between the output audio-frequency voltage delivered to the grid of the power valve in terms of the voltage applied to the frame aerial by means of the screened resistance. This resistance had a value of 0·76 ohm, and consequently the effective resistance of the frame aerial was slightly increased by this amount. However, the error introduced by this factor is small. To cover the wavelength range of 50–500 m two different frame aerials were needed, together with various coils for tuning the frame circuit and the secondary circuit (see Fig. 23). The various oscillator coils were marked to signify the approximate range of wavelength as follows:—Ultra-short, 100–200, 250–800, and the coils are referred to in the final results in this manner. Each wavelength can be received with two settings of the oscillator, one corresponding to the high setting of the oscillator condenser, and therefore to an oscillator frequency lower than that of the incoming signal, and the other corresponding to the low setting, in which case the oscillator frequency is higher than that of the incoming signal. These two conditions are referred to as the "high" and "low" settings respectively.

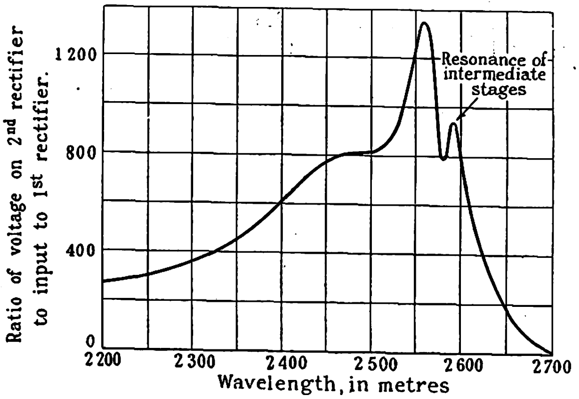

FIG. 25.

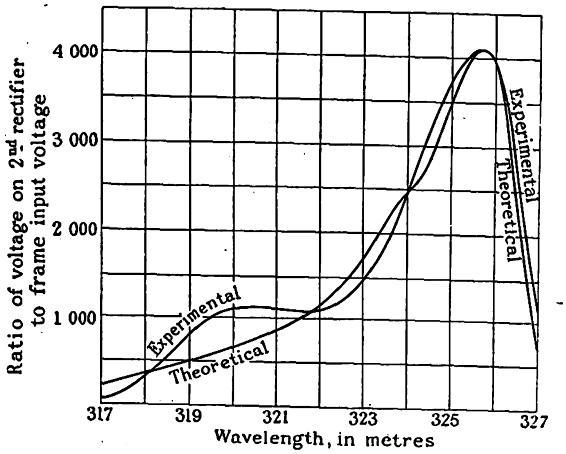

FIG. 26.

For the purpose of expressing the results in the most useful form, a constant output signal has been taken, corresponding to average telephone strength. This was found to be given by a voltage of 3 mV on the grid of the power valve. Accordingly all the measurements have been referred to this value. In Fig. 27 the e.m.f. required in the frame aerial at a modulation percentage of 100 to give the standard output of 3 mV is plotted against the wavelength for the different ranges and oscillator coils. For other modulation percentages the output is found to be proportional to the modulation percentage and would thus be reduced proportionately. The large difference in sensitivity between the two oscillator settings is most marked, particularly at the longer wavelengths. The current in the oscillator was found to rise almost proportionately with the wavelength. With the long-range oscillator coil (250–800) the sensitivity is far greater on the low setting, i.e. with a weaker local heterodyne, and the shape of the curve suggests that the sensitivity falls as the local heterodyne is increased with increase in wavelength. The obvious conclusion to be drawn from the form of this characteristic is that the local heterodyne is too strong. This could be improved by weakening the coupling to the frame aerial. On the other hand, the form of the remaining three sets of curves suggests that the local signal is too weak, since the maximum sensitivity always occurs when the oscillator wavelength is high, i.e. the local signal is large. It is well known that there is an optimum intensity for the local oscillation, and since no control is provided, it is not surprising that the optimum has not been obtained in this particular case. The two conditions, above and below this optimum, represented by the long and short oscillator coils illustrate the utility of such characteristics as a guide to improving the design of a receiver. The difference between the sensitivity characteristics for the high and low oscillator settings is small at the short wavelengths owing to the small difference between the condenser settings and consequently the small difference in the strength of the local signal, whereas at higher wavelengths the difference is very large.

---

* H. A. THOMAS: "The Performance of Amplifiers," *Journal I.E.E.*, 1926, vol. 64, p. 253.

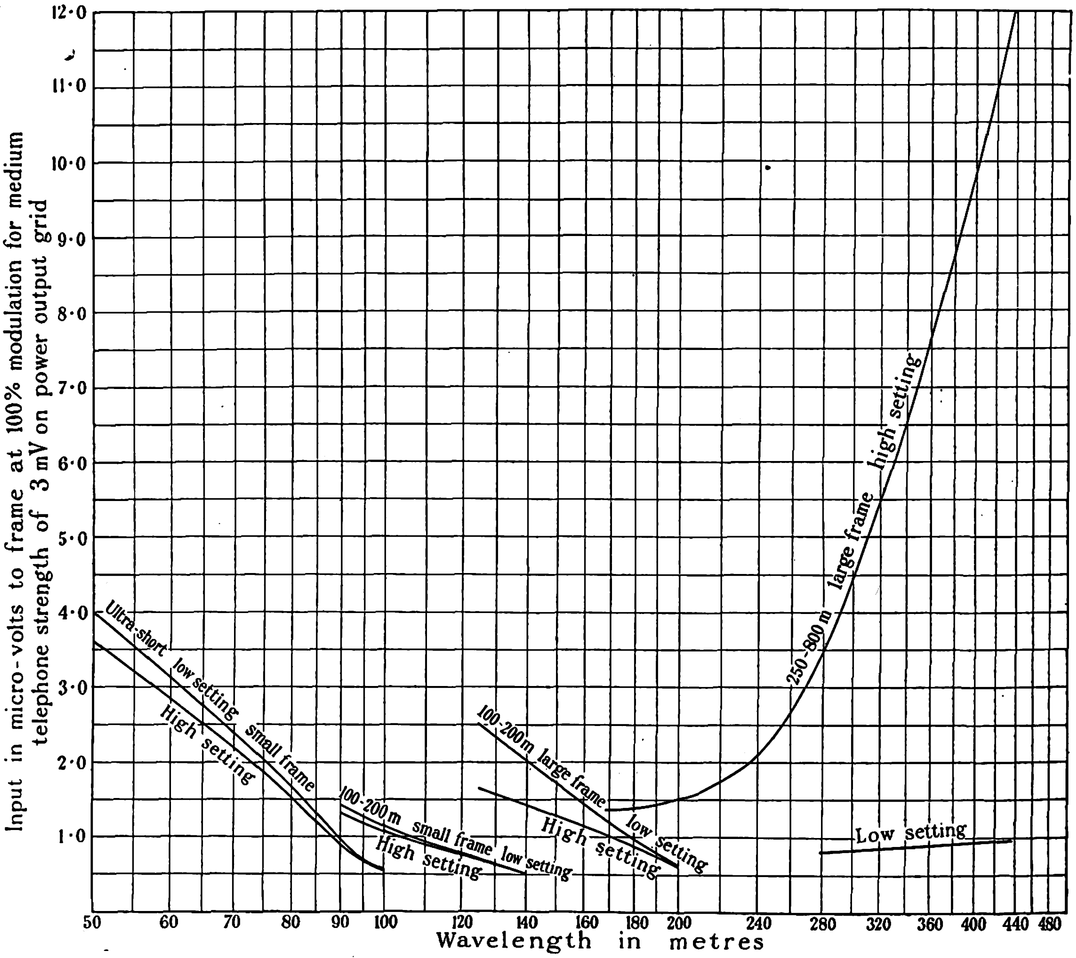

FIG. 27.

By means of the known dimensions of the frame aerials, the potential gradient required to give the standard signal of 3 mV can be readily calculated. This has been done in Fig. 28. By the use of this characteristic, the field intensity (μV/m) required to give the standard signal can be obtained for any wavelength, and this characteristic represents the complete performance of the receiver.

SECTION (3).—SUGGESTIONS FOR SPECIFYING THE PERFORMANCE OF RECEIVERS.

From a perusal of the foregoing examples of the properties of receivers, it is apparent that the overall properties of any receiver can be expressed in terms of three characteristics:—

(*a*) The input voltage required at a definite modulation percentage to produce a definite standard output signal at all wavelengths within the designed range.

(*b*) The sensitivity variation in the neighbourhood of certain fixed wavelengths—this gives the selectivity of the receiver.

(*c*) The output variation with constant input and modulation percentage but variable modulation frequency—this gives the frequency distorting properties of the audio-frequency stages.

The limiting range of any receiver is easily obtained by this means, and the range for medium loud-speaker reception can also be obtained in a similar manner. In the case of an open antenna this latter characteristic involves a knowledge of its effective height. In view of the accuracy with which field-intensity measurements can now be made, and the consequent knowledge of the field distribution from a transmitting station, the author feels that if similar field-intensity/output characteristics were forthcoming for receivers, a considerable step would be taken towards more scientific classification of types, and the immediate result of such a classification would be to improve the design of radio receivers.

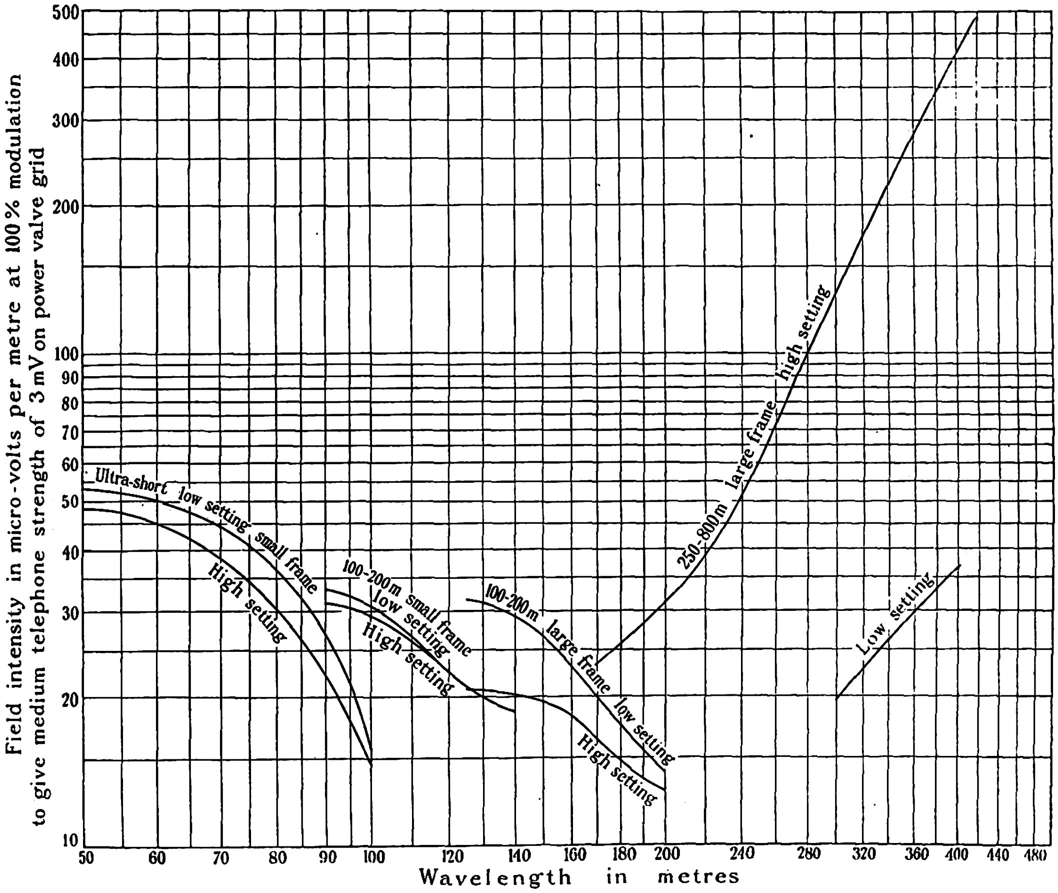

FIG. 28.

These three characteristics completely define the overall properties and, by means of them, the utility of a particular receiver can be obtained for any particular function. Oakley * has similarly concluded that these three properties are required to specify the overall performance of a receiver.

To determine the range of a receiver with respect to a particular transmitting station, two characteristics are required:

(i) The field-intensity characteristic of the transmitter expressed in the form of contour lines on a map.

(ii) The field-intensity/output characteristic of the receiver.

In a somewhat similar manner the classification of receivers into various selectivity categories would help towards the correct selection of a receiver for a particular purpose. The selective properties of a receiver could be expressed as a figure which could be appended to the previous characteristic at the different wavelengths covered by that characteristic. Such a simple system would simplify the final statement of performance and would, in fact, enable the radio-frequency properties to be expressed in the form of a single curve.

The audio-frequency properties of a receiver have received considerable attention, chiefly because such results are comparatively simple to obtain, and undoubtedly the progress in the design of audio-frequency amplifiers has followed measurements which have revealed the faults in the older types of amplifier. By means of an overall measurement, however, this characteristic would form a part of the tests and would take its place with the complete statement of the performance.

---

* *Loc. cit.*

This work was carried out as part of the programme of the Radio Research Board and is communicated by permission of the Department of Scientific and Industrial Research. The author wishes to acknowledge the assistance given him by Dr. R. L. Smith-Rose and Mr. F. M. Colebrook, and also by his assistant, Mr. C. W. Spencer, in the latter portion of the work.

DISCUSSION BEFORE THE WIRELESS SECTION, 15TH JANUARY, 1930.

Dr. J. Hollingworth: In considering such a comprehensive piece of work as that described in this paper I think it is right that some recognition should be made of the special problems which have had to be dealt with. In a subject which is developing as rapidly as radio-telegraphy, one of the chief difficulties is that developments on the practical side tend to take place so rapidly that the scientific side has difficulty in keeping pace with them. In this particular case, when the research first started about six years ago bright-emitter valves with factors of 2 or 3 were still in general use and overall amplifications were comparatively small. With the development of valves of ever-increasing factors, however, continual re-design of the apparatus was needed to cope with the increasing sensitivity and accuracy needed. Another factor which invariably occurs in developing apparatus for a measurement which has not reached the stage of a routine technique is the difficulty of proving that the apparatus really measures the quantity it is designed to measure. It is, of course, impossible to determine this by a direct method and it can only be decided by a long and difficult process of cross-checking. The paper also emphasizes a most important point which, though generally accepted now, had a long fight for recognition, namely that a receiver-amplifier is fundamentally a single unit from aerial to loud-speaker, and except for pure theoretical study cannot be treated as an aggregate of parts. On the instrumental side two small points arise, both in connection with the screened resistances. The first is that the intervals of resistance given on page 477 seem to be rather irregular; one would have expected the interval given as 0·96 ohm to be nearer 2 ohms to give a regular series. The other is that these resistances, although absolutely suitable for their work, are rather elaborate to construct. In the light of experience gained with their use can the author say whether any form of simpler and less expensive construction could be used without sacrifice of accuracy? The remark on page 479 with regard to the loads placed on a circuit by a valve voltmeter may surprise many, but is not altogether unexpected by those of us who know from practical experience how extremely sensitive an amplifier may be to alterations in the output circuit. With regard to the statement on page 480, " It has been found that the output current given by the radio-frequency oscillator is sensibly proportional to $(V-K)$, where V is the high-tension d.c. voltage and K is an experimental constant," do not variations sometimes occur in the value of K? Some time ago, when valves were not so reliable, I used to find that K varied from day to day. With regard to the actual amplifiers themselves, the results completely confirm my experience that on short waves, retroaction is the vital factor. In a paper by myself and Mr. Naismith, read before this Section in 1929 * we described the application of this idea to the use of an untuned aerial. The hope which we then held, viz. that we were not losing a great deal, seems now to be justified. In my opinion it pays to sacrifice to a limited extent the amplification of the set in order to ensure optimum conditions for the retroaction. In the author's opinion, what is the probability, in the average set, of accurately repeating a reading? Although at one time such an achievement was regarded as impossible with an amplifier, this should not be the case provided that the retroaction is carefully designed.

Mr. P. K. Turner: I should like to know whether there is any means of communication between the two cabins A and B. The point is important, because if, for example, a telephone is connected between them the screening will probably be adversely affected. In the first paragraph the author states that the most important measurement which can be made in connection with a receiver consists of the characteristic relation between input and output, together with an analysis of the behaviour of the individual portions of the apparatus. Does not such a measurement embrace all the information which is obtainable in connection with the receiver? In connection with the statement that the whole of the screening was done with iron sheet, I should like to know whether this material was employed merely because it was found to be satisfactory, or whether it was considered to be definitely superior to copper in its screening effect. With regard to the point which Dr. Hollingworth has also mentioned, in connection with the heavy load imposed by a valve voltmeter, I have used a number of valve voltmeters under many varying conditions and have never encountered any serious trouble from the load at audio frequencies,. A valve voltmeter which produces an apparent saturation curve of the type shown in Fig. 4, is open to question, and I should like further information about it. In measuring up to 40 or 50 volts with such instruments I find the load imposed by the voltmeter to be that of a small condenser with a power factor of the order of 0·1 and a capacity of 12 to 20 μF. These values are quite definite, and, within the limits for which the voltmeter is designed, are independent of the voltage actually being measured. The type of receiver used for broadcast reception is of greatest interest to me. Most of the measurements made by the author are not of importance in connection with instruments of that type. For example, the measurements given on page 479, where the modulation percentage is never greater than 15, are not of much interest to me. In the general circuit diagram of Fig. 5 and elsewhere there are indications that the output is being measured across a 100-ohm resistance in series with the loud-speaker. Thus the reading of the output is a function of the loud-speaker impedance, and as in many cases the set has to be considered apart from the loud-speaker it may, in those cases, considerably falsify the results. Such would be the case in connection with Fig. 16, which shows the audio-frequency response characteristic. Unless the loud-speaker and set are designed to be invariably used in conjunction one with the other, it is not justifiable to measure their performance together. An alternative method is to put a pure resistance load on the last valve, usually of about twice the impedance of the latter, and to measure the amplification of the set under these conditions. By a simple calculation the change introduced by the loud-speaker can be found. In Fig. 6 the screened resistance is shown on the grid side of the tuned circuit; if the resistance, one side of which is earthed, were, in fact, to be inserted at that point, no measurements upon the receiver would have any meaning, because of the alteration to the input circuit of the set. Should not the resistance be connected on the earthed side of the input circuit? Critical retroaction is usually understood to be the condition which approximates most closely to oscillation. This definition is not, in my opinion, altogether satisfactory, and I would therefore ask the author how it is possible to ascertain whether or not a system is in a state of critical retroaction. In cases where the retroactive arrangements are bad, the voltage is fed back several degrees out of phase with the input voltage, and critical retroaction is easily obtained. The output rises to a maximum and then diminishes slightly just before oscillation occurs. If, however, the retroactive arrangements are well designed the voltage fed back is almost in phase with the input, the critical stage before oscillation is very indeterminate, and the degree of amplification is closely dependent upon the precise setting. On page 482 the relationship between the output and the modulation percentage is mentioned. This is of first-rate importance, and I am sorry that no curves are given for varying modulation percentage at constant carrier voltage, showing how nearly the rectification is linear. The author states on page 481 that "a typical modern 4-valve receiver" was examined, but I am doubtful whether this is an accurate description of the receiver in question.

---

* " Portable Radio Intensity-Measuring Apparatus," *Journal I.E.E.*, 1929, vol. 67, p. 1033.

Mr. W. J. Brown: On page 479 the author states:—"the amplification must be expressed in terms of the voltage output delivered to the grid of the power stage with respect to some input voltage." Overall measurements on the receiver should definitely be made behind the output stage, as Mr. Turner has already suggested. His idea of including in the output circuit a resistance equal to twice the valve impedance seems to be a good one. Many of the author's measurements have been made under varying conditions of input and output, so that it is necessary in some cases to take input and output characteristics of the detector valve in order to interpret the measurements for constant input or constant output. I should like to suggest that, when specifying the performance of a receiver, all tests should be taken at a constant output power, and not necessarily with constant grid voltage on the power valve. The standards laid down by the Institute of Radio Engineers of America state that the measurements shall be made with a constant output of 50 milliwatts into an appropriate impedance. The sensitivity of the receiver is then expressed as the input signal which will give this constant output. A fixed percentage modulation of 400 cycles (40 per cent) is used for the purpose, while the input signal is usually expressed in terms of the field intensity in microvolts per metre, assuming a 4-metre aerial. In selectivity measurements the same principle of constant output might be employed in defining a standard test. The selectivity would then be measured by detuning the receiver by a certain amount and then increasing the input signal until the standard output had been obtained. The selectivity could then be expressed in terms of the detuning necessary when the input signal had been increased 10 or 100 times, for example. I am strongly in favour of the standardization of some form of test specification of the type suggested on page 489. I should like to ask the author how he has disposed of the difficulties to be met with in making measurements on a receiver which is close to oscillation. I suggest that it is almost impossible to measure, for instance, the selectivity of a receiver when the reaction is closely approaching its critical value. It may, therefore, be necessary to agree that such measurements should be made with the reaction adjusted to give, say, half the maximum attainable sensitivity.

Mr. T. H. Kinman: The measurements obtained on the higher frequencies are of particular interest to me and I should like to ask whether the inductive reactance of the input resistance, which is, of course, common to both filter circuit and input circuit of the receiver under test, was sufficient to cause interaction between these circuits when tuned to 10 megacycles and above. Such interaction would give rise to a variable reading on the input thermal meter "Q," Fig. 5. The author questions the value of the triode as a high-frequency amplifier for these higher frequencies. Has he made any measurements using a screen-grid valve for this purpose? My experience has been that with this type of valve not only is there a very useful high-frequency gain, but the tuning operation is, if anything, simpler, owing to the more uniform and less critical reaction adjustment required. No mention regarding the design of the thermo-couple is made in the paper, except that it was of the non-contact type. A thermo-couple designed for high-frequency measurements has been developed in America. It is assembled in such a way that the shunting capacity between its extremities is negligible. When dealing with very high frequencies, the usual construction is unsuitable owing to the shunting capacity across the pinch through which all the wires are usually brought out to base terminals.

Mr. A. G. Warren: I have encountered some difficulty in attempting to deduce Fig. 11 from Figs. 6, 7, 8, 9, and 10, arising from the fact that the conditions under which Fig. 9 was obtained are not given. The paper would be improved if these particulars were inserted.

In connection with the voltage measurement, can it be assumed that the voltage applied is equal to the product of the measured current and the resistance? Although this is usually the case, it may be incorrect when low-loss tuning coils are employed. I cannot agree that the three characteristics given on pages 488 and 489 for specifying the performance of receivers supply all the necessary information. The first deals with sensitivity which, in broadcast receivers, is not important as the signals received are usually strong. With regard to the third characteristic, which is of great importance, I would re-write the closing phrase in this way: "This gives the frequency-correcting possibilities of the audio-frequency stages." As has been already remarked, the set has to be designed with the loud-speaker, and even the best loud-speakers call for correction by adjustment of the audio-frequency characteristics of the set. A listener requires that his receiver shall be able to discriminate at all intensities between wood-wind and strings, and that the tone of a piano shall be correctly reproduced. These conditions are not, in my opinion, included in the three characteristics. The first condition may be put into a practical form as the measurement of the second harmonic at a standard modulation of, say, 50 per cent. With the parabolic rectification which the author shows, the second harmonic might be rather distressing. I cannot, without further consideration, suggest a test appropriate to my second condition, but doubtless a means of estimating the response of the set to transients could be devised.

Mr. M. G. Scroggie: The author describes in detail his screened cabin for the oscillator, and then goes on to state: "The amplifier, too, must be housed in a screened room to prevent induction from external sources." Surely the oscillator is an external source and therefore need not be screened, provided that the screening of the amplifier is satisfactory. It is common practice in America to have only one screened compartment in apparatus for measuring the overall performance of receivers. The oscillator is just outside the screened compartment containing the amplifier, and cannot affect the latter except through the chosen channel. In production tests it is found possible in a number of cases to dispense even with the screening of the amplifier. This can be effected by doubling the frequency of the oscillator so as to produce sufficient difference in tuning between the amplifier and the oscillator to prevent direct action between them. Although used only for comparatively inaccurate tests, the method should be valuable because, as Mr. Turner mentioned, the apparatus shown by the author is rather difficult to operate. It differs from accepted American practice in the method of measuring the high-frequency input to the amplifier. Rather than to measure directly the small current applied through the resistance might it not be more convenient to use a less delicate current-indicating instrument followed by a calibrated attenuator? The method of measuring the output, which necessitates a separate calibration of the power stage in each case, seems to me to be unsatisfactory. In my opinion a suitable type of valve voltmeter presents no difficulty when used in an audio-frequency circuit. The difficulty of defining critical retroaction seems to be the one outstanding problem in this class of measurement. In America the standard broadcast receiver uses no intentional reaction and is usually incapable of oscillation, so that the difficulty does not arise to the same extent. In broadcast practice, at any rate, the difficulty will probably disappear from this country also, owing to the tendency to abolish intentional reaction. It is unfortunate that some receivers of more modern design were not included as examples. The standard practice, at any rate in broadcast apparatus, is to use screen-grid valves. These would show a far closer approximation to the amplification one would expect and would give, with ordinary components, a stage amplification of the order of at least 30 to 40 on the usual broadcast wave-band. The effect shown in Fig. 11, where the amplification increases rapidly at the high-frequency end, which effect is clearly due to unintentional feed-back, would not occur to anything like the same extent under the conditions of standard broadcast practice. The curve in Fig. 8 does, however, show up in exaggerated form the effect which is obtained even with screened-valve amplifiers, owing to the use of tuning circuits in which the capacity is variable and the inductance is fixed. If a curve of amplification against frequency is drawn, either for the threshold of instability or for constant stability, it will fall towards the high-frequency end owing to the greater admittance of the anode-grid capacity of the valve, as indicated in Fig. 8. It is desirable for the tuning characteristics to be such that the actual amplification curve is one of constant stability and therefore parallel to the threshold curve and on the lower side of it. This is obtained if both capacity and inductance are varied in a definite relationship, but a very good approximation to this ideal is obtained if the capacity is fixed. The amplification curve in the case of a variable-capacity tuning circuit cuts across the ideal curve almost at right angles. The result is that the amplifier tends to be too unstable at the high-frequency end and too "dead" at low frequencies. One advantage of a screened-valve amplifier is that the constant-stability curve is far more horizontal than that, for example, of Fig. 8.

Mr. J. H. Reyner (*communicated*): It is clear from an examination of the paper that a great deal of time and trouble have been involved in the preparation of the apparatus described. The author dismisses in a few words difficulties which must have taken weeks to overcome, and those conversant with methods of testing receivers must feel some disappointment that these difficulties have not been dealt with more fully. Previous speakers have commented upon the fact that the apparatus is of a precise nature and unsuitable for commercial use, although much of the data will be of value in the preparation of simpler equipment. It will be interesting to have the author's views on the possibility of producing a less complicated apparatus. I have been experimenting for some time with the production of small modulated high-frequency voltages which can be introduced into a receiver for the purpose of checking the performance. The voltage has been introduced into a dummy aerial or directly induced in the frame aerial of the receiver, according to circumstances. This is the American practice and does not involve any alteration to the receiver itself. It has been found possible with a small apparatus some 2 ft. long, doubly screened, to produce and control voltages as small as 0·1 millivolt, which corresponds to a signal strength of 0·025 millivolt per metre, assuming a 4-metre aerial. This value of signal strength is distinctly smaller than that of the customary foreign stations which may be tuned in on any good modern set. It should be added that the experiments have been concerned mainly with frequencies below 1 500 kilocycles per sec., but some work has been done on much higher frequencies, with fair success. The most difficult part has been the production and calibration of a suitable method of coupling the receiver to the oscillator. The method which appears to be most satisfactory is an inductively coupled system which is calibrated by direct measurement, using a primary current many times larger than that employed in practice. This involves the assumption that the mutual inductance remains the same for small currents, which seems a reasonable supposition. The author condemns the inductively coupled method early in the paper, but it would appear to be the only practical method for a commercial testing equipment, since in order to obtain voltages as low as 0·1 millivolt by the voltage-drop system described in the paper the current would have to be too small to be measurable on any commercial instrument. An alternative method is the use of an attenuator, as mentioned by Mr. Scroggie. In this connection the Standardization Report for 1928 of the Institute of Radio Engineers is of considerable interest. Regarding the proposed specifications mentioned in Section (3), there can be no doubt that some such characteristic should be measured definitely on receiving equipment in order to obtain figures of merit. There is, however, a fourth characteristic about which we seem to know very little. This concerns the question of proportionality of input and output strengths. If the modulation of the incoming signal is increased by a certain amount, the low-frequency output should increase in strict proportionality, which it does not do in the majority of present-day receivers. The question is entirely separate from considerations of frequency distortion and is responsible for the poor behaviour of the average reproducing system on such instruments as the piano and similar instruments having a high percentage of transients. Mr. Warren has referred to this defect, but I believe that the root cause of the unsatisfactory reproduction is not well known. My experiments for some time past have all pointed to the lack of truly proportional amplification on differing strengths of signal as the fundamental defect. The greatest difficulty in the way of all such measurements arises from the use of reaction, which is still very popular in this country and is likely to remain so for many years. Not only does this affect the first of the proposed standard tests, but the second and third are also bound up with the amount of regeneration employed, while Mr. Turner has pointed out the extreme difficulty of defining the oscillation point. The attitude which I have continually encountered in discussions on receiver-testing is that while the performance of the receiver is dependent to such an extent upon the adjustment of the reaction control, any definite measurements are of academic interest only, and this point of view is difficult to combat. In America, simple modulated high-frequency oscillators are used as a matter of course by all concerns of any magnitude in the design, production and testing of their receivers. The technical public is, in consequence, educated to the idea and some real progress is being made in the matter. It would appear that the best method of procedure in this country is for the manufacturers themselves to commence forthwith to make receiver tests on the lines suggested in the paper. They will encounter difficulties peculiar to our own conditions and will doubtless devise their own methods of overcoming them. In due time, the industry as a whole will acquire the measurement habit which involves thinking and speaking in terms of definite data. If the present paper is responsible for development of this nature, the author will have rendered the industry a valuable service.

Mr. H. A. Thomas (*in reply*): With reference to Dr. Hollingworth's remarks, I would point out that many apparent defects in the final apparatus are due to the successive processes of rebuilding, modification and improvement which the equipment has undergone from time to time as points once considered essential have turned out to be of little account, whereas other details have been found to be all-important. All original apparatus is built in this way and, when in its final form, it is usually found that a great simplification can be made. If the apparatus were to be rebuilt it would take a quite different form as a result of the experience obtained with the original model. The input resistances have values which are not very accurately progressive, this being due to the difficulty of obtaining accurate lengths of the small-gauge resistance wire. The difficulties encountered in connection with the instruments were considerable and, since the range obtained by the first set of resistances was found to be sufficient for the purposes in hand, no modifications were made. Although it would be possible to simplify the design of these resistances, it must be remembered that accurate centring of the wire and adequate insulating and screening of the tapping lead involve rather a delicate construction. Comment is made regarding the effect of the valve voltmeter as a load on the output circuit, and I am glad that Dr. Hollingworth appreciates the effects which can be produced by such small loads when successively passed through the earlier stages of the amplifier. I have found that the value of K remains sensibly constant for the dull-emitter, low-amplification-factor, low-resistance valves that have been used. Undoubtedly the setting of the retroaction control to give critical reaction is delicate and the difficulty of reproducing conditions considerable, but with great care it was found that these critical reaction figures could be repeated to within 5 per cent in most cases.

In reply to Mr. Turner's remarks, I would point out that telephonic communication is maintained between the two cabins by means of screened leads which traverse a filter circuit of such design that no appreciable radio-frequency current passes along the line. Iron was used as the screening metal because of its superiority over copper. I would refer Mr. Turner to a paper by Dr. Smith-Rose * in which it is shown that the penetration of the eddy currents into the conductor is governed by the well-known "skin-effect" formula; the latter therefore determines the fraction of the original magnetic field which penetrates to any depth into the conductor. The decay factor governing the amplitude of the radio-frequency current at a depth x below the surface of the metal is $\epsilon^{-2\pi\sqrt{[(\mu f/\rho)x]}}$, where μ and ρ are respectively the permeability and resistivity of the metal, and f is the frequency of the alternations. Using this formula, the reduction in the field strength can be calculated for a screen of any given thickness and it can easily be shown that at medium radio-frequencies iron is 5·5 times more effective than copper if its thickness is the same. It is also clear that the screening effect is greatest at very high frequencies and that at audio frequencies effective screening becomes increasingly difficult. The load imposed by the valve voltmeter is not large if the last stage only is considered, but the effect of a small load may be serious when this load reacts back through the earlier stages of the amplifier. These were the conditions which were obtained in Fig. 4, and in view of the results it was considered expedient to use the voltmeter in the manner finally adopted. The figure for modulation (taken as 15 per cent) is an average value for good telephony transmission. Admittedly the figure is often greatly exceeded, but this fact does not invalidate the contention that 15 per cent is considered to be sound practice. In any case, the results with a greater percentage of modulation can be readily deduced from the curves given in the paper, since proportionality was found to exist up to a modulation percentage of 60. Mr. Turner criticizes my method of measuring the output and suggests that the properties of the amplifier should be determined with a resistance load, from which the actual properties with a loud-speaker can be estimated by "a simple calculation." I disagree with this—a view which is only too common. If the performance is determined with such a resistance load the input impedance of the last stage is greatly modified, and this impedance reacts back successively through each stage to the input. The effect on the early stages may be very considerable, especially if these stages have a high voltage-factor, and the calculation of the performance with an inductive load instead of a resistance load is far from simple. Again, the loud-speaker impedance is a very complex quantity involving a variable static and dynamic resistance and a static and dynamic reactance at different frequencies. In view of this fact it is essential that the receiver be measured under the actual conditions of use and I have laid great stress upon this point in the paper. Mr. Turner will see that I calibrate the last stage by applying to the grid an audio-frequency e.m.f. of the same frequency as the modulation, and obtain readings on the valve voltmeter. The 100-ohm shunt of the latter produces a negligible series modifying effect, and by this method the actual load is always in circuit. I agree that it would be an advantage to have a definite figure of amplification for the amplifier irrespective of the load, but this cannot be obtained, since every change in load affects the amplification characteristic. I must apologize for an error in drawing Fig. 6. The screened input-resistance is always used on the earthed side. My reply to Dr. Hollingworth covers the next portion of Mr. Turner's remarks on critical retroaction. A maximum figure was felt to be necessary and, as previously stated, it was found possible to obtain this with sufficient accuracy for most purposes.

---

* R. L. Smith-Rose: "On the Electromagnetic Screening of a Triode Oscillator," *Proceedings of the Physical Society of London*, 1922, vol. 34, p. 127.

My reply to Mr. Turner covers the first part of Mr. Brown's comments. I cannot see that any advantage is to be gained by substituting a power relationship. It appears to me that an amplifier is essentially a voltage device and that, having obtained the voltage on the power-valve grid, it is easily possible to obtain the output power if the last stage is considered to be a power relay and the input is regarded as a controlling voltage. The American tests give selectivity characteristics in terms of the input signal at the various radio frequencies necessary to provide a constant output; these characteristics have the appearance of an inverted resonance-curve. Either method of expressing selectivity is permissible, but I do not see that much is to be gained by departing from well-established practice in this matter. The appearance of these characteristics is puzzling at first. The suggestion that the reaction should be so set that the amplification is one-half of the maximum attainable is interesting, but does this not involve a previous determination of the maximum value?

With reference to Mr. Kinman's remarks, the reactance of the input resistance was always so small that its effect was negligible up to a frequency of 10 000 kilocycles per sec., and at 20 000 kilocycles it only added about 5 per cent to the net impedance of the input resistance. The tests were performed before the screen-grid valve was manufactured commercially, and consequently the remarks made in the paper are not meant to apply to such valve circuits. The thermo-junction used was of a well-known standard commercial type. It is interesting to note that recent work by Mr. F. M. Colebrook at the National Physical Laboratory has confirmed the fact that this type of junction is suitable for current measurement up to frequencies of the order of 10 000 kilocycles per sec., with an error not exceeding a few per cent.

I must thank Mr. Warren for pointing out the absence of sufficient information in Fig. 9. I have inserted the necessary information for the *Journal*. The point raised regarding the value of the voltage inserted in the tuned circuit is important. I agree that if the tuned circuit has a very low resistance it will exert an appreciable shunting effect upon the input resistance. In the tests described, however, the magnitude of this effect was never in excess of 7 per cent. In the case of critical reaction the shunting effect may be serious, but difficulty arises as to the determination of the effective resistance of the input tuned-circuit. I agree with Mr. Warren that a test of the response of the audio-frequency portion of the amplifier to transients would be very valuable, but the technique of this problem is not at present available. The response to a sudden applied signal, such as a square wave-shape, would be an indication of the effects which would be produced if a transient were applied.

Mr. Scroggie refers to the use of two cabins: it would be possible to dispense with one of them in a reconstruction of the apparatus, but the remaining small cabin, which at present contains the permanent oscillators, would have to house the receiver—and the latter could not be erected in such a confined space without radical alterations in the construction of the cabin. It must be remembered that the apparatus described has been produced by repeated modifications and the final arrangement is, admittedly, not perfect. I do not agree that a larger current and an attenuator are preferable to the method described. In the first place, it is not true that the accuracy of measurement of a large radio-frequency current is superior to that of a small current. As has already been stated, recent work by Mr. Colebrook has shown that the small current measurements given by vacuum junctions are reliable to a few per cent up to very high frequencies of the order of 10^7 cycles per sec., and, even if attenuators were accurate, I see no necessity for using them if the ideally simple screened resistance can be employed. Again, the impedance of the secondary of the attenuator introduces an impedance into the input tuned circuit which must be allowed for, and the screening needs to be more elaborate in the case of the larger current.

In reply to Mr. Reyner, I fear that a detailed statement of all the difficulties encountered would make the paper unduly long and would make rather tedious reading. As I have already pointed out, the apparatus could undoubtedly be materially simplified if there were a demand for such a complete reconstruction. I do not think there is any great difficulty in obtaining an input of 0·1 mV by means of a screened resistance. H. D. Oakley * uses this method with satisfactory results. With reference to Mr. Reyner's concluding remarks, I hope that the manufacturers of this country will adopt statements of a more scientific nature regarding the performance of their receivers than they have done hitherto. The object of the paper is mainly to indicate the lines along which development in this direction should take place.

---

ADDRESS TO THE SHEFFIELD SUB-CENTRE

By Colonel Sir Thomas F. Purves, O.B.E., President.

(*Address delivered at* Sheffield *19th February*, 1930.)

In seeking for a suitable subject on which I might address you, I experienced a kind of *embarras de richesses*. The field of interest of our Institution is a very wide one, for within its ranks the Institution includes engineers dealing with practically all the multifarious uses to which electricity is applied in the service of man. Since, however, I am to some extent a representative of communications engineering, whilst many in this audience are representative of the heavy-current engineering activities of the great industrial areas of the Midlands, I have thought it well to address myself to what we may call the meeting point of these two branches of electrical engineering and to the problems which arise from their co-existence side by side.

It can be said that practically every application of electricity to a special purpose derives some of its success from the work of all the other branches of the art. On the other hand, there are characteristics associated with some applications of electricity to the purposes of industry which can, or may, be harmful to work in other branches providing equally important public services.

The first successful applications of electricity to the every-day practical needs of the community were concerned with communications, and as the use of stronger currents for lighting, power and traction purposes developed, it speedily became evident that difficulty would be experienced in preventing the latter from paralysing the activities of its elder, but weaker, brother.

Efforts to devise means of safeguarding the existing and essential art of electrical communication have been reflected in various Acts of Parliament, and much has been written of the so-called conflict between the "weak current" and "strong current" interests in the past. Solutions have now been found of many difficulties which appeared to be almost insurmountable in the early days, but the urgent public need for the increase of both power and communications services continuously presents new difficulties in more and more acute forms, and the subject is still of great interest and importance. I propose therefore to devote a little time this evening to dealing with recent developments, and more particularly with the efforts now being made to solve the outstanding problems by the co-operation of all the parties concerned.

Many of you know that there has now existed for some years an international organization called the "Comité Consultatif International des Communications Téléphoniques à Grande Distance," fortunately capable of being referred to in brief as the "C.C.I." This organization was inaugurated for the purpose of solving technical problems in connection with long-distance telephonic transmission and for the standardization, as far as possible, of line transmission plant, apparatus, and methods of exploitation. The C.C.I. consisted at first of representatives of the various telephone administrations of Europe, but more recently the field of membership has been extended and made practically world-wide.

An important special matter which has been the subject of continuous study by the International Committee is the protection of communication lines against interference set up by power circuits in their vicinity. Such interference may take the shape of electrolytic damage to the lead sheathings of cables by leakage currents from traction systems, of inductive interference with communications, or of direct injury to plant or personnel by contact with high-voltage lines. The questions of electrolytic damage and inductive interference have hitherto been given most consideration, and in arriving at its conclusions the C.C.I. has had the advantage of co-operation with representatives of the power side of the industry through certain international bodies, including the Union Internationale des Chemins de Fer (International Union of Railways), the Conference Internationale des Grands Reseaux Electriques à Haute Tension (International Conference on High-Tension Electrical Lines), the Union Internationale des Producteurs et Distributeurs d'Energie Electrique (International Union of Producers and Distributors of Electricity), and the Union Internationale de Tramways et Chemins de Fer d'Interet Local (International Union of Tramways and Local Railways).

The " Recommendations " issued by the C.C.I. in connection with the protection of cables against corrosion due to electrolytic action follow Continental practice in that the " isolation " system is favoured, in preference to the system of " electrical drainage " or the connection of cable sheaths and pipes with the negative return or busbar. At the moment there is a decided difference of opinion among engineers as to the best way of tackling the universal problem of protection against electrolysis set up by stray currents from tramway systems.

One school advocates the " isolation " system and the other " drainage." In Switzerland, Germany and other Continental countries the connection of cable sheaths or pipes to the uninsulated rails or negative busbar of a tramway system is forbidden, whilst in America such connections are common practice.

In this country the position is somewhat peculiar. Although the Regulations of the Ministry of Transport appear to aim at an isolated system—except that the negative busbar or the points of connection of negative feeders to the rails have to be earthed—the practice of connecting the sheathings of their cables to the rails and/or to the negative busbar has grown up amongst tramway undertakers.

The " drainage " school claim that their method tends to ensure immunity from electrolytic action by stray currents, whilst the advocates of " isolation " say that drainage systems extend the danger area and thus jeopardize, or increase the danger to, the cables and pipes of other users of the soil. It should be observed that the Advisory Committee on Railway Electrification appointed by the Ministry of Transport, advised isolation for electric railways in this country.

So far as a telephone administration is concerned, the isolation system has much to commend it. At all events it is clear that the connection of cable sheathings to rails and negative returns should only be made after careful electrolytic surveys have been carried out in order to determine the proper positions for the connections, and that, when the connections have been installed, there should be continuous control and supervision to ascertain whether plant extensions and developments may have made it essential to alter the positions of the drainage connections.

Apart from the question as to which method of providing protection is the more effective, it is clear that the " isolation " system places the responsibility for maintaining satisfactory stray-current conditions upon the traction authority, whilst the " drainage " system shifts the responsibility to the shoulders of the cable or pipe owner, who is burdened with additional and recurring expenditure for maintenance and supervision of drainage connections.

In connection with the inductive interference problem the C.C.I. has issued *Directives* (guiding principles) which indicate the best practice to be followed by the electric power industry and by the telephone administrations in order to minimize trouble. Current and voltage waveshape, tooth ripples, harmonics and methods of protectively balancing the telephone lines, are all dealt with. Tolerable limits of induced voltages, etc., are defined and methods are specified for the predetermination of the induced voltages which will be set up under given conditions by all the usual types of power installations.

Whilst the *Directives* cover the subject so far as up-to-date experience and research have taken us, there are many outstanding questions which require further investigation, and arising out of this an international body has been set up to carry out research into problems that jointly concern the power and communication interests. This offshoot of the C.C.I. is called the " Commission Mixte International " (C.M.I.). It is composed of representatives of the C.C.I. and of the international bodies I have already referred to.

Responsibility for necessary investigations has been distributed between the various European telephone administrations and the power interests, and a programme of work has been drawn up. At the last meeting of the C.M.I. it was decided to extend the programme to include the protection of pipes and cables against electrolytic and chemical action, and to enlarge the membership to embrace the gas and water industries, who are equally concerned with this problem. Further, it was decided to include a class of " associate members " in the organization, as it was evident that a very large proportion of the electrical industry is not represented by the international bodies now acting.

The problem of adequate representation of the electric light and power industry of Great Britain, both in connection with the work of the C.C.I. and the C.M.I., has been a matter of considerable concern to me, since the international associations mentioned do not appear to receive any considerable degree of support from this country. The formation of the associate membership class of the C.M.I. appears to afford a way out of the difficulty. The Institution of Electrical Engineers has itself joined as an associate member.

The outstanding problem at the moment in connection with inductive interference is concerned not with "disturbance," but with "dangerous" induced effects. The great increase in the use of electrical energy for power and traction purposes, and the transmission of such power by means of overhead lines working at very high voltages, has brought about conditions which may endanger not only telegraph and telephone plant and apparatus but also the engineering and operating staff, and the members of the public using the communications circuits, even when there is no direct contact between the two sets of plant.

These dangerous effects are produced inductively and, ignoring traction systems, take place only on the occurrence of faults or in some cases during switching operations on the power systems. The telephone plant may be damaged by the breaking down of insulation of apparatus or lines, and in severe cases by the outbreak of fire.

In the matter of danger to staff, the lives of personnel may be jeopardized by shock; for example, a man may be caused to lose his hold when in a hazardous position on a pole, or, if very severe, death or permanent injury may be caused by the passage of the induced current through his body.

Further, and this is much the more common, operators and telephone users may be adversely affected by "acoustic shock." Serious acoustic shock is caused when voltages sufficient to operate the lightning protectors (about 350 V) are induced in the two wires of the telephone circuit. When this occurs it is certain that the lightning protectors, one of which is in each leg of the circuit, will not act simultaneously, and the consequence is that the charge passes through the operator's set, and the diaphragm of the telephone receiver is brought into violent contact with the pole-pieces. The ear may be damaged and, even if it is not, frequent disturbance of this kind adversely affects the nerves of the person listening, and in the case of telephone operators may cause such loss of *moral* that continued work is impossible. In such countries as Germany and America where power systems are highly developed, the amount of trouble caused in this way has been very serious.

It should be observed that "acoustic shock" appears to be chiefly associated with the operations of 3-phase systems employing an unearthed neutral point, as with this type of system "arcing earths" may be set up by the failure of an insulator, and these may persist without the circuit breakers coming into action. The unearthed neutral system has, however, an advantage over the earthed neutral in that it is not necessary with the former to arrange for such great separating distances in cases where the power lines run parallel with communication circuits.

With the earthed neutral system, which is the common practice in this country, the occurrence of a fault to earth, on any phase, results in the passage of a considerable current between the fault and the earthed neutral point. This current, passing through the faulty phase and earth, acts by electromagnetic induction on neighbouring communications circuits and may produce very dangerous effects. The intensity depends upon the strength of the fault current to earth, the separating distance between the power line and the communication circuit, and the length of parallelism.

This problem is of first-rate importance at the moment in connection with the installation of the "grid" by the Central Electricity Board, which, as you are aware, is to be operated at 132 kV with the neutral point directly connected to earth at all feeding points.

The Post Office has adopted the figure of 300 volts, given by the *Directives* as the maximum longitudinal voltage that can be allowed in a communication circuit on the occurrence of a fault to earth. The calculation to determine whether under any given condition this voltage will be exceeded is a matter of great difficulty. Formulæ for the calculation of the coefficient of mutual induction have been developed by Breisig, Rüdenberg, Pollaczek and Carson. These formulæ agree with experimental results in certain circumstances, but none of them can be said fully to meet the general case. Further, in applying the formulæ one of the principal factors, the specific resistance of the earth, is difficult to determine, since the earth is not homogeneous and in any case the measurement is a difficult one. In the first instance the C.C.I. recommended that the Rüdenberg formulæ should be used, with an assumed value of 20 000 ohms per cm^3 as the resistivity of the earth.

Subsequent to this recommendation a number of investigations were carried out in Germany, and also in this country, which go to show that the formula of Pollaczek gives results more in agreement with those obtained by actual tests, and, further, that 20 000 ohms per cm^3 is too high a figure for general use. On the other hand, investigations in Sweden show that the earth resistivity of 20 000 ohms is exceeded in some parts of that country. It should be observed that the higher the specific resistance of the soil the greater will be the induced voltage.

The investigations in this country were carried out in co-operation with the Central Electricity Board, utilizing for the purpose the British Electrical and Allied Industries Research Association, and as a result it has been agreed that Pollaczek's formula shall be employed when calculating the probable inductive effects on the occurrence of earth faults on the Board's 132 000-V overhead lines. The resistivity of the earth will, in general, be assumed to be 4 700 ohms, in accordance with a modification of the *Directives* adapted at the plenary meeting of the C.C.I. held in Berlin in June last.

It is stipulated, however, that where power lines are projected in neighbourhoods where it is known that the geological conditions point to higher resistances of the soil, tests will be made beforehand to ascertain whether a higher figure than 4 700 ohms should be taken.

The calculation of the values of earth fault currents to be expected where an extensive and complicated network is concerned appears to be a matter of some difficulty. Although fault currents to earth as great as 5 000 amperes have been suggested as possible, the engineers of the Central Electricity Board are at the moment somewhat non-committal. To ensure safe conditions for such large currents the power lines and communication circuits would have to be separated by great distances if the routes ran parallel for any considerable distance.

With the existing extensive system of Post Office overhead and underground lines it is a difficult matter to find routes for the " grid " which will avoid parallels with relatively close separation. The design of the Central Electricity Board's " grid system " includes a high-conductivity steel-cored aluminium earth-wire connected to every tower and thereby to earth. It has been proved, both theoretically and by experiment, that a reduction of about 33 per cent in the induced voltage is brought about by this arrangement. Making due allowance for this, however, the position is not free from anxiety, which only satisfactory working experience can remove.

Although this Address is already larger than I had intended, I should like to add a few words about " Crossings of Post Office Lines by the ' Grid ' Transmission Lines."

The construction of the " grid " has confronted the Post Office with a difficult problem as regards the course to be followed in providing satisfactory protection to Post Office lines where they are crossed by the transmission lines.

It has been urged that the factors of safety used in the construction of the " grid " are so liberal that risk of a breakdown which would result in direct contact with Post Office circuits is so small that it might be ignored. The breakage of conductors from various causes which are not covered by factors of safety cannot, however, be ruled out of the range of possibilities, and in view of the consequences of an accidental contact, especially as regards risk to life of Post Office personnel and to users of the telephone system, it is felt that the attitude of the Courts and of the public would be such that the absence of any specific precautions would be condemned in the event of a serious accident.

In the case of subscribers' circuits there is no particular difficulty in following the normal procedure of putting the Post Office circuits underground at the crossing points, but the position as affecting trunk lines gave rise to some concern.

In the past every effort has been made to avoid the degradation of the transmission efficiency of important aerial trunk lines produced by the insertion of short intermediate lengths of underground, and protection has been provided at high-tension crossings either by placing the power line underground or, where this course was not feasible, by the erection of a cradle guard beneath the power line. Neither of these measures is practicable in the case of the " grid," and the alternative of placing the trunk circuits underground at the danger points has had to be accepted.

In deciding on this procedure we were also influenced by apprehension of the disturbance likely to be produced by electrostatic induction where an aerial telephone line is crossed by a 132-kV overhead line. German experience and calculations have indicated that where voltages exceed 100 kV, and there is more than one crossing, excessive noise will be produced in the telephone circuits during normal operation of the power line, with the possibility of acoustic shocks on the occurrence of faults.

It can be taken that an induced difference of potential of 5 mV between the two sides of a telephone circuit will result in excessive noise when the frequency of the induced current is of the order usually produced by power-circuit harmonics.

Unfortunately, the main roads in this country along which telephone trunk lines have been built are on the whole rather tortuous, and consideration of the routing proposed by the Central Electricity Board showed that many important telephone trunk circuits would be crossed several times. The effect on telephone transmission of a number of short underground lengths is serious, but in view of the considerations which I have mentioned it was reluctantly decided that there was no reasonable alternative to burying the Post Office lines at the crossing points.

The placing of trunk telephone circuits underground at crossings is, in practice, being effected by the use of a number of 8-pair, 70 lb. star quad cables appropriate to the size of the overhead route. This cable has a specially low wire-to-wire capacity designed to alleviate somewhat the prejudicial effect of the underground section. The use of a number of small cables, in place of a single cable large enough to carry all the circuits, should tend to limit the possible effect of damage to the underground section in the event of the overhead line suffering from the effects of lightning.

I think it will be obvious to all that the difficulties to which I have briefly referred to-night will necessarily be accentuated as the use of electricity expands and greater and greater amounts of power have to be generated and transmitted over long distances.

No doubt new problems will also arise and, if they do, I trust that they will all be tackled on the lines which I have described, that is, by co-operation between the interested parties. The " Commission Mixte International " is an attempt to provide the machinery for such co-operation. It is perhaps necessary to point out that the C.M.I. is solely concerned with the solving of technical problems and has nothing to do with any legal questions that sometimes, unfortunately, arise out of these matters.

MEASUREMENTS ON LONG TELEPHONE LINES BY THE "OPEN AND CLOSED" METHOD.[*]

By A. Rosen, B.Sc.(Eng.), Ph.D., Associate Member.

(*Paper first received* 30*th August, and in final form* 22*nd November*, 1929.)

SUMMARY.

Simplified approximate formulæ are given for calculating the attenuation, wavelength constant and characteristic impedance from the "open" and "closed" impedances. The limits of error of these expressions are ascertained, and the formulæ are developed directly in terms of the bridge readings. The limitations of the "open and closed" method on long lines are discussed, and the sensitivity of the bridge necessary to obtain a given accuracy in the measurement of attenuation is found.

INTRODUCTION.

The "open and closed" method of determining the attenuation of telephone lines consists of measuring the impedance from one end with the distant end of the line successively open and closed. Generally an alternating-current bridge is employed.

This method is the one commonly used where accuracy is desired, and it has the advantage that the characteristic impedance and wavelength constant (and thus the primary constants of the line) can be determined from the same readings. It has, however, hitherto suffered from the disadvantage that, owing to the system of the calculation adopted, the work became more laborious and the accuracy decreased as the attenuation became greater, and for long lines with an attenuation of 2·0 népers or more it was desirable to use another method, such as the potentiometer arrangement described by Mayer.[†]

It is shown below that the "open and closed" method can be employed for long lines with considerable accuracy and without undue labour in the calculations, by making use of the sum and difference of the "open" and "closed" impedances instead of their ratio, and formulæ are given for obtaining the attenuation and wavelength constants directly from the bridge readings. The corresponding expressions for the characteristic impedance are also given; in this case, as the calculations by the usual method are comparatively short, there is not such a great saving in labour.

Where it is necessary to distinguish between a complex vector and its modulus, a capital letter is employed to denote the complex quantity, and the corresponding small letter is used for the modulus.

FORMULÆ USING RATIO OF IMPEDANCES.

Let Z_f and Z_c be the impedances measured at one end with the distant end respectively open and closed. Then

$$Z_f = Z_0 \coth \gamma l \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$Z_c = Z_0 \tanh \gamma l \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where Z_0 = characteristic impedance,
γ = propagation constant = $\beta + ja$,
β = attenuation constant,
a = wavelength constant, and
l = length.

The usual method of solving these equations to obtain β and a is to divide (2) by (1), in which case

$$\gamma l = \text{arc tanh}\,(\sqrt{Z_c/Z}\,) \quad . \quad . \quad . \quad (3a)$$

If we write $\sqrt{(Z_c/Z_f)} \equiv H \equiv h\underline{/\phi}$

we obtain $\gamma l = \text{arc tanh}\, H = \frac{1}{2}\log_e \dfrac{1+H}{1-H} \quad . \quad . \quad (3b)$

$$\beta l = \tfrac{1}{2}\,\text{arc tanh}\left(\frac{2h\cos\phi}{1+h^2}\right) \quad . \quad . \quad . \quad (4a)$$

$$= \tfrac{1}{4}\log_e \frac{h + (1/h) + 2\cos\phi}{h + (1/h) - 2\cos\phi} \quad . \quad . \quad (4b)$$

$$al = n\pi + \tfrac{1}{2}\,\text{arc tan}\left(\frac{2h\sin\phi}{1-h^2}\right) \quad . \quad . \quad (5)$$

where n is an integer.

Multiplying (1) by (2) we have

$$Z_0 = \sqrt{(Z_f Z_c)} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

It will be seen that as γl becomes large and Z_f approaches Z_c in value, it is necessary to determine H to several significant figures in order to evaluate β and a.

FORMULÆ USING SUM AND DIFFERENCE OF IMPEDANCES.

From equation (3b) we have

$$\gamma l = \tfrac{1}{2}\log_e \frac{\sqrt{Z_f} + \sqrt{Z_c}}{\sqrt{Z_f} - \sqrt{Z_c}}$$

$$= \tfrac{1}{2}\log_e \frac{Z_f + Z_c + 2\sqrt{(Z_f Z_c)}}{Z_f - Z_c}$$

$$= \tfrac{1}{2}\log_e \frac{Z_f + Z_c + 2Z_0}{Z_f - Z_c} \quad . \quad . \quad . \quad . \quad (7)$$

Now as γl becomes large,

$$2Z_0 \rightarrow Z_f + Z_c$$

$$\therefore \gamma l \doteqdot \tfrac{1}{2}\log_e \frac{2(Z_f + Z_c)}{Z_f - Z_c} \text{ very nearly} \quad . \quad (8)$$

Writing $(Z_f + Z_c)/(Z_f - Z_c) \equiv U \equiv u\underline{/\psi}$

we obtain $\beta l \doteqdot \frac{1}{2}\log_e 2u$ very nearly . . . (9)

and $al \doteqdot n\pi + \frac{1}{2}\psi$ very nearly . . . (10)

where n is an integer.

---

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

LIMITATIONS OF SUM AND DIFFERENCE FORMULÆ.

The error involved in the approximation in equations (8), (9) and (10) can be evaluated by deriving equation (8) in another way.

From (1) and (2)

$$\frac{Z_f + Z_c}{Z_f - Z_c} = \frac{\coth \gamma l + \tanh \gamma l}{\coth \gamma l - \tanh \gamma l}$$
$$= \frac{\cosh^2 \gamma l + \sinh^2 \gamma l}{\cosh^2 \gamma l - \sinh^2 \gamma l}$$
$$= \cosh 2\,\gamma l$$

$$\therefore \quad \gamma l = \tfrac{1}{2} \operatorname{arc\,cosh} \frac{Z_f + Z_c}{Z_f - Z_c} = \tfrac{1}{2} \operatorname{arc\,cosh} U \quad . \quad (11)$$

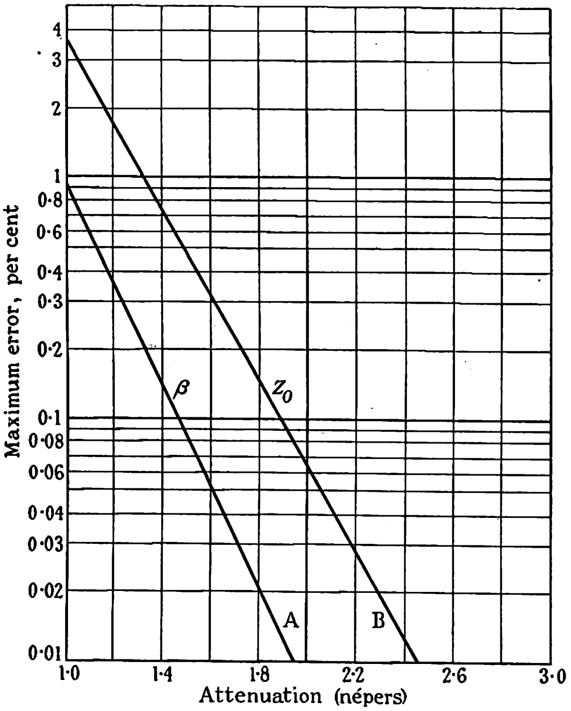

FIG. 1.

Since $U > 1$, we can expand it in the series

$$\operatorname{arc\,cosh} U = \log_e 2U - \tfrac{1}{2} \cdot \tfrac{1}{2}(1/U)^2$$
$$- \tfrac{1}{2} \cdot \tfrac{3}{4} \cdot \tfrac{1}{4}(1/U)^4 - \tfrac{1}{2} \cdot \tfrac{3}{4} \cdot \tfrac{5}{6} \cdot \tfrac{1}{6}(1/U)^6 - \ldots$$

whence

$$\beta l = \tfrac{1}{2}\left(\log_e 2u - \frac{\cos 2\psi}{4u^2} - \frac{3 \cos 4\psi}{32u^4} - \ldots\right) \quad (12)$$

and

$$\alpha l = \tfrac{1}{2}\left(2n\pi + \psi + \frac{\sin 2\psi}{4u^2} + \frac{3 \sin 4\psi}{32u^4} + \ldots\right) \quad (13)$$

When βl is large, the third and subsequent terms in (12) are negligibly small. The magnitude of the second term, $\cos 2\psi/(4u^2)$, varies with the angle ψ, but in any case it can never be greater than $1/(4u^2)$, i.e. the maximum error in equation (9) cannot be greater than $1/(8u^2)$.

Curve A in Fig. 1 shows the maximum error calculated as a percentage of βl for different values of βl. It will be seen that for lines of 1·5 népers equation (9) is correct to 0·1 per cent, and that when βl is 2·0 népers the error is less than 0·01 per cent.

Similarly the error in αl as calculated by equation (10) cannot be greater than $1/(8u^2)$, and as αl is greater than βl the percentage error is even less than that shown in curve A, Fig. 1.

The approximate formula for Z_0 is

$$Z_0 \doteqdot \tfrac{1}{2}(Z_f + Z_c) \text{ very nearly} \quad . \quad . \quad (14)$$

The degree of approximation in this equation may be ascertained as follows:—

From equations (1) and (2)

$$Z_f + Z_c = Z_0(\coth \gamma l + \tanh \gamma l)$$
$$= 2Z_0\left(\frac{e^{2\gamma l} + e^{-2\gamma l}}{e^{2\gamma l} - e^{-2\gamma l}}\right)$$
$$= 2Z_0(1 + e^{-4\gamma l})\,(1 - e^{-4\gamma l})^{-1}$$
$$= 2Z_0(1 + 2e^{-4\gamma l} + 4e^{-8\gamma l} + \ldots) \quad . \quad (15)$$

When γl is large this becomes

$$Z_f + Z_c \doteqdot 2Z_0(1 + 2e^{-4\gamma l})$$

and the error in equation (14), expressed as a ratio, is $2e^{-4\gamma l}$.

The maximum percentage error in Z_0 as given by equation (14) has been calculated for various values of βl, and is shown as curve B in Fig. 1.

FORMULÆ IN TERMS OF BRIDGE READINGS.

Two bridges are in general use for measuring the impedance of telephone lines. In the inductance bridge (Fig. 2*a*), a variable inductometer and resistance in series are employed * and the impedance is obtained in the form $Z = R \pm j\omega L$, where R and L are the readings in ohms and henrys respectively, and $\omega = 2\pi \times$ frequency. Means are provided for reversing the sign of L when the angle is negative.

In the capacity bridge (Fig. 2*b*) a variable condenser and resistance in parallel are used, and the impedance is $Z = R(1 \pm j\omega CR)/(1 + \omega^2 C^2 R^2)$, C and R being the readings in farads and ohms respectively. The corresponding expression in terms of the admittance Y is $Y = G \mp j\omega C$, where $G = 1/R$. When the impedance angle is positive the condenser is connected across the line and C is given a positive sign; when the angle is negative the condenser is placed across the variable resistance and C is given a negative sign. The signs are reversed when dealing with admittances.

(*a*) *Inductance Bridge.*

Let R_f, L_f = readings with the distant end open,
R_c, L_c = readings with the distant end closed

Further, let $R_s \equiv R_f + R_c$
$R_d \equiv R_f - R_c$
$X_s \equiv \omega(L_f + L_c)$
$X_d \equiv \omega(L_f - L_c)$

---

* P. E. ERIKSON and R. A. MACK: *Journal I.E.E.*, 1924, vol. 62, p. 676.

Then $$u\underline{/\psi} = \frac{Z_f + Z_c}{Z_f - Z_c}$$
$$= \frac{R_f + R_c + j\omega(L_f + L_c)}{R_f - R_c + j\omega(L_f - L_c)}$$
$$= \frac{R_s + jX_s}{R_d + jX_d}$$

(i) *Attenuation Constant.*

$$u^2 = \frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}$$

∴ from equation (9),

$$\beta \doteqdot \frac{1}{4l}\log_e 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ népers} \quad . \quad . \quad . \quad (16a)$$

$$\doteqdot \frac{0\cdot57564}{l}\log_{10} 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ népers} \quad . \quad (16b)$$

$$\doteqdot \frac{5}{l}\log_{10} 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ decibels} \quad . \quad . \quad (16c)$$

(*b*) *Capacity Bridge.*

Let $R_f(= 1/G_f)$, C_f be the readings with the distant end open
$R_c(= 1/G_c)$, C_c be the readings with the distant end closed

Further, let
$$R_s \equiv R_f + R_c$$
$$R_d \equiv R_f - R_c$$
$$X_s \equiv \omega R_f R_c(C_f + C_c)$$
$$X_d \equiv \omega R_f R_c(C_f - C_c)$$

Then $$u\underline{/\psi} \equiv (Z_f + Z_c)/(Z_f - Z_c)$$
$$= (Y_c + Y_f)/(Y_c - Y_f)$$
$$= \frac{G_c + G_f - j\omega(C_c + C_f)}{G_c - G_f - j\omega(C_c - C_f)}$$
$$= \frac{R_s - jX_s}{R_d + jX_d}$$

(i) *Attenuation Constant.*

$$u^2 = (R_s^2 + X_s^2)/(R_d^2 + X_d^2)$$

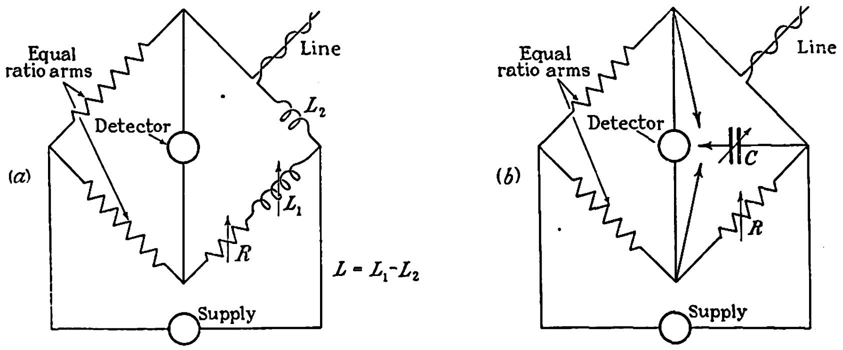

FIG. 2.

(*a*) Inductance bridge; (*b*) Capacity bridge.

(ii) *Wavelength Constant.*

$$\psi = \arctan\frac{X_s}{R_s} - \arctan\frac{X_d}{R_d}$$

Let $\theta_s \equiv \arctan\frac{X_s}{R_s}$ and $\theta_d \equiv \arctan\frac{X_d}{R_d}$

Then from equation (10),

$$a \doteqdot \frac{1}{l}\left\{n\pi + \tfrac{1}{2}(\theta_s - 0_d)\right\} \text{ radians} \quad . \quad . \quad (17)$$

where n is a suitable integer.

(NOTE.—In determining the values of θ_s and θ_d, regard must be paid to the signs of X_s, R_s, X_d and R_d. The quadrant in which the angle lies may be found by considering R_s, R_d as "real" quantities, and X_s, X_d as "imaginary" quantities at right angles to R_s, R_d respectively.)

(iii) *Characteristic Impedance.*

$$Z_0 \doteqdot \tfrac{1}{2}(Z_f + Z_c)$$
$$\doteqdot \tfrac{1}{2}\sqrt{(R_s^2 + X_s^2)}\underline{/\theta_s} \text{ vector ohms} \quad . \quad (18)$$

∴ from equation (9),

$$\beta \doteqdot \frac{1}{4l}\log_e 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ népers} \quad . \quad . \quad (19a)$$

$$\doteqdot \frac{0\cdot57564}{l}\log_{10} 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ népers} \quad (19b)$$

$$\doteqdot \frac{5}{l}\log_{10} 4\left(\frac{R_s^2 + X_s^2}{R_d^2 + X_d^2}\right) \text{ decibels} \quad . \quad . \quad (19c)$$

(ii) *Wavelength Constant.*

$$\psi = -\theta_s - \theta_d$$

where $$\theta_s \equiv \arctan\frac{X_s}{R_s}$$
$$\theta_d \equiv \arctan\frac{X_d}{R_d}$$

Therefore from equation (10),

$$a \doteqdot \frac{1}{l}\left\{n\pi - \tfrac{1}{2}(\theta_s + \theta_d)\right\} \text{ radians} \quad . \quad . \quad (20)$$

where n is a suitable integer.

[NOTE.—The remarks concerning the values of θ_s and θ_d in equation (17) apply also to equation (20).]

(iii) *Characteristic Impedance.*

$$Z_0 = 1/Y_0$$

Now $$Y_f + Y_c = Y_0(\coth \gamma l + \tanh \gamma l)$$

$$\therefore Y_0 \doteqdot \tfrac{1}{2}(Y_f + Y_c)$$

to the same degree of approximation as equation (14), which deals with the corresponding impedances,

i.e. $$Y_0 \doteqdot \tfrac{1}{2}\left\{G_f + C_c - j\omega(C_f + C_c)\right\}$$

$$\doteqdot \frac{R_f + R_c - j\omega R_f R_c (C_f + C_c)}{2R_f R_c}$$

$$\doteqdot (R_s - jX_s)/(2R_f R_c)$$

$$\therefore \quad Z_0 \doteqdot \frac{2R_f R_c}{\sqrt{(R_s^2 + X_s^2)}}\underline{/\theta_s} \text{ vector ohms} \quad . \quad (21)$$

SUMMARY OF FORMULÆ.

For convenience, the formulæ relating to the inductance and capacity bridges are summarized in the following table, which shows the points of resemblance.

<table>
<tr><th></th><th>Inductance bridge</th><th>Capacity bridge</th></tr>
<tr><td>Resistance reading, end free</td><td colspan="2">R_f</td></tr>
<tr><td>Resistance reading, end closed</td><td colspan="2">R_c</td></tr>
<tr><td>Reactance reading, end free</td><td>L_f</td><td>C_f</td></tr>
<tr><td>Reactance reading, end closed</td><td>L_c</td><td>C_c</td></tr>
<tr><td>Derived values R_s</td><td colspan="2">$R_f + R_c$</td></tr>
<tr><td>Derived values R_d</td><td colspan="2">$R_f - R_c$</td></tr>
<tr><td>Derived values X_s</td><td>$\omega(L_f + L_c)$</td><td>$\omega R_f R_c (C_f + C_c)$</td></tr>
<tr><td>Derived values X_d</td><td>$\omega(L_f - L_c)$</td><td>$\omega R_f R_c (C_f - C_c)$</td></tr>
<tr><td>θ_s*</td><td colspan="2">$\text{arc tan}\,\frac{X_s}{R_s}$</td></tr>
<tr><td>θ_d*</td><td colspan="2">$\text{arc tan}\,\frac{X_d}{R_d}$</td></tr>

* See note on page 501 following equation (17).

Example.—Using the capacity bridge at a frequency of 800 cycles per sec., i.e. $\omega = 5\,024$ radians per sec., the readings obtained were:—

$$R_f = 238\cdot 0 \text{ ohms}, \quad C_f = -\,0\cdot 1537\ \mu\text{F},$$
$$R_c = 258\cdot 3 \text{ ohms}, \quad C_c = -\,0\cdot 0765\ \mu\text{F}.$$

Whence $$R_s = 496\cdot 3, \quad R_d = -\,20\cdot 3$$
$$X_s = -\,71\cdot 1, \quad X_d = -\,23\cdot 84$$
$$\theta_s = \overline{\backslash 8^\circ\, 9'}, \quad \theta_d = \underline{/180^\circ + 49^\circ\, 37'}$$
$$\beta l \doteqdot 1\cdot 733_2 \text{ népers}$$
$$al \doteqdot n\pi - 1\cdot 933 \text{ radians}$$

From a knowledge of the approximate values of the capacity C per mile, and the inductance L per mile, and using the well-known formula $a \doteqdot \omega\sqrt{(CL)}$, n was deduced to be 4. We therefore have

$$al \doteqdot 10\cdot 634 \text{ radians.}$$
$$Z_0 \doteqdot 245\cdot 2_6 \overline{\backslash 8^\circ 9'} \text{ vector ohms.}$$

Calculated by the full formulæ, using 7-figure logarithms, the following results were obtained:—

$$\beta l = 1\cdot 733_1 \text{ népers.}$$
$$al = 10\cdot 634 \text{ radians.}$$
$$Z_0 = 245\cdot 2_9 \overline{\backslash 8^\circ\, 2'} \text{ vector ohms.}$$

LIMITATIONS OF THE "OPEN AND CLOSED" METHOD ON LONG LINES.

In any process of measurement it is desirable to know the effect of a given deviation in the readings or in the calculations on the final result. In the case of attenuation of a long line, the simplicity of the formulæ given in terms of the bridge readings makes it easy to calculate the effect of such a deviation.

Let δu be a small change in u, and $\delta(\beta l)$ the corresponding small change in βl.

Then, differentiating equation (9), we have

$$\frac{\delta(\beta l)}{\delta u} \doteqdot \frac{1}{2u}$$

i.e. $$\frac{\delta(\beta l)}{\beta l} \doteqdot \frac{1}{2\beta l}\cdot\frac{\delta u}{u} \quad . \quad . \quad . \quad . \quad (22)$$

Here $\delta u/u$ is a small proportional change in u and $\delta(\beta l)/\beta l$ the resultant proportional change in βl.

Calculation by Slide Rule.—In using a 20-inch slide rule for calculating u, the possible error is, say, 0·1 per cent. Putting $\delta u/u$ in equation (22) equal to 0·1 per cent, we find that when βl is 1·5 the resultant error is 0·033 per cent, and when βl is 2·0 the error is 0·025 per cent. Hence the 20-inch slide rule will give a precision which is probably greater than the exactness of measurement. For the same order of accuracy using the "ratio" formula, computation by 7-figure logarithms would be necessary.

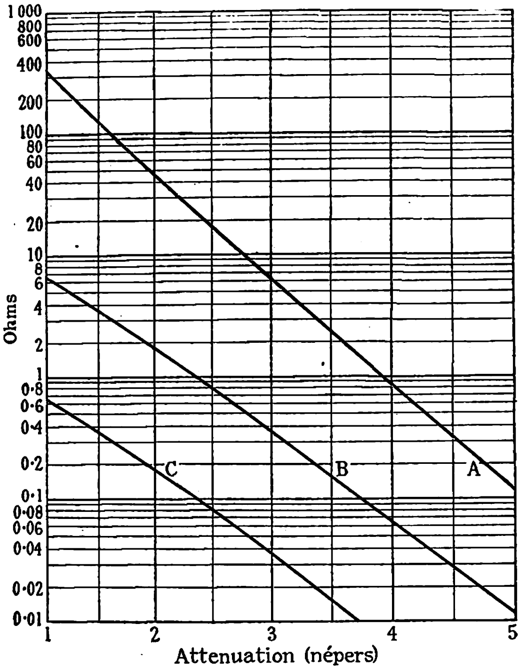

FIG. 3.

A = Difference between "open" and "closed" impedances on 600-ohm line.
B = Bridge sensitivity for 1 per cent accuracy in attenuation on 600-ohm line.
C = Bridge sensitivity for 0·1 per cent accuracy in attenuation on 600-ohm line.

Required Sensitivity of Bridge.—Equation (9) can be written

$$\beta l \doteqdot \tfrac{1}{2}\log_e \frac{4z_0}{z_d} \quad . \quad . \quad . \quad . \quad (23)$$

where z_d is the modulus of the difference between the "open" and the "closed" impedances. It is evident that as the attenuation increases, z_d decreases, and the limit of this method of measurement will be reached when z_d is so small that it cannot be measured with sufficient accuracy. Equation (23) is plotted in Fig. 3, which shows how z_d varies with increase of βl for a line having a characteristic impedance of 600 ohms.

It will also be seen from equation (23) that small errors in the readings will affect z_d much more than z_0. Thus the sensitivity of the bridge necessary to obtain a given accuracy in βl will be determined by the error permissible in measuring z_d. Let this error be δz_d. Then from equation (23) we obtain

$$\delta z_d \doteqdot -8\beta l z_0 e^{-2\beta l}\frac{\delta(\beta l)}{\beta l} \quad . \quad . \quad . \quad (24)$$

In this equation the sensitivity δz_d is expressed in terms of the attenuation, characteristic impedance and accuracy of the final result. Fig. 3 shows the precision required for a 600-ohm line for the two cases in which the limits for the error in βl are 1 per cent and 0·1 per cent respectively.

Effect of Bridge Errors.—For a given value of attenuation, the accuracy with which β can be determined is directly proportional to the exactness with which u can be measured.

The numerator of u is proportional to the characteristic impedance, and in it will appear all the errors due to departures from absolute accuracy of the bridge, such as incorrect calibration and effects of interference and of impedance to earth of bridge components.

The denominator of u is proportional to the difference between the "open" and "closed" readings, and in it the errors due to earth impedance and interference will practically cancel out, as will also those due to incorrect calibration of the coarse adjustments which are not altered between the two sets of readings. Thus the denominator will contain only the errors due to incorrect calibration of the fine adjustments, which are generally small, and those due to insufficient sensitivity of the detector.

The sensitivity can be increased by the use of an amplifier in the detector circuit. As a rule, unless elaborate precautions are taken, an amplifier introduces errors which decrease the absolute accuracy of the bridge. Fortunately, when the attenuation is high and an amplifier is desirable, a lower absolute accuracy is permissible. For example, on a 600-ohm line with an attenuation of 4 népers, to secure a precision of 1 per cent it is necessary to be able to detect an impedance change of the order of 0·1 ohm (see curve B, Fig. 3); the absolute accuracy of the bridge, however, which is given by $\delta u/u$ in equation (22), need not be greater than 8 per cent. Thus the "open and closed" method could be used at carrier frequencies where large attenuations are frequently encountered, although bridge measurements at these frequencies are not of such a high order of absolute accuracy as can be obtained over the audio range.

The author wishes to express his thanks to the management of Messrs. Siemens Brothers and Co., Ltd., for permission to present this paper, and also to Messrs. M. Reed, M.Sc., and E. S. Ritter, Member, for suggesting simpler proofs of some of the equations than those given in the original draft.

DISCUSSION ON

"THE DIESEL ENGINE APPLIED TO RAILWAY TRACTION."

ARGENTINA LOCAL CENTRE, AT BUENOS AYRES, 20TH JUNE AND 15TH JULY, 1929.

Mr. A. C. Kelly: The conditions of suburban passenger service are, as far as the Diesel engine is concerned, much more severe than those of long-distance main-line service, because in the former case high acceleration is necessary, and during starting this involves a very large output in proportion to the output required when the train has reached full speed. In suburban service this large output is required for only a small portion of the time, and the engine is therefore giving alternately maximum output and zero output every few minutes. In main-line working with low rates of acceleration the loading is much more uniform and therefore the conditions for the engine are more favourable. Apart from the fuel economy of the Diesel engine, there is the advantage (of particular importance in the Argentine) that such an engine can work through bad water areas for a long time without requiring a fresh supply of water.

Mr. J. Wilson: Various tests with Diesel-electric motor trains have been made on the Canadian National Railway, and as a consequence that railway has ordered the largest Diesel-electric locomotive in the world, consisting of two units of about 1 300 h.p. each.

Mr. P. C. Saccaggio: Investigations which I made into the subject led me to recommend my company to purchase four different units for trial purposes. These are now being erected in this country, and I shall have more to say about them after the trials have been completed. Whilst I have great faith in the future of the Diesel engine in traction work, I think that much still remains to be done to avoid complication in the engine and in making it so thoroughly reliable that it will be able to run for considerable periods without requiring skilled attention. I consider this feature to be of much more importance than the attainment of the highest fuel economy. I should be content with a moderate fuel economy, provided I could obtain a machine which would give reliable and satisfactory service in the hands of an ordinary driver. I consider that it is not essential to cut down weight to the lowest limit, and I should prefer the speed of the engine not to be excessive; between 700 and 800 r.p.m. is quite sufficient for a 1 000-b.h.p. engine. The cost of such engines is at present excessive, but when the industry is more fully developed and orders for 20 or 30 similar machines can be placed, there will probably be a very substantial reduction in the price. On the question of transmission, I am of the opinion that at the present time electric transmission is the most satisfactory, but that an increase in the dead load or un-springborne load on driving axles is very undesirable. I advocate an arrangement of motor drive without side rods or jack shafts in which the motor load can be entirely spring-borne. Although hydraulic transmission, using oil as the medium, has not hitherto been satisfactory, I believe that difficulties with this type can be surmounted and that possibly water may be used as the medium instead of oil. In conclusion, there would appear to be urgent need for the fullest co-operation between Diesel-engine designers and railway engineers, in order that the many interesting and important problems involved may be solved in the shortest time. When the work which I am now carrying out has been completed I shall be pleased to welcome any members who may wish to visit the works.

[At this point the discussion was adjourned until the 15th July.]

Mr. J. Brunner: For Diesel locomotives the airless injection type of engine is the only one to be considered. Mechanical means must therefore be employed to atomize the fuel and admit it to the working cylinder. That early Diesel locomotives were not fully satisfactory can to a large extent be traced to the use of air compressors with all necessary regulating devices for traction conditions. The water radiators on Diesel locomotives must necessarily be compact. This involves higher cooling-water temperatures than are used on stationary Diesel engines. Air compressors working to as high a pressure as 70 atmospheres will not stand this higher cooling temperature. By omitting air compressors the engine is simplified, which is important on a locomotive. It can be said generally that the speed limit is determined not by the combustion or chemical process, but by the physical and dynamic actions and their results, chiefly frictional losses and the quality of materials. The usual basis for comparison is the mean piston speed. My firm have carried out very detailed experiments to determine the permissible mean piston speed for locomotive work up to 12 metres per sec. As a result of these experiments they have decided that the mean piston speed should not exceed 8 metres per sec. It seems unreasonable to the designer that the Diesel engine, the primary part of the locomotive, should be pressed so much to its maximum revolutions and specific output that safety of working suffers, whilst it is not uncommon in railway work to strengthen the rolling stock so as to increase safety. Diesel engines for land and marine work are generally limited to a mean piston speed of about 5 metres per sec., and nobody believes that less reliability is required on a locomotive than on stationary plant. In addition, railway companies, owing to their experience with steam locomotives, expect a high standard of durability. In no other application of the Diesel engine is absolute reliability of starting so important. Economy of fuel and lubricating oil and reduction of noise at stations, particularly covered stations, makes it necessary frequently to shut down the engine. This involves the necessity for making quick, reliable and repeated starts from the driver's cab. Starting by compressed air involves storage of air at high pressure and air compressors working under conditions already described as undesirable. For this and other reasons, which have less importance in Argentina than in cold countries, my firm decided over 10 years ago to adopt electric starting. The current is taken from the storage batteries which supply the auxiliary services. Starting, therefore, is not influenced by high or low temperatures and is easily carried out from the driver's compartment. Further, in the case of electrical transmission the generator is already coupled to the engine and an insignificant change is necessary to convert this to a motor. There should therefore be no hesitation in adopting electrical starting. The Diesel engine, which must be considered as the most economical heat engine to-day, is, from its nature, not without difficulties when applied to locomotive work. The combination of chemical and physical processes in one machine provides great advantages as well as disadvantages. For instance, a unit of a given size is able to burn only a definite amount of fuel, independent of the engine revolutions. From this it follows that for a given size of engine and load the torque and revolutions are constant—an overload cannot generally be carried by an internal-combustion engine. If it were a technical possibility to separate the physical and chemical actions without affecting the high thermal efficiency, it would be possible to vary the torque and the number of revolutions independently, and the ideal Diesel engine for traction work would be obtained. Unfortunately this cannot be expected at present. The Diesel locomotive designer must therefore find a way of transmitting the power of the engine to the driving wheel which takes into account the interdependent values, tractive effort and velocity. The algebraic product of these must equal the normal power of the engine. Up to the present, the following transmission systems are known: (*a*) Direct drive to locomotive axle; (*b*) electrical transmission; (*c*) hydraulic transmission; (*d*) toothed variable-speed gear; (*e*) pneumatic transmission; and (*f*) combined internal-combustion and steam engine.

(*a*) *Direct Drive to Locomotive Axle.*—My firm began more than 20 years ago the study of Diesel locomotives, and built in 1910–1913 the first locomotive of 1 000 h.p. for the Prussian State Railways. Thorough tests on both the Swiss and Prussian Railways were carried out during 1913 and 1914 until stopped by the War. In spite of applying to the Diesel engine a system allowing a considerable increase of the torque, its adoption for traction service was not satisfactory, in particular the starting acceleration being insufficient. It is clear from the above that with this transmission the starting of the Diesel engine, and therefore also the train, has to be performed by means of compressed air, which is very disadvantageous. The trials, however, gave valuable indications of the course of future development.

(*b*) *Electrical Transmission.*—As a result of the experience gained with the first locomotive, the Prussian State Railways ordered from my firm in 1913 three 200-h.p. Diesel-electric motor-cars; these were delivered in 1914. The control and flexibility of operation of the electrical transmission was satisfactory in every way. In spite of this, the designers still looked for other means of transmission to avoid the high first cost, which weakened the chances for the development of the Diesel locomotive. In addition, designers were not sufficiently experienced in locomotive requirements to be able to provide against all the difficulties involved. Moreover, steam locomotive engineers were obstinate in their ideas and did not as a rule appreciate the Diesel engine. Under these conditions, new proposals were worked out during 1915–1925.

(*c*) *Hydraulic Transmission.*—My firm were the first to try out hydraulic transmission for Diesel locomotives. In 1920 they constructed, with the aid of the inventor, a special "Lenz" fluid driving gear of 400 h.p. for traction purposes. The trials failed, chiefly through poor regulation, low efficiency and noisy working, so that my firm declined to develop this type, and did not give it further consideration. In the following years, several European makers developed different types of fluid drive for traction purpose. Without exception these all failed for different reasons, so that now neither Diesel engine builders nor railway companies believe in the possibility of using hydraulic transmission. The difference in price between hydraulic and electric transmission is small. Hydraulic transmission has a lower efficiency, and the construction of the locomotive, arrangement of the axles, etc., and the starting of the Diesel engine, cannot be solved in such a simple and reliable way as with Diesel-electric drive.

(*d*) *Toothed Variable-Speed Gear.*—Considering the further development of manufacturing methods for variable-speed gears, the gear manufacturers believed that they could be applied to power transmission in the same way as for motor-cars. This view was strongly supported at first as it seemed to offer higher transmission efficiency. It was soon found, however, that, in comparison with a Diesel-electric locomotive of the same motor output, the geared locomotive was not able to deal as well with the normal motor capacity; in other words the efficiency of transmission was lower. Further, it had not been sufficiently considered that working conditions on a main-line locomotive are very different from those on a motor-car. Toothed gear transmissions can only be considered for small powers up to a maximum of 200 h.p., while to-day locomotives of 2 000 h.p. and over are required. Another objection is that starting with toothed gear transmission is just as unfavourable as with direct drive.

(*e*) *Pneumatic Transmission.*—To this class belong all kinds of transmission effected by means of air, gas or steam. As in hydraulic transmission, the Diesel engine is directly connected to the primary part, the air, gas or steam compressor. The transmitting medium expands in the secondary part, which is constructed like a piston engine in a steam locomotive, and circulates back to the compressor. The character of the tractive effort in this type is similar to that of a common steam locomotive. In Diesel locomotives the power of the engine is constant, and in steam locomotives the boiler output is approximately constant. The different trials of this type of locomotive have so far not given much practical result as the efficiency of this transmission is very low and the price and weight but little less than for electric drive.

(*f*) *Combined Internal-Combustion and Steam Engine.*—Direct drive gives the highest transmission efficiency. It is natural, therefore, that schemes have been worked out to use this advantage, whilst the disadvantage of poor starting torque is compensated by combination with the steam locomotive. In such a case the steam engine would be mainly used for starting the train and on gradients for compensating the reduction of Diesel engine output, owing to the lower number of revolutions. Even when the Diesel engine takes over the whole tractive work, the boiler must be in operative condition, and it would be convenient or even necessary that the steam engine should work with reduced output during that time. For this reason the thermal efficiency of this combination will be low, and for certain districts a very important advantage of the Diesel engine, i.e. that it requires practically no water, will be lost. Both price and weight are higher than for electric drive.

The various auxiliary services on a Diesel locomotive are not without influence on the decision as to the kind of transmission to be employed. For large Diesel locomotives with other than electric drive, the arrangement of the radiators and the drive of their fans would occasion some difficulties to the constructor. The same can be said regarding the air-brake compressor and, to a greater extent, regarding the vacuum pump. Drives other than electric can scarcely be applied to the vacuum pump, as the latter has to work with maximum speed, mainly in the stations for releasing the brakes. For well-known reasons the Diesel engine ought to be shut down whilst the locomotive is at rest in a station. The best arrangement is to connect the vacuum-pump motor to the battery in such a way that the motor can be fed by the exciter as soon as the latter has reached the corresponding voltage. Train heating by means of electrical resistances directly connected to the generator terminals is advantageous and very simple, does not need any attendance, and the efficiency is better than for any other system. With an adequate system of connection the heating current taken from the generator is automatically adjusted to the profile of the line, i.e. with increasing gradient the train speed and consequently the generator voltage have to be reduced, thereby lowering the heating effect proportionally to the square of the voltage variation, and thus the tractive power is increased. It is advantageous to connect the complete lighting of the locomotive, including the headlights, to the starting battery. In order to satisfy the usual condition for low-voltage lamps, the battery is divided accordingly, and it is periodically switched from one section to another. I hope that these remarks have given the members some idea of the development of the Diesel locomotive, together with an idea as to the lines along which designers should work in the future. There is no doubt that the Diesel-electric locomotive with mechanical injection and electrical starting is the most probable type for future requirements. The relatively small increase of price, compared with other systems, should not prejudice the chance of such a locomotive, the main points to be considered being the financial and operation results obtained over a lengthy period. A railway company would agree to a higher first cost for the locomotive material if equivalent advantages could be obtained in traction service. On the other hand, it is the duty of the designer to deliver what is, in his opinion and according to his experience, the most serviceable article. Experiments can so much affect a cause that years of hard work are required to eliminate certain prejudices. It can be said that the Diesel-electric locomotive has passed through its infancy and has proved its vitality. It has also proved, in service over several years, that with a high standard of manufacture and correct treatment its maintenance charges are less than those of the steam locomotive. Closer study of the electrical equipment as regards its rating and co-ordination with the Diesel engine has led to important progress with regard to prices and weights. To-day electrical transmission has an average efficiency of over 80 per cent, with a maximum peak value of 84 per cent. The lubricating-oil consumption of a Diesel-electric locomotive is about equal to that of a steam locomotive, but the fuel consumption in the former case is only about one-fourth to one-fifth of that in the latter.

Mr. Val Stewart: In my view too much publicity has been given to this subject up to the last year or two. It is quite a good thing to record in due course the difficulties in connection with any new development in engineering, but to do so too soon when the way out is not so apparent often results in wrong conclusions being drawn. The difficulties get an exaggerated status and when the solution by research is proved to be simple there is quite frequently an inclination to be sceptical about its achievement which is quite difficult to overcome. However, the best method of overcoming that difficulty is to give actual operating experience and what I have to say bears the seal of main-line operation, amounting in Canada alone to 3 200 000 km. This is particularly gratifying as it is *inter alia* an assurance that Britain has again taken a lead in an important development in railway engineering. I shall now endeavour to give briefly the history of the development of the Beardmore high-speed Diesel engine, my object in going into this particular detail being to show that the parentage of this engine is quite removed from that of other engines in course of development. In 1923 the British Government asked the Beardmore Co. to start the development of a Diesel-type engine for air service, more particularly to assist in the solution of the difficulties of the development of the airship. Of course there were many difficulties to face in arriving at a suitable design where permissible weight was so extremely small for the power necessary, but the development stage was retarded by an almost unlooked-for difficulty. This was the impossibility for many months of obtaining a crankcase casting, which had, of course to be made of an aluminium alloy. The difficulty was a foundry one. Owing to its area and necessarily light scantlings a portion of the case always contained metal that had reverted. This difficulty became so acute and so effectively prevented the proving-out of the remainder of the engine, that I took the patterns into our steel foundry and at the third attempt made a satisfactory case. When the engine was assembled with this case and operated on the test-bed, it soon became apparent that, while much remained to be done to put it in the air, we had something which could be made to apply to commercial work. The speed was reduced, the weight was increased where to do so meant adding to the engine's life, and the mean effective pressure was reduced. This is the essential difference between the Beardmore and all other engines, because while with the Beardmore engine the speed has been reduced, the weight increased and the mean effective pressure brought down, others have been developed from low-speed engines where the reverse has been the case, leading to compromise to obtain results. Now just at the time the developments referred to were in progress, the Canadian National Railways were in much difficulty on account of their finding various branch lines quite uneconomic to operate. Sir Henry Thornton sent to Europe a mission, headed by Mr. Brookes, the chief mechanical engineer of the line, to look into any alternative methods of operating that would solve their problem. They spent their time largely on the Continent and finished in Britain in the autumn of the year, having found nothing. Almost by chance Brookes was told in London of what was going on in Glasgow for the air service and that it was rumoured that we had something that was going to be applied to railways. He took the next train to Glasgow, saw a single-cylinder engine operating on the test-bed, the experimental air engines going through the shops, and our drawings and data on the application to rail traction. In three weeks he sailed to Canada followed by plans of 4- and 8-cylinder engines, and in a couple of months orders came through for seven 4-cylinder and two 8-cylinder engines on the understanding that we should see them through jointly. I think that too much prominence cannot be given to Brookes for the part he has played in the development of the Diesel-electric locomotive. His perception, courage and technical attainments made the practical application of the system possible very much more quickly than could have been the case had it been left in the hands of a manufacturing company to develop. The 4-cylinder engines were fitted into cars with an overall length of 60 ft. and seating capacity for 57 passengers. The cars weighed 45 tons and the engine, which developed 200 h.p. at 750 r.p.m., was quite equal to giving the required operating speed with trailer loads of 30 tons attached. The 8-cylinder engines were fitted to a double articulated coach with an overall length of 102 ft. and seating capacity for 126 passengers. The cars weighed 85 tons and the engine developed 350 h.p. at 750 r.p.m., giving the required train speed when also hauling a trailer of 30 tons weight. The average speed at which these cars were designed to run was 30 m.p.h. On the track both cars were operated comfortably at 60 m.p.h. Started in 1925, they were responsible for the bulk of the 3 200 000 km of operating experience to which I have already referred. By the courtesy of the Canadian Railway organization it is possible for me to give operating results that speak more eloquently than any calculation. The gross excess of income over expenditure on the portion of the line now operated by Diesel-electric locomotives amounted in 1923 to 1·3 cents per mile and in 1924 to 2·1 cents per mile. The Diesels were introduced in the following year but only a small proportion of the total mileage was operated by them. However, the excess of income over expenditure rose to 5·5 cents per mile, in 1926 it rose to 13·4 cents per mile, and in 1927 when over 50 per cent of the total mileage was operated by Diesels the figure had risen to 17·7 cents per mile. The 1928 figures were not to hand before I left England. On these results the Canadian authorities have equipped 10 more trains for their service, but the most important development arising from the success of these relatively small units was their decision to build a main-line locomotive for the express freight traffic. The locomotive was built in Canada and the engines were ordered from Messrs. Beardmore. The total power installed was 2 500 h.p. in two units of 1 250 h.p. each. The engines are of the 12-cylinder V type, the cylinders having a bore of 12 in. and a 12-in. stroke. Their power is developed at a designed speed of 750 r.p.m. On the test-bed both these engines were run for long periods at 900 r.p.m., at which speed they developed 1 500 h.p. with a clear exhaust and almost equal oil consumption. Later, as an experiment, one of them was fitted with a supercharger and developed 1 800 h.p. very satisfactorily. I cannot give you the results of operating the double unit, as they have not reached me, but the trials of the single unit gave the following leading result. Operating a load of 1 950 tons a distance of 400 km, the fuel consumption was 2·94 litres per 1 000 ton-kilometres excluding the weight of the locomotive, and 2·73 litres per 1 000 ton-kilometres including the weight of the locomotive. Speeds were attained up to 60 m.p.h. and the operation of the engine is reported as being most impressive. The engine was governed perfectly at speeds varying between 300 and 900 r.p.m. The fuel oil consumption is about 1/15th by weight of what a good steam locomotive would require. The complete locomotive when loaded weighs 290 tons, of which the Beardmore engine with its under-bed but excluding the electric generator accounts for just over 30 tons. At this point I should like to touch on one or two points that have been raised elsewhere. It is rather strange that when one is pioneering a development in engineering, the majority of one's fellow-craftsmen endeavour to prove that it cannot be done. Only a few years ago people rejected the possibility of the Diesel engine for traction work on the ground that it involved weights that could not be supported by the tracks. Now, having evolved an engine that removes that difficulty, I often hear the objection that the engine is too light. After 4 years' running experience I feel I am entitled to say that the theory that the engine is too light for railway work is disproved. Of all the amendments that have had to be made since the first unit was placed in service, not one of them has been caused by the necessity of increasing scantlings, and each one of them would have had to be made if the engine had been twice the weight. In an engine of this type, that must of necessity be high-speed, there is a positive danger in the inclination, that is perhaps quite natural with the majority of railway engineers, to make what is called a more robust job because they fear that their personnel cannot handle the light proposition. Then there are some who question the wisdom of having the cylinder liner made out of a solid-drawn steel tube. It is held that a cast-iron liner would give greater immunity from mishap in the hands of the operator. I must again refer to experience. There is no record of a mishap due to this cause in all the running that has been done. Six liners had to be replaced on the second 8-cylinder engine sent to Canada owing to these distorting, but on the matter being investigated the liners were found not to be at fault. At the time we had not fully appreciated the necessity of dead-annealing the crank-case casting and sufficient care had not been taken with the annealing of the second case. After it was put into operation it started to creep and this creeping continued until the cylinder centres became altered to such an extent that either a bad break had to occur or the liners had to distort, and fortunately the latter occurred. The incident has given rise to a statement that there has been trouble with these somewhat unorthodox liners. The reason for their adoption is twofold. Firstly, cast iron, even when very specially treated, is not a good material for withstanding shock, while steel in a refined state is the best. Secondly, to get the required strength in iron it is essential to have a relatively thick liner and that is bad from the point of view of getting rid of the heat passing into the cylinder walls. It is the careful arrangement in the Beardmore engine that has been made for heat exchange that, in my opinion, is mainly responsible for the relatively small upkeep charges that are incurred. Any marine superintendent, if asked, will say that what causes him most trouble in Diesel engines is cast-iron liners. Coming to other interesting applications of this system which are operating, pride of place should perhaps be given to the converted electric train on the London, Midland and Scottish Railway. This work is not altogether satisfactory to the Diesel engine, as compromises had to be made where compromises are not advisable. The train consists of a 4-coach unit, the power unit being carried in a new motor bogie. The train is running what is known as a shuttle service between Blackpool and Lytham, a distance of 7½ miles with five stops. Operating costs, while not yet official before I left England, were showing that the service was being run at less than half the cost of steam. The engine of this train fractured its crankshaft at the end of last year, and my company called in Dr. Lancaster to investigate the matter. To show how unsatisfactory it is to work on compromises on a new departure of this kind, I may say that the cause of fracture was traced back to the instability of the under-frame of the power coach. The equipment of the Spanish Pyrenees service from San Sebastian to Pamploma is interesting from the point of view that this line approximates to some of the difficulties to be met with in the hill districts of South America and more particularly on the other side of the Andes. The line is 56½ miles long and, starting at sea-level, rises to an altitude of 2 200 ft. at about 35 miles. The maximum gradient is 3 per cent. The power unit is a 200-h.p. engine and draws the coach in which it is mounted and two trailers, weighing, in all, 67 tons. Three other similar engines have been fitted into rail-cars manufactured by the English Electric Co. for the Venezuelan Railway, and these units are by now starting operation. Two 6-cylinder engines are in course of manufacture for the General Electric Co. and are destined for the Indian State Railways. These engines will be fitted to work as locomotives. An interesting proposition which has been settled subsequent to my departure is a 1 000-h.p. goods locomotive for the London and North Eastern Railway. This was also a job of conversion, the locomotive having first been built for all-electric service. The engine which will be installed in this unit will be an 8-cylinder straight 12-in. bore by 12-in. stroke. The locomotive will weigh 88 tons and is designed to haul 1 100 tons at 25 m.p.h. Although I am a strong advocate of the adoption of the Diesel engine for railway work, I do not wish it to be thought that I hold the opinion that under all circumstances it has advantages over the all-electric system. Where there is a very dense population that has to be moved from the city to a limited radius, and where, at the same time, current can be purchased at a cheap rate, there will always be a case for the all-electric locomotive. It is very often stated that the Diesel-driven locomotive is unsatisfactory as regards acceleration, but this all depends upon what power it is decided to employ. It must not be forgotten, also, that the fuel consumption of the Diesel engine is very good down to about half full load. Even where the all-electric drive might be desirable it is possible, by using a Diesel engine in addition, to cut down the initial outlay very greatly on account of the fact that the sidings, etc., will not have to be equipped, and one can contrive without difficulty to run the express long-distance service all-electrically to the point where it no longer pays and then without loss of time change over to the Diesel-electric set. Largely on account of the initial cost, however, there are relatively few cases to be made for complete electrification, and even then only for quite a small portion of the track mileage. In comparison with the steam engine the Diesel engine will reduce the operation bill by anything from a quarter to a half, depending upon the cost of fuel. These figures are not calculated from test results but are obtained over long periods of operation. I have been privileged to see the calculation of saving to be effected, made by a highly experienced railway engineer; this showed a clear reduction in his fuel bill to one-fifth of the present cost, but in that case fuel was obtainable only at a very high figure. Apart from the saving arising from fuel economy the use of the Diesel engine will result in very large savings due to the abolition of round-houses with their attendant staffs, and much less in the form of spares will have to be carried, all parts being interchangeable and concentrated at one centre. Water troubles, with their attendant cost, will be non-existent, and there will be no necessity to maintain fuel depots or to incur the heavy cost of fuel transport. Fire risks from cinders at large goods termini and docks will be eliminated, and a smaller number of locomotives will be required to operate the line for a given service. In Canada they find that one Diesel-electric car replaces two locomotives.

Mr. D. B. Parsons : During my visit to Europe in

1928, I found that some prominent engineers in Germany were convinced that mechanical transmission with toothed gears was entirely feasible, and more economical than electric transmission. I therefore think that, in spite of the view held by the majority that electrical transmission is the best method available, the possibilities of mechanical transmission should not be lightly dismissed but should be taken into further consideration.

Mr. P. C. Saccaggio : Since the last discussion I have been able to make a trial run with one of the Diesel-electric locomotives under construction for the Buenos Ayres Southern Railway. The unit was a Diesel engine giving 450 h.p. at 900 r.p.m. and 375 h.p. at 700 r.p.m., the speed which was used in the trial, and the total weight of locomotive and train was 160 tons. The outward run of 1 240 km to Cipolletti was made without a stop. Shortly after beginning the return journey, a defect which developed in the exciter made it necessary to run on the battery for some 345 km until Bahia Blanca was reached. With the help of a recharged battery the return journey was completed without assistance. During the outward run of 1 240 km a speed of about 60 km per hour was maintained on the average, a distance of about 105 km being covered at 75 km per hour. The consumption of current was 2 980 kWh, or 2·4 kWh per train-kilometre. The consumption of Diesel fuel of 0·88 specific gravity was 1 114 litres (980 kg). This corresponds to 329 grammes per kWh, 4·94 grammes per ton-kilometre, and 791 grammes per train-kilometre. I consider that a steam locomotive under the same conditions would have consumed at least 6 kg of fuel oil per train-kilometre. In commenting on the mean piston speed for Diesel engines, which, according to Mr. Brunner, should not exceed 8 metres per sec. (1 575 ft. per min.) I should like to point out that it is not uncommon to find steam locomotives working with a piston speed of 1 600 ft. per min. Personally, I think that for Diesel engines in traction work a mean piston speed of 1 300 ft. per min. is the maximum advisable. As I have already stated, I have a strong belief in the ultimate success of hydraulic transmission, and I wish to urge that all concerned should concentrate on making the whole of the mechanism robust, simple and reliable, basing their efforts on a machine of about 2 000 h.p. output, which output I consider to be now required to meet conditions on the Argentine broad-gauge railways. I am strongly of the opinion that in a short time really reliable machines of this type will be developed which can be counted on to run at least 15 000 km per month in regular service, with overhauls at infrequent intervals. At the present time, and under all the difficulties caused by labour conditions in Argentina, it is not possible to get a steam locomotive to run more than 7 000–8 000 km per month on the most reliable services. Bearing in mind the growth of road transport and the very high cost of wages and fuel for steam locomotive traction, I believe that the Diesel engine offers the one means open for reducing operating cost and enabling the railways to hold their own. Taking into account all the items which make up the cost of steam traction, I think it may ultimately be possible by employing Diesel locomotives to reduce the total costs to about one-fifth of present-day costs.

Mr. J. M. Eddy : I should like to add a few words from the administrative point of view. The railways in Argentina are faced with growing competition from road transport, which they have to meet with the additional disadvantage of ever-growing demands from labour which increase the cost of operation. I look to engineers as a whole to do their utmost to produce more economical methods of transportation. I believe that the railway companies must aim at giving the same sort of service that road transport companies are able to give, that is, collection of goods at the producers' doors and delivery at the final destination with rapidity and efficiency. The railways would have this one advantage over their competitors that the greater part of such transport could be carried over their own right-of-way at higher speeds and lower costs than by motor vehicles running on ordinary roadways. I wish to appeal for wholehearted co-operation between the railway companies, their engineers, and the manufacturers and their staffs to solve this problem as early as possible and on sound economic lines. It will require a considerable expenditure, but I believe that by joint action and enterprise the individual burden will not be heavy, and the ultimate gain to the railway companies will be very well worth the initial expense. In conclusion, I should like to suggest that as this discussion has already produced excellent results, and as the subject is one of such vital importance, a further discussion might be held in about 6 months' time to report progress.

Mr. F. Recknagel also took part in the discussion and described the part which the American Westinghouse Co. had taken in developing the "constant torque" system for use with Diesel engines for traction purposes.

DISCUSSION ON

"THE MODERN USE OF PULVERIZED FUEL IN POWER STATIONS."*

NORTH-WESTERN CENTRE, AT MANCHESTER, 12TH NOVEMBER, 1929.

Mr. V. Walker: Many misunderstandings have been created by the statement that pulverized-fuel boilers can deal with any class of fuel. While most solid fuels can be burnt in the pulverized form, they cannot all be burnt in the same furnace, put through the same burner, or ground in the same mill. The author has proved that low-grade coal can be successfully used in a pulverized-fuel plant. An efficiency of 84·69 per cent, as shown by the test on the Simon-Carves boiler, over a period of 52 hours and using coal with an ash percentage of 21, is certainly good practice, and I doubt whether this performance could be beaten by stoker-fired boilers. The loss of 0·87 per cent due to radiation, given in this test, is rather low; I should imagine that it would be more like 3 to 4 per cent. Prior to 1926 the unit system was only considered in connection with relatively small plants, but now it is being installed for units of much larger size. Perhaps its chief advantage is the elimination of the complication and expense of drying. This was overcome by introducing hot air into the mill, the temperature of which can be raised to 600° F. In the case of the Hams Hall plant, the author is using a temperature of 350° F., which appears rather low if coal of a moisture content of over 10 per cent is used. The temperature of the coal leaving the mill should not be more than 150° to 180° F., otherwise trouble is caused by the volatile constituents of the coal adhering to the burner piping and hampering the travel of the coal. With the unit mill, wide variations of moisture content have a marked influence on output and fineness. With the storage system, the intervening equipment between boiler and pulverizer cuts these variations out. In some plants where a single pulverizer feeds a number of burners there has been considerable trouble in getting an even feed to each burner, but the difficulty has been overcome by the use of larger burners and an improvement in the design of the distribution system. I should like to know what the author considers to be the maximum heat-release per cub. ft. of furnace volume for air-cooled and water-cooled walls respectively, assuming an ash fusion-point above 2 500° F. Those given in the tests are relatively low, about 11 000 B.Th.U. per cub. ft. It would also be interesting to know whether any difficulty is experienced in dealing with the ash in the design shown in Fig. 2. Does the lining of the ash-pit cause trouble? What was the volatile content of the coal used during the tests? With regard to the elimination of grit, the large American stations have installed grit-catchers of the water type and, although the sulphur fumes are not greatly reduced in quantity, only about 5 per cent of the original ash is discharged from the chimney. The development of the stoker is worth noting. At one large London power station a stoker with a grate-width of 30 ft. is being installed. A few years ago at least 3 stokers would have been required for this particular boiler.

Mr. W. Bayliss: Regarding the statement that higher efficiency can be obtained with pulverized-fuel firing as compared with stoker firing, we must be careful only to make comparisons between up-to-date plants of each system, when we shall find that the gross efficiency in favour of pulverized fuel is not more than 1 per cent. In the application of pulverized fuel one has to look beyond the question of efficiency, even of net efficiency, and decide whether a process of firing has advantages in the direction of the utilization of coal which otherwise could not be burnt, or in some other respects. Actual records of pulverized-fuel-fired and stoker-fired boilers, both in this country and in America, show that quite as high an efficiency has been obtained from the latter as from the former, and the adoption of one or the other depends mainly on local conditions. As regards the possibility of the use of larger boiler units with pulverized-fuel firing as compared with stoker firing, this is a general statement and is correct only as regards magnitude. The United States is the home of large boiler units, and the following figures give the output of steam per hour for certain large stoker-fired units:

Beacon Street, U.S.A.	418 000 lb.
Hudson Avenue, U.S.A.	352 000 lb.
Norfolk Street, U.S.A.	275 000 lb.
Battersea, England	300 000 lb.

From these figures the possibility of large stoker-fired units is apparent. The largest pulverized-fuel units of which I have knowledge are those that are being installed by the United Electric Light and Power Co. for the Hell Gate power station. These boilers, which evaporate 800 000 lb. of water per hour (maximum rating), are of Babcock and Wilcox type, designed for a steam pressure of 400 lb. per sq. in. Each unit, operating at maximum capacity, will consume 1 000 tons of coal per day. Two boilers supply steam for one 160 000-kW turbo-generator. This unit is no doubt beyond the capabilities of stoker-firing. There is no doubt that, within the range of stoker-fired units, these are cheaper than pulverized-fuel-fired units of equal evaporative capacity. With reference to Fig. 1, with the later experience of pulverized-fuel firing it is easy to see where trouble will arise. The system of coal drying, as explained by the author, is unsatisfactory and more or less obsolete. The storage of pulverized fuel in bunkers is undesirable on account of moisture difficulties and the risk of spontaneous combustion; the brick combustion chamber will not permit of operation with high CO_2 content, otherwise maintenance will be very high, and trouble will arise due to slagging on the lower boiler tubes, and also the slagging of ash in the bottom of the combustion chamber, creating difficulties in the removal of ash. Fig. 2 shows a plant that is in some respects an advance on that illustrated by Fig. 1. The method adopted for drying the raw coal is not now regarded as the best practice; the central system is also out of favour, and the brick-lined combustion chamber, even when backed with water tubes, proves costly in maintenance and very liable to encourage slagging of the boiler heating surface when excessive CO_2 is present. The author mentions that the covering by refractories of the furnace water-tubes is to be abandoned and bare tubes adopted. This step is liable to introduce other troubles, such as failures of the bare tubes, or over-cooling of the combustion chamber, with the losses consequent upon the carbon contents of the ash passing through the boiler system, particularly if the coal grinding is coarse and when the boiler is operating at light loads. In published records of pulverized-fuel-fired stations in the United States, investigations have revealed a carbon content of from 12 to 30 per cent in the ash, due to various causes, and this is a matter which should not be overlooked. Regarding Fig. 3, this is again in advance upon Fig. 2. The unit system of pulverized-fuel firing has been adopted with turbulent burners. Bare water-tubes are arranged on three sides of the furnace, and may give trouble such as I suggest in the case of the boiler in Fig. 2. I should also expect the front refractory wall to involve high maintenance costs. As regards the test figures given at the end of the paper, I appreciate how difficult it is to obtain reliable figures from pulverized-fuel-firing equipments of the central system. Referring to the first test, 80·35 per cent overall efficiency is not good enough to sell, or to induce the installation of, pulverized-fuel plant. The loss of 7 per cent in radiation, combustible in ash and unaccounted for, is very high and is probably mainly accounted for by the combustible matter in the ash. With regard to the second test, I should like to know whether the dust-precipitation plant was in use before or after the test. It is probable that a very material quantity of combustibles escaped into the atmosphere. This test gives a better overall efficiency, namely 84·69 per cent, but this figure is unacceptable owing to the figure of 0·87 per cent loss on account of radiation, combustible in ash and unaccounted for. If this were corrected to read between 3 and 4 per cent, and the overall efficiency correspondingly reduced, the test would then reveal merely a normal operating figure. A plus water gauge in the combustion chamber is very undesirable, as it will involve high maintenance charges. The gases passing to the chimney have a high temperature in both tests. The liberation in the combustion chamber is only about 10 000 B.Th.U. per cub. ft., and the present-day practice for a pulverized-fuel combustion chamber is, under favourable conditions, three times that figure. Summarizing the points, the problem of successful pulverized-fuel firing is not simple. The character of the coals to be used must be known and understood. The plant must be of simple construction and very robust. The grinding of the coal must result in a fine and continuously fine product. The combustion chamber must be so constructed as to give low maintenance costs whilst being operated with high values of CO_2 to maintain the highest temperature possible whilst obviating slagging of boiler heating surface. It must permit of easy ash-removal and of a continuous CO_2 content at the boiler outlet of 14 to 16 per cent without introducing operating troubles or high maintenance charges. What percentage is it correct to subtract from the gross efficiency in order to arrive at a net efficiency? It is the latter which is important. What have been the maintenance costs per 1 000 lb. of steam evaporated? What has been the experience as regards the dust problem; i.e. what percentage of the total ash in the coal has been removed from the combustion chamber, the boiler and economizer and the dust collector arranged near the chimney? What is the average percentage of sulphur in the coal, and what is the average fusing temperature of the ash?

---

* Paper by Mr. R. A. CHATTOCK (see vol. 67, p. 1213.)

Mr. H. C. Lamb: The figure of 72 per cent given for the boiler-house efficiency for stoker firing presumably refers to the relation between the heat value of the coal and the heat value of the steam leaving the boilers. It would be interesting if we could have the corresponding figure for the pulverized-fuel-fired boilers. I should also like to know the comparative net efficiencies of the two types of firing, after making allowance for the auxiliary plant; also the difference in the operating costs. Very few pulverized-fuel-fired plants exist in Lancashire, and Manchester, in particular, has strongly favoured mechanical-stoker firing. It would, however, be a mistake to infer from this that either Manchester or Birmingham is wrong in the decision which has been made. In my opinion both are right, because the problem in the two areas is entirely different. Pulverized fuel has the best chance where coal is very dear and the smallest gain in efficiency is important, or where there are large quantities of coal of low heating value available at a low price. This, I believe, is the position in Birmingham, where low-grade coal from the Warwickshire coalfields is obtainable at very cheap rates because the freightage costs are low. This slack cannot be fired efficiently in the solid condition but is quite suitable for use as pulverized fuel. In Lancashire, on the other hand, the quality of the coal is much better: at Barton power station, for instance, excellent slack is available at a reasonable price, whereas cheap, low-grade slack is only procurable in limited quantities owing to the high freight charges incurred in bringing it from the Midlands, whence the bulk of it is obtained. When the question of pulverized fuel was under consideration in connection with Barton power station, the problem had to be discussed with reference to a working boiler-house efficiency of 80 per cent over a period of 12 months, which is a great improvement on the Birmingham figure of 72 per cent. The reasons for this are (i) that the Barton plant, being equipped with economizers and air-heaters, is a more efficient unit than the stoker-fired boiler at Birmingham; and (ii) that, as already mentioned, the quality of the coal available in Manchester is very suitable for stoker-firing, whereas that obtained in the Birmingham area is not. It was decided some time ago to install an experimental pulverized-fuel-fired boiler at Barton, in order to obtain experience. Originally, this plant, which has a normal rating of 130 000 lb. per hour, was similar to that shown in Fig. 1. When it became apparent that an installation of that kind was rapidly becoming out of date, it was remodelled, and it now resembles that in Fig. 3. We have not, as yet, had much experience of the remodelled boiler, and I am unable to give any definite results. The general conclusions which have been reached, however, may be of interest. The difference in the annual capital charges of that boiler as compared with a stoker-fired boiler is approximately £600 per annum; that is, the capital charges for the pulverized-fuel boiler are £600 more than for the stoker-fired boiler. Coal of 11 500 B.Th.U. costs about 15s. per ton. The improvement in net *test* efficiency, making allowance for auxiliaries, when firing coal of this quality as pulverized fuel, compared with stoker fuel, is nil, but the improvement in net *working* efficiency is about 2 per cent. Such a boiler consumes 35 000 tons of fuel per annum and, with coal at 15s. per ton, an improvement of 2 per cent in boiler efficiency is equivalent to a saving of £500. Thus there is an increase in capital charges of £600 (neglecting altogether the question of maintenance) and a saving in the cost of coal of £500. The other comparison is with fuel of 9 000 or 10 000 B.Th.U. The author obtains this fuel at a very low price, but in Manchester 10s. per ton has to be paid; in fact, it is very often sold at as much as 12s. per ton in this district. Comparing the net test efficiency, when using this class of coal a pulverized-fuel-fired boiler shows a saving of about 2½ per cent, and we estimate that, on the working efficiency over a long period, there is an increase in the efficiency of 5 or 6 per cent, which represents a saving of £900 a year on 12 months' working, so that the balance in this case is on the right side. The quantity of such fuel available, however, is not large. We have no reason to regret these experiments, but shall require much more experience before we feel justified in installing more boilers for pulverized fuel and discarding the stoker-fired boilers.

Mr. H. L. Guy : The use of pulverized fuel as a firing agent for boilers is not new, and really owes its inception to work done in this country. We should all bear in mind the efforts of Mr. Bebbington in this connection. I remember seeing pulverized-fuel-fired boilers in operation in Trafford Park 18 years ago, and they will tell you in the United States that the system was an English idea which underwent development there because in that country financiers are more ready to take up and finance new developments than in our own. The situation appears to have changed considerably as compared with conditions 4½ years ago. The position is being stabilized. It is now appreciated that the correct system of firing by stokers or pulverized fuel depends on the character of the fuel to be burnt. It is impossible to say whether pulverized-fuel or stoker firing is the correct solution in a particular case, except by an examination of the fuel used and the local conditions at the station concerned. Claims made a few years ago in respect of both methods have had to be modified in the light of accumulated experience. In the early days, stress was laid on the claim that pulverized fuel enabled larger boilers to be operated than were possible with stoker-firing. Although that claim still holds good it is considerably modified by the fact that there are stoker-fired boilers in operation with an output of 400 000 lb. of steam per hour. As far as the requirements of this country are concerned, these cannot be regarded as small boilers. With regard to the difference in test efficiency, it has been established in American experience that the efficiencies obtained with stoker-fired boilers are much the same as can be obtained with pulverized-fuel-fired boilers. In commercial service the latter show a slight advantage over a long period, and the figure, which a previous speaker mentioned, of about 2 per cent is one which finds general acceptance among users of both types of plant in the United States. It also appears to be accepted that the higher efficiency obtained by the use of pulverized fuel does involve an increased capital expenditure. We hear less, too, of the claims made a few years ago as to the possibility of using a very poor-grade fuel by the adoption of pulverizers, because it has been recognized that the main disadvantage of the pulverized-fuel system is the capital cost of the plant, plus the maintenance and working charges. It is not an attractive proposition to pulverize 40 per cent of stone for the sake of burning 60 per cent of coal. I was interested in the passage dealing with boiler tests, in which the author indicates the difficulty experienced in assessing the quantity of coal burnt during the test. I gather that the calorific value which has been used as the basis of these calculations is the calorific value of the fuel as supplied to the boilers. In assessing the weight, the author mentions that the weight of fuel had to be "calculated forward to obtain the net weight of pulverized fuel fed to the furnace." I should be glad if he would explain what that means, i.e. whether the calorific value of the coal as fired into the boilers, and as the weight is assessed, could have been different from the calorific value of the coal as supplied to the boiler and used as the basis in these tests. Can he give us any information regarding his experience of the merits of the two particular types of mills which he used? I should also like to know whether the provision of the Lodge-Cottrell dust-eliminator represents a sensible increase in the cost of the plant. Finally, do the figures of tests include the auxiliary power required for the boiler services and the pulverizing services, and the steam or fuel used for drying?

Mr. A. B. Mallinson : It is interesting to see the great evolution which has taken place as a result of experiments on a large scale, gradually changing the complicated bin-and-feeder system to a comparatively simple unit pulverizing lay-out. There is one point on which I desire further information. Although the author adopts the unit system, he uses the peg type of pulverizer on what is rather a large unit for a unit pulverizer, viz. between 8 000 and 9 000 lb. per hour. My experience has been entirely confined to unit pulverizers. In the United States in 1923–4 the centrifugal type of pulverizer was in great demand, but in New York last month I ascertained that this type of mill was considered unsuitable for above 7 500 to 10 000 lb. ratings, and that, following the installation of some hundreds of peg and centrifugal pulverizers, the ball mill was now being adopted. My experience has been that, from the start, the efficiency of the pulverizer gradually drops due to the wear of the hammers, and that unless the operators are careful and systematic in maintenance the overall efficiency falls in proportion to the wear which must take place. In Mexico, the company with which I am associated has a battery of 6 Babcock and Wilcox boilers with unit pulverizers, burning native coal which contains from 20 to 22 per cent ash. Our experience over some 5 years' operation is that the cost of maintenance of the combustion chamber and arches is materially greater than that of pulverizer hammer renewals. What overload rating has been possible with the boilers of the different lay-outs? In the United States great claims are made for the overload capacity obtainable with pulverized-coal firing. Finally, I think we are all glad to have figures which, though perhaps not nearly as satisfactory as we may have expected, relate to British practice.

Mr. J. Frith: This discussion has demonstrated that some rational means of comparison between the various methods and performances is essential. Regarding the figures of efficiencies given, it is not stated whether these take into account the auxiliaries, nor are we told what sort of coal has been used. It is impossible, with the information given, to make any real comparison. The function of a boiler is to supply steam, and the real criterion is how much steam it can supply per pound sterling. This is a much more satisfactory basis for comparison between the various methods. A boiler with only 50 per cent efficiency, if it could supply 1 000 lb. of steam for less money than one having an efficiency of 85 per cent, would be the better proposition. Can the author tell us the cost, under the various systems, of raising 1 lb. of steam? Some plants work better with cheap coal and others with dear coal, and therefore the weight of steam per lb. of coal is not a sound basis of comparison.

[The author's reply to this discussion will be found on page 515.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 2ND DECEMBER, 1929.

Mr. E. F. Hetherington: Although the use of pulverized fuel is now well established in this country, the question still arises, when the design of a new power station is contemplated, as to whether the advantages of powdered-fuel firing are sufficient to justify its adoption in preference to a stoker-fired plant. A pulverized-fuel equipment offers the advantages of flexibility and ease of control, particularly to stations which operate at a variable load. These advantages are not so obvious in the case of stations designed for base-load operation. A further advantage claimed for this type of fuel is that of greater efficiency. While this claim is undoubtedly upheld so far as combustion is concerned, there is a much smaller margin of efficiency in comparison with the ordinary stoker when due allowance has been made for the power required for operating the auxiliaries. The extensive adoption of powdered fuel has, however, acted as a stimulus to the designers of stoker plant, and by considering alternative sets of equipment for a large station it is found that the guaranteed efficiencies of the two types of equipment agree very closely. The operation of powdered-fuel plant over long periods undoubtedly involves a saving, but on the other hand it cannot be denied that at present the most efficient stations in this country have stoker-fired plants. Powdered fuel, however, exhibits a decided advantage by reason of the wider variety of fuels which may be satisfactorily consumed; the stoker equipment is far more restricted in this respect. My own view is that for boilers up to a rating of about 100 000 lb. per hour there is very little to choose between the two systems, but apart from the fact that with larger units stoker equipment becomes very large and unwieldy, a definite saving in capital cost can be shown in favour of powdered fuel. I have found that a saving of about 15s. per kW of plant installed is obtained by employing three boilers each having a capacity of 225 000 lb. per hour and fired by powdered fuel instead of four stoker-fired units with boilers rated at 150 000 lb. per hour. The question of grit-catching is one upon which all engineers connected with either the design or the operation of powdered-fuel plant are at present very vitally concerned. The electrostatic system of grit-catching has proved very effective in certain cases, despite the fact that it is expensive and, in my opinion, somewhat difficult of application where large stations are concerned. Wet washing has also been successful in some instances, although it has unpleasant features. Because of the curvature of the smallest dust particles, it is difficult to break down the effect of surface tension and so allow the dust to become wet. Unless high-pressure sprays are employed the wetting process occupies a considerable time. To provide for this period large chambers are usually necessary, making the design even more intricate, especially where the plant has to be carried over the boiler house. The disposal of the effluent, heavily charged with sulphur products, is, however, a problem of even greater difficulty. When the power station is situated alongside a river such as the Thames, there is little difficulty, particularly as the waters of the Thames are definitely alkaline. The station with which I am concerned, however, will be situated on the banks of a river into which it is not permissible to introduce any effluent of this nature, and as no satisfactory and commercially practicable means has been found for treating the effluent it is necessary to rely upon cyclonic extraction. If the cyclone separators are too large their efficiency is very materially diminished; the solution of the problem of the use of this type of plant for grit-catching will probably be found in the application of smaller cyclones in multiple.

Mr. G. H. Rogers: During the discussions on this paper great prominence has been given to the grit problem which arises as the result of the use of pulverized fuel. No doubt this prominence is due to the serious difficulties which certain supply undertakings are experiencing because of their failure to prevent the escape of quantities of grit, soot, and sulphur fumes from the chimneys. The author states that it has been found possible to remove some 90 per cent of the grit before the gas is passed to the chimney, although this must clearly involve considerable expense. I should like to ask whether any attempt has been made to trap the 10 per cent of grit which now escapes. Would it not be possible to install a cowl, adapted for operation in the direction of the wind, into which the gases could be blown, and then sprayed by a pair of water sprays in series? Such an arrangement would not cost a great deal in the first instance and it would, I think, be quite successful in removing all traces of grit before the gases were allowed to escape into the atmosphere.

Mr. T. E. Boothby: From the thermal standpoint, the firing of fuel in pulverized form should be more efficient than other methods of combustion. In this, however, as in every other process of development, experiments have been necessary before the theory could be turned to practical account. In the early stages of its development pulverized fuel was a failure, not because the principle was at fault, but on account of the imperfect knowledge and unhappy experiments of the pioneers in the subject. The paper explains some of the troubles which occurred in connection with the earlier equipment. It was in France that I came across the two largest installations which I inspected while studying the question of pulverized fuel on the Continent. Both were in poor condition. In Belgium there were two plants similar in design, one clean and very efficient, the other dirty and giving poor results. A study of these two plants revealed factors which are, no doubt, universal; the former was worked by a man who was sympathetically inclined to pulverized fuel, and who aimed at efficiency, while the latter was under the care of one who, on his own statement, wished to reveal all its disadvantages. It was impossible for me to recommend the system which I saw in use there. The coal was raised about 100 ft. and placed in the overhead bunkers, dropped into a cellar through a drier and pulverizer, lifted to a powdered-fuel storage bunker, and finally lowered once more to the burners. Extensions for the Stourport station were being planned at that time. A specification which eliminated overhead bunkers and employed a simple system of direct firing with unit pulverizers was drawn up. The system now adopted by the Birmingham Electricity Committee marks, in my opinion, a further improvement in design, and a considerable reduction in capital cost. Whatever his previous experience with pulverized fuel, the author would be forced to adopt it in the new installation on account of the size of the boilers. It is interesting, however, to note that the stoker makers are putting forth every effort to hold their own against the serious competition offered by pulverized fuel. There is little doubt that the stoker-fired plant can produce results equal to those of the pulverized-fuel installations which have been described. Local conditions vary considerably; power stations situated near mines which can produce high-class fuel have an advantage over those less fortunately situated. As an example of the strides which are being made in stoker design, it may be mentioned that a new Stirling boiler of 90 000 lb. normal rating, fired by an "L" type underfeed stoker, has recently been installed at the Stourport station. It has a water-cooled arch and the side walls of the combustion chamber are also water-cooled. The installation includes an economizer and air heater. The contractors have guaranteed an overall efficiency of 86 per cent on this plant, but up to the present it has not been possible to carry out the necessary tests. In my opinion, equipment of this type will become increasingly popular in connection with boilers of upwards of 100 000 lb. evaporation. The engineers responsible for pulverized-fuel installations appear to be open to the criticism of everyone whose premises suffer from an accumulation of dust. Until those who control the electricity supply industry unitedly insist on clean coal, the grit problem will remain unsolved. There is an impression among mine owners, particularly in the Midlands, that electric power stations are really refuse destructors. If a particularly dirty seam containing some 30 per cent of ash is opened, it is always worked on the assumption that the coal will be burnt at the power stations. Although it is perhaps too early for the author to give us any figures of costs and efficiencies in connection with the new plant, I should be interested in the corresponding figures relating to the earlier equipment.

Mr. J. Burns: In the discussion before the Institution (vol. 67, p. 1220) I referred to the general design of the new Hams Hall power station and congratulated the author on his vision, not only in proceeding with two storage systems of pulverized fuel at Nechells, but also in making further advances at the new station. One speaker referred to the flexibility of pulverized-fuel firing in general, but thought that a unit system would be less flexible compared with the case in which a bin of pulverized coal is available. This is easily shown to be unnecessary, in view of the fact that the operation of a unit mill and burner can be closely controlled, particularly where the "Atritor" type of mill is used. Only a few pounds of coal are passing through the mill at any moment, and any variation in the coal feed produces an immediate effect upon the burner. Further, where, as at Hams Hall, there are five mills and five burners for each boiler, a temporary stoppage of one mill is of very little moment. The question of the emission of dust and sulphur fumes has become more acute in view of recent events at Manchester. Further developments with the wetted-surface flue-gas washer on the Continent and in this country make the problem appear much less difficult. With a guarantee of the removal of 90 per cent of the dust and at least 70 per cent of the sulphur content of the flue gases, this apparatus is well on the way to a solution. A small water-spray plant on the uptake from the washer should remove another 20 per cent of the sulphur. The removal of the ash and sulphur by wet or dry cleaning at the colliery would reduce the problem to very small dimensions. With regard to high rates of evaporation, a small boiler could be designed to give a large transference of radiant heat, but the outlet-gas temperature would of necessity be high. A set of air heaters or economizers would be necessary to ensure a reasonable outlet temperature of the flue gases.

THE AUTHOR'S REPLY TO THE MANCHESTER AND BIRMINGHAM DISCUSSIONS.

Mr. R. A. Chattock (*in reply*): Several speakers have referred to the very low loss of 0·87 per cent due to radiation, etc., on the Simon-Carves boiler, and suggested that this was too low. The boiler casing and combustion-chamber walls of this boiler were designed so that the external surface temperature should not exceed 130° F. with an air temperature of 75° F. This should account for a loss of approximately 0·25 per cent only, so that after adding other losses unaccounted for the figure given of 0·87 per cent seems fairly reasonable, especially as the combustion was perfect on this test.

Mr. Walker suggests that the temperature of the hot air introduced into the mills should be 600° F. The mills are designed to operate with air at any temperature between 250° and 400° F. and no difficulty is being experienced in practice. He also asks what was the maximum heat release per cub. ft. of furnace volume for air-cooled and water-cooled walls. The figures for the three installations described are as follows:—

Vickers-Spearing boiler (air-cooled walls)	10 880 B.Th.U.
Simon-Carves boiler (water-cooled walls)	14 450 B.Th.U.
Hams Hall boiler (water-cooled walls)	21 900 B.Th.U.

He inquires, in addition, as to the difficulty experienced in dealing with the ash on the Simon-Carves boiler. As I mentioned in the paper, it was found that the brick tiles in front of the tubes became burnt away if the proportion of CO_2 was allowed to rise above 14 per cent, and it had been decided to place the tiles behind the tubes so as to leave the latter exposed to the furnace gases. This arrangement has now been tried and found to be a complete success. The furnace has operated continuously for a period of 8 months without any injury, and the proportion of CO_2 has been raised to 16 per cent. The volatile content of the fuel used for the tests, expressed on a completely-dried fuel basis, was 30·4 per cent on the Vickers-Spearing boiler and 31·91 per cent on the Simons-Carves boiler.

As regards Mr. Bayliss's objection that the overall efficiency of 80·35 per cent during the test on the Vickers-Spearing boiler was too low for selling purposes, I explained in the paper that this figure included periods of 6 hours during each 24 hours when the boiler was banked; a comparable figure for stoker-fired boilers is 72 per cent. A test run at a continuous full load would, of course, give a higher figure. Mr. Bayliss's anticipation of trouble due to exposing the furnace tubes has not been borne out in practice. As explained above, this arrangement is operating with a high CO_2 percentage without any injurious results and with complete success. The sulphur content of the fuel is approximately 1·5 per cent. The fusing temperature of the ash lies between 2 250° F. and 2 600° F.

Mr. Lamb asks for a figure of overall efficiency of the boiler house for pulverized-fuel operation to correspond to an efficiency of 72 per cent for stoker operation. This is 80·35 per cent. The net efficiencies in each case, after allowing for the auxiliary power required by the two types of operation, are:—

For stoker-fired boiler house ..	71·5 per cent.
For pulverized-fuel-fired boiler house	76·5 per cent.

This shows an improvement in net efficiency for pulverized fuel of 5 per cent over the stoker-fired boilers. Mr. Lamb estimates a saving of only 2 per cent on the Manchester boiler, so that if 5 per cent can be obtained his cost figures should show a considerable improvement in favour of pulverized fuel.

None of the speakers has mentioned the question of the labour costs of operation. With the Hams Hall lay-out it is possible, owing to the large boiler units and to the simplicity of the controlling apparatus, to operate 60 000 kW of boiler plant with only 3 men per shift, compared with the 12 men required for stoker-fired boilers. This represents a saving of between £3 000 and £4 000 per annum.

Replying to Mr. Guy's questions, the calorific value used as the basis of the calculation of the test efficiencies is that of the fuel supplied to the combustion chamber. The net weight of the fuel fed to the furnace was "calculated forward" in the following way. The weight of the raw fuel fed to the driers was determined by actually weighing it. Samples of this fuel were taken and its moisture content was accurately determined. The total weight of moisture in the fuel was subtracted from the total weight of the raw fuel to obtain the weight of the fuel when completely dried. The percentage of moisture in the pulverized fuel as fed to the furnace was then determined from samples. The total weight of the moisture was calculated and this was added to the weight of the completely-dried fuel to obtain the actual weight of the pulverized fuel as fed to the furnace. This was the only method available as it is impossible accurately to weigh the fuel after it has been pulverized. The installation of the Lodge-Cottrell coal-dust interceptor increased the cost of the boiler equipment by about 6 per cent. In the Hams Hall lay-out the driers have been entirely eliminated, so that the Lodge-Cottrell plant is not required.

Mr. Mallinson is quite right in referring to the necessity for systematic maintenance of the pins or hammers of the mills. If these are given proper attention the efficiency of grinding can be maintained. A figure of under 2d. per ton of coal ground should cover these replacements. As regards overload ratings, the Vickers-Spearing boilers were designed for an overload of 20 per cent or 42 000 lb. per hour; this has been obtained for short periods only, as a harmful effect upon the furnace brickwork is feared. The Simon-Carves boilers were also designed for an overload of 20 per cent, or 180 000 lb. per hour. However, since the combustion chambers have been modified there has been no difficulty in obtaining an overload of 33 per cent or 200 000 lb. per hour.

The points raised by other speakers are all dealt with in the above or in my reply to the discussion in London.

STANDARDIZATION OF DISTRIBUTION VOLTAGE.

The Council have authorized the publication of the following statement for the information of members:—

A standard lamp voltage of 230 having been adopted by the British Engineering Standards Association (B.E.S.A. Publication No. 77—1925: British Standard Voltages for New Systems and Installations) for both alternating-current and direct-current systems, after prolonged consultation with all the interests affected, and having been approved by the Electricity Commissioners, the Council felt that it was desirable for consideration to be given to various problems arising therefrom. These problems have been reviewed under the following heads:

(A). The practicability and cost of raising or lowering to 230 the declared lighting voltage on the general supply networks of all systems in Great Britain which at present have a declared voltage below or above 230.

(B). The ways in which the Electricity Commissioners may be able to assist voltage standardization.

(C). Other matters affecting the general question of the standardization of voltage on low-voltage distribution systems.

As a first step in the study of the problem of voltage standardization, it was necessary to have some knowledge of the extent to which different voltages are at present in use on low- and medium-voltage distribution systems. As no such information was available the Electricity Commissioners were asked if they would be prepared to assist by taking a census. This they consented to do. Replies were received from practically all undertakers and were tabulated by the Commissioners' staff. This tabulation is given in an Appendix and it certainly emphasizes the confusion caused by the present medley of voltages. In many cases it was found to be impossible to allocate the number of lamps and other items of apparatus connected to the different voltage systems; the tabulation is, therefore, necessarily somewhat incomplete. It gives, however, quite a clear picture of the position and one which is certainly far more complete than any data hitherto available.

A general idea of the situation is given by the following figures, which refer to the total lighting connections in the country as at the 31st March, 1927. These are taken from the attached tabulation, but where figures are not allocated to specific voltages an assumed allocation has been adopted.

	230 volts	Range 220/240 volts (excluding 230 volts)	Range 200/215 volts	Above 240 volts	Below 200 volts
Connections expressed as equivalent number of 30-watt lamps	12¼ millions	18 millions	21 millions	2½ millions	2¼ millions

(A). Practicability and Cost of Standardization.

The Council can foresee no engineering or administrative difficulties in carrying out a policy of voltage standardization, and on several large systems a change in the general distribution voltage has already been successfully carried out.

It is the Council's opinion that, with assistance from the Commissioners as referred to later, declared voltages within the range of 220/240 volts can be standardized at 230 volts by a gradual adjustment over a period of a few years and with very little expenditure.

For voltages below 220, a change to the standard voltage would involve a considerable expenditure. It is not easy to estimate the actual amount of this, but from data at the disposal of the Commissioners it was found possible to make an approximate estimate for the country as a whole, on four different bases. The four figures obtained were £9 750 000, £14 000 000, £16 250 000 and £10 750 000 respectively. The last of these estimates is based on a detailed study of the estimated cost of standardizing a large municipal undertaking now operating at 200 volts. The second is based on actual costs incurred by two comparatively small undertakings which have changed their voltage. The first and third are based entirely on estimated figures. The Council consider that it would be safe to take the minimum figure as £10 000 000 and the maximum as £16 000 000.

For voltages above 240 the cost would be about 10 per cent of the above figures, but it is felt that it is not practicable to attempt any standardization of these at the present time. If, and when, the greater part of the country is using the standard voltage the addition of the undertakings now operating at 250 volts would probably take place automatically. At the present time, however, it does not seem fair to ask such undertakings to make an immediate sacrifice in distribution efficiency without a more immediate prospect than now exists of obtaining the more indirect benefits of standardization.

Undertakers with voltages below 220 would, by raising their voltages to the standard, gain very greatly in distribution efficiency and better utilization of mains. The extent to which this could be set against the cost of standardization depends largely on the rate at which the increased capacity of the existing mains can be absorbed by increased growth.

(B). Assistance from Electricity Commissioners.

In discussions which have taken place the Commissioners have assured the Council of their sympathy with all possible steps to extend the use of the standard voltage, and they are already taking steps to ensure that the standard voltage shall be adopted for all new areas.

The Commissioners fully appreciate the extent to which new developments frequently take the form of extensions of existing systems into adjoining areas, and they have promised to do everything possible to promote the adoption of the standard voltage in all extensions of old areas and in all changes of system. They have agreed that, in urging this policy on undertakings, they will make reference to any preferential terms for standard-voltage lamps and apparatus which may be arranged with the makers, and also to any special terms which may be arranged with the makers for lamps and apparatus bought as part of a standardization programme.

The Council feel, however, that the greatest assistance in promoting standardization is the Commissioners' agreement:

(1) To call the attention of all undertakers who have a non-standard supply voltage near the standard voltage of 230 (i.e. say within a range of 220–240 volts) to the powers reserved to the Commissioners under No. B3 of the Regulations for Securing the Safety of the Public and ensuring a Proper and Sufficient Supply of Electrical Energy, enabling them to modify the specified voltage variation; and

(2) To intimate to such undertakers their readiness to exercise such powers in favour of any undertaker who wishes to have a wider range of voltage variation for the specific purpose of making an immediate commencement with standardizing the distribution voltage.

(C). Other Matters Affecting the General Question of the Standardization of Voltage.

Conferences were arranged with the British Electrical and Allied Manufacturers' Association and the Electric Lamp Manufacturers' Association to ascertain whether the views of the general body of manufacturers were in support of standardization of voltage and whether they would assist by price differentiation in favour of standard apparatus and lamps.

As a result of these Conferences:—

(1) The B.E.A.M.A. Council agreed:

> "That this Council recognize the importance and value of voltage standardization and desire to encourage the more rapid adoption of the standard voltage of 230 throughout the country. Further, that this Council recommend each of the Sections concerned to take all practicable steps to assist in accelerating the change-over of existing systems to the standard voltage of 230."

(2) The Section of the B.E.A.M.A. dealing with domestic appliances agreed:

(*a*) "The Section fully appreciate the value of standardization of voltages in connection with the manufacture of domestic appliances of all kinds and will be glad to give their support to any steps which may be taken towards the more general adoption of a standard voltage of 230.

"The general adoption of 230 volts as the standard would be welcomed, particularly as this would bring about simplification in manufacture and consequent reduction in prices. This effect will be the more noticeable as the adoption of 230 volts becomes more nearly universal.

(*b*) "When the change-over is made in any particular district, they will be glad to assist as far as possible by giving a preferential discount on parts of apparatus supplied to replace those rendered useless by the change-over. It would facilitate matters greatly if this preferential discount were to apply only to orders received from supply authorities and not to replacement orders received from contractors, as it would be easier in this way to confine such orders to those for replacement parts only."

(3) The E.L.M.A. indicated their support of endeavours to induce the supply authorities to adopt one standard voltage for domestic use, and issued a notification to the public on the 2nd April, 1929, indicating that the prices of certain popular types of lamps for general lighting-service purposes were being reduced on and from that date, and that in each instance where a price reduction was taking place the list prices of the 230-volt lamps would be 1d. cheaper than the list prices of similar lamps in the 200/260-volt range.

(4) The E.L.M.A. addressed a letter on the 1st February, 1929, to the I.M.E.A. and other associations of supply authorities, stating that, with a view to facilitating the change-over of supply stations to a pressure of 230 volts and recognizing the expense to which such stations would be put, they were prepared to quote the following additional scale of discounts off the net invoice prices for lamps delivered to any supply authority which were bought directly from the members of the E.L.M.A.

for specific change-over work in connection with the adoption of a standard 230-volt pressure:—

Number of such lamps ordered within a period of three months	Additional discount off net invoice prices
5 000 or more	7½ per cent
25 000 or more	10 per cent
50 000 or more	12½ per cent
100 000 or more	15 per cent

As a result of the meetings and discussions which have taken place during this investigation the Council have been more and more impressed with the advantages which would result to the industry from a wider standardization of voltage throughout the country. This view is also strongly supported by the Electrical Contractors' Association, whose Council have recently been considering the matter. A copy of a letter addressed by their Secretary to the Electricity Commissioners was forwarded by him to the Council for its information. The following is an extract from such letter:

> "My Council, at its last meeting, considered reports from various centres as to the comparatively large extensions which were being carried out at the present time differing from the standard voltage of 230/400 volts. . . .
>
> "My Council does not think, for one moment, that the Electricity Commissioners are not doing their best to deal with the situation, but my object in communicating with you is to ask that every possible effort should be taken to ensure standardization as extension at non-standard voltage seriously affects the selling costs due to the large stocks of lamps and domestic appliances which it is necessary to manufacture and stock, and to the fact—and we regard this as a very important one—that it deters consumers who contemplate changing their residence, from purchasing electrical equipment which they would otherwise do at the present time. . . .
>
> "My Council would also be pleased to learn what steps, if any, the Commissioners have in view for the standardization of existing voltages of supply, particularly in adjoining areas, where the difference in some cases is only 10 or possibly 20 volts. . . ."

APPENDIX.

ELECTRICITY COMMISSION.

LOW AND MEDIUM VOLTAGE DISTRIBUTION.

(General supply, not exceeding 250 volts for lighting and 500 volts for power, etc.)

Analysis of returns from authorized undertakers, showing, for the different declared voltages, the number of lamps connected, the number and horse-power of motors connected, and the total kilowatts of heating and cooking apparatus connected to supply systems at 31st March, 1927.

LIGHTING SUPPLIES.

(A). *Voltages for which separate particulars have been returned by authorized undertakers.*

Voltage	Number of lamps connected at 31st March, 1927 (generally returned as equivalent to 30-watt lamps)
100	1 191 399
104	410 916
105	221 125
110	194 241
125	1 200
150	163 540
200	16 134 854
204	841 054
205	1 090 714
210	2 029 265
215	65 862
220	8 001 127
225	80 090
230	11 436 570*
240	8 872 028
250	2 297 150

* Includes 113 899 lamps representing the equivalent of the lighting, heating and cooking supplies for 2 undertakers.

(B). *Voltages for which grouped or amalgamated figures not capable of sub-division have been returned by authorized undertakers.*

Voltage	Number of lamps connected at 31st March, 1927 (generally returned as equivalent to 30-watt lamps)
100 and 110	46 101
100 and 200	275 807
105 and 210	976 428*
105 and 240	80 382
105, 210 and 230	126 225
110 and 220	423 254
110 and 230	41 184
110, 230 and 250	304 425
200 and 230	13 204
200 and 240	350 666
210 and 230	74 283
210 and 220	219 747
210 and 240	6 402
220 and 230	24 255
230 and 240	368 926†
230 and 250	344 143

* Includes 495 000 lamps representing the equivalent of the lighting, heating and cooking supplies for 1 undertaker.

† This total includes the equivalent of the heating and cooking supplies for 1 undertaker.

POWER SUPPLIES.

(A). *Voltages for which separate particulars have been returned by authorized undertakers.*

INSTITUTION NOTES.

Graduateship Examination Results: November, 1929.

SUPPLEMENTARY LIST. *

Passed.†

Beaumont, G. H. (South Africa).
Mukerjee, H. N. (India).
Page, T. H. D. (South Africa).
Rhenius, S. T. (India).
Siret, E. C. (India).
Smith, J. A. (New Zealand).
Stephens, M. N. B. (South Africa).
Wadhera, C. L. (India).

Passed Part I only.

Dewan, H. G. (India).
Fisher, W. J. H. (New Zealand).
Grant, D. L. (New Zealand).
Krishen, B. (India).
Newman, P. L. (New Zealand).
Sagar, Y. P. (India).
Soin, P. N. (India).
Wadhwa, H. R. (India).

The Benevolent Fund.

On the last page of the cover of this issue of the *Journal* will be found an appeal for donations to the Benevolent Fund.

Proceedings of the Wireless Section.

80TH MEETING OF THE WIRELESS SECTION, 15TH JANUARY, 1930.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

On the motion of the Chairman, votes of condolence were passed on the death of Dr. S. Z. de Ferranti, F.R.S. (a Past President and Honorary Member), and Admiral Sir Henry B. Jackson, R.N., G.C.B., K.C.V.O., F.R.S., the members standing in silence.

The minutes of the meeting of the Wireless Section held on the 4th December, 1929, were taken as read and were confirmed and signed.

A paper by Mr. H. A. Thomas, M.Sc., entitled "A Method of Measuring the Overall Performance of Radio Receivers" (see page 475), was read and discussed.

---

* See page 314.

† This list also includes candidates who are exempt from, or who have previously passed, a part of the Examination and have now passed in the remaining subjects.

The meeting terminated at 8 p.m. with a vote of thanks to the author, which was moved by the Chairman and carried with acclamation.

81ST MEETING OF THE WIRELESS SECTION, 5TH FEBRUARY, 1930.

[Held at the City and Guilds (Engineering) College.]

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the 15th January, 1930, were taken as read and were confirmed and signed.

The following papers were read:—

"An Ammeter for Very High Frequencies." By Prof. C. L. Fortescue, O.B.E., M.A., Member, and Mr. L. A. Moxon.

"A Method of Measuring Mechanical Impedance." By Prof. E. Mallett, D.Sc.(Eng.), Member, and Mr. R. C. G. Williams, B.Sc.(Eng.), Graduate.

"Some Notes on the Design of a Gramophone Pick-Up." By Mr. G. W. Sutton, B.Sc.

"Frequency Stabilization of Valve Oscillators." By Prof. E. Mallett, D.Sc., Member.

"An Instrument for Projecting and Recording the Response Curves of Electrical Circuits." By Prof. C. L. Fortescue, O.B.E., M.A., Member, and Mr. F. Ralph.

An adjournment was then made to the laboratories of the College, where the apparatus described in the above papers was demonstrated and informally discussed.

At the dinner held at the Imperial College Union after the meeting the Chairman proposed a vote of thanks to the Delegacy of the College, to which Mr. W. M. Mordey (one of the Governors of the College) and Prof. C. L. Fortescue responded.

Elections and Transfers of Members.

At the Ordinary Meeting held on the 23rd January, 1930, the following elections and transfers were effected:—

ELECTIONS.

Associate Members.

Albertyn, Adriaan Moorrees, B.Sc.
Barratt, Gilbert Alfred, Commander R.N.
Berg, Gustave, B.Sc.(Eng.)
Bowen, William Oswald, Captain R.C.S.
Briggs, William Thomas.
Brock, John Frederick.
Brown, George Anthony D.
Cecil, The Hon. Henry Mitford A., Lieut.-Commander R.N.
Chatterjee, Satyendra N., B.Sc.
Crabtree, John Ashworth.
Currey, Charles Norman E.
Debenham, William Richard, B.Sc.
Dixon, Murray Deighton, M.A.
Dupere, Thomas Rex.
Everitt, Richard Allen, Lieut.-Comdr. R.N.
Fegen, Richard Fogarty, Lieut.-Comdr. R.N.
Fisher, Harry.
Fry, Cedric Edmund.
Gardner, Fred Gilpin.
Gemmell, William Thomas.
Grace, George Edward.
Groves, Robert.
Harpham, Arthur Thomas.
Kinsman, Clarence.
Kirk, John Henry.
Knight, Henry de Boyne, B.Sc.
Leighton, Leopold.

Associate Members—continued.

McClean, Herbert George, B.Sc.(Eng.).
MacSheehy, James Graham J.
Meynell, Guy D'Arcy.
Minter, John Henry C., Lieut.-Comdr. R.N.
Mulleneux, Harry Joel.
Murphy, Frank, B.Sc. (Eng.).
Noakes, Cecil Stanley D., Lieut.-Comdr. R.N.
Pendry, Samuel Dunsdon.
Roberts, David William A.
Roberts, Kenneth William D.
Sarginson, Richard, B.Sc. (Eng.).
Slight, George Mure.
Smith, Dudley Sharrington, B.Sc., B.E.
Somerville, Henry Benson.
Ta'Bois, Percival Leo.
Thompson, Derrick Henry H., Lieutenant R.N.
Towers, Herbert Cecil.
Vaughan-Williams, Hugh Laurence, Lieut.-Comdr. R.N.
Waddington, Henry Randall.
Watson, Louis Robert C.
Whitehead, George Ethelbert.
Wield, Ronald Cunningham, Lieut.-Comdr. R.N.
Williamson, Hubert.
Winch, Gordon Thomas.

Companion.

Haigh, Alfred.

Associates.

Baskerville, James J.
Best, Eustace Charles.
Burbridge, William.
Champion, George Thomas.
Clift, William Harry.
Forrester, John.
Griffin, Ernest Philip.
Harbottle, George Robert.
Hodge, George Nicholl.
Jeffs, Arthur Joseph.
Jolly, Richard Ward.
Jones, George Bickerton.
Lindley, Norman Macdonald.
Long, Frederick Henry.
Mackenzie, Francis James R.
Moody, Wilfred.
Penrose, John.
Price, Benjamin Thomas Ll.
Ridler, Percival Herman.
Robinson, Bernard Carlton.
Shreder, Peter.
Spurling, Walter Everard.
Taylor, James Edward.
Vandal, Sidney.
Ward, John Gillies.
Whittick, Robert Baker.
Willey, Arthur Martin H.
Wilson, Milton Boss.

Graduates.

Ambady, Govindan Kutty M., B.Sc.Tech.
Andrews, Robert Cyril P., B.E.
Bates, Herbert Owen.
Bayles, John Wallis, B.Sc. (Eng.).
Capp, Percy Frederick.
Cliffe, Allen William F., B.Sc.(Eng.).
Deakin, George Woolliscroft.
Espley, Dennis Clark, B.Eng.
Fyfe, Leslie John G., B.E.
Gill, William Ernest.
Hay, George Bertram M.
Henderson, George, B.Sc.
Hollingworth, Charles Eric, B.Eng.
Humphreys, Meredith Noel, B.A.
Innes, John, B.Sc.(Eng.).
Jackson, Arthur Norman, B.Sc.(Eng.).
Kalra, Dharm Chand, B.Sc.(Eng.).
Kerse, William Harold.
Laing, Walter Barron.
Langshaw, William Greenhough.
Levy, Joshua.
McKenzie, Duncan Buchanan, B.Sc.
Marks, Horace Beaumont, B.E.
Mason, Cyril Arthur, B.Sc. (Eng.).
Millar, Thomas.
Mowat, James McKinnon, B.Sc.

Graduates—continued.

Murchison, Roderick Impey, B.Sc.(Eng.).
Narayanaswami, N. V., M.A.
O'Donovan, Thomas J.
Oldham, Bernard Cyril.
Palmer, Hugh Leslie, B.Sc. (Eng.).
Paul, Shudhir Kumar.
Petch, Thomas Hayes, B.A.
Pither, Thomas Frederic.
Pontifex, Claud Edmund C.
Rooney, James Louis, M.Eng.
Rouse, Edward Kenneth, B.A.
Sanderson, William Troutbeck, B.A.
Singh, Bhagwan, B.Sc., B.Eng.
Smith, Frank Arthur.
Sowter, Robert John, B.Sc.
Spence, James Allan, B.Sc.
Stevenson, Allan Brown, B.Sc.
Swan, Earle Percy.
Swan, Stanley Robert B., B.Eng.
Taylor, Ernest George, B.Sc.(Eng.).
Tregurtha, Frederick Charles P.
Tsao, Tsen Cha, B.Sc.

Students.

Adams, Robert Whitehouse, B.Sc.
Advani, Ramchand Chainrai, B.Sc.Tech.
Ahuja, Chuni Lal.
Ahuja, Indar Sain.
Aitken, James Glendinning.
Allen, Douglas Charles.
Allured, Basil Murray.
Anderson, Richard Henry.
Baker, Charles Henry.
Bana, Minoo Bejonji.
Barber, Bernard Davie.
Barford, Frank Cecil.
Barham, Donald William C.
Barnard, John Henry.
Barrie, Edward Foster.
Bates, Frederick William.
Bayford, Arthur.
Beasant, Frederic Harry.
Beaumont, Arthur.
Beaumont, George Harold.
Bhavnani, Narain.
Bird, John.
Blakeley, William Firth.
Blakey, Albert Edward H.
Blount, James Arthur.
Blythe, Henry Stephen.
Bourne, George Ronald.
Bourne, Harry Kebbell.
Bowen, William Harold.
Bowman, Henry Charles R.
Bowyer, Kenneth Charles.
Boyd, John S.
Boyton, Edward Morris.
Brace, Edward Charles.
Bradwell, John Arthur.
Braithwaite, Robert Cecil.
Bramhall, Ervin Hicks.
Bristow, Kenneth Walter.
Brunner, Henry Theodore.
Brunton, Robert Laurence.
Buswell, Harry.
Buttle, Arthur Vickery.
Byford, Max Arnsby.
Calvert, Rupert Hector.
Cameron, Ewen.
Candler, John Lawrence.
Carpenter, John Ernest.
Carr, George Ralph.
Carr, Thomas Henry.
Carroll, Desmond Conway.
Carstairs, Eion.
Cary, Anthony Lucius.
Caton, George.
Cayton, Joseph.
Chambers, Arthur Oswald.
Chappell, Albert William T.
Chopra, Kundan Lal.
Clark, Francis James.
Clark, William Brindley.
Clarke, Ralph Charles.
Coles, Raymond Schofield.
Cook, Joseph Edward.
Cornfield, Maxwell.
Cornish, Lionel James.
Coundon, Leslie.
Craig, Donald Hugh C.
Craster, Thomas Yvo.
Crawford, William George B.
Cundill, George Douglas.
Dancy, Charles Romney.
Davidson, Kenneth.
Davies, Arthur Cyril, B.Sc. (Eng.).
Davies, Trevor Hewitt.
Davis, John Sydney.
Day, Benjamin Lionel.
Day, William John.
Desbruslais, Eric Leonard, B.Sc.(Eng.).

Students—continued.

SURGES AND OVER-VOLTAGE PHENOMENA ON TRANSMISSION LINES, DUE TO LIGHTNING.

By Dr. H. Norinder.

(*Lecture delivered before* The Institution *5th December, and before the* Scottish Centre *16th December,* 1929.)

Introduction.

Lightning surges on high-voltage transmission lines have always been a very troublesome source of disturbance, and their importance has grown with the general development of overhead transmission systems. This is particularly the case in the United States, where electrification is highly developed and many long overhead lines are already in existence.

The yearly losses due to lightning surges will thus increase as transmission systems are more widely adopted. When electric power is more generally used for specialized purposes—for instance, for railway electrification—interruptions due to lightning will have much more serious effects than was the case when electric power was used in smaller machines and for less important purposes.

It will thus be seen that the problem of protection against lightning surges is a very important one. This must be borne in mind when the attempts that have already been made to solve the problem of surges are considered.

The Lack of Suitable Research Methods.

The problem of lightning surges on transmission lines arose right at the commencement of high-voltage transmission, but for some years its solution has been slow, due not to lack of interest, but to the absence of suitable instruments and research methods.

In the early days the surge problem was attacked by some very simple methods. From observations of the damage by lightning to transformers and other plant in electrical installations, conclusions were drawn as to the nature of surges. The method was analogous to the study of a disease by superficial observation. It sometimes resulted in the employment of protective devices that were potentially more dangerous to the transmission systems than were the lightning surges themselves. It must not, however, be thought that I am of the opinion that all existing protective devices are valueless.

With the growth of knowledge, scientific methods can now be applied to the problem. The construction of effective protective devices against lightning surges involves an exact knowledge of the source of the trouble—the natural lightning surges themselves.

The Development of Specific Methods of Research.

The great development which has taken place in electrophysical methods during the last 15 years, especially in connection with high vacuum, has led to the introduction of special devices for research on the effects of lightning on transmission lines. There are three chief groups of instruments or devices, and these are in many respects complementary. They are the klydonograph, the cathode-ray oscillograph and the lightning-surge generator.

By a cathode-ray oscillograph is meant an oscillograph in which the cathode rays impinge upon a photographic film or plate situated within the vacuum tube. The intense bombardment of the electron jet on the plate makes it possible to record transient phenomena of as short a duration as 10^{-6} sec.

The first to construct such an oscillograph was A. Dufour. The original instrument with its accessories has now been perfected, and a modern cathode-ray oscillograph, with its accessories in the form of kenotron rectifiers, oscillator circuits and evacuation systems, represents quite a laboratory in itself.

The klydonograph, on the other hand, is an astonishingly simple piece of apparatus. The principal part of the klydonograph is a small insulated electrode which is pressed against the sensitive layer of a photographic plate, the other side of which is covered by an earthed metal plate. An impulse voltage of slightly more than 2 kV causes a Lichtenberg figure to develop. The duration of an impulse capable of affecting the plate need only be of the order of micro-seconds, and it is possible to estimate the impressed voltage and its polarity from the diameter and shape of the figure.

The klydonograph and the cathode-ray oscillograph can be used to record lightning surges produced either naturally on transmission lines under full-load conditions, or artificially in a laboratory, and they may thus be regarded as controlling devices for lightning surges.

The surge generator, on the other hand, is a device for producing surges. The artificial production of surges under controlled conditions, either in the laboratory or on the line, will, without doubt, considerably facilitate the work of providing effective protection against lightning troubles.

Some Experimental Difficulties and Limitations.

(*a*) *The Klydonograph.*

This device is, as I have already mentioned, very simple in its operation, and this has been one of the reasons for its widespread use on transmission systems. It gives the amplitude and polarity of a surge, but it fails when an analysis is required in which it is necessary to determine the time within a few micro-seconds. On the other hand it is a very reliable control instrument for recording surges on transmission-line systems, and should be more widely used.

(*b*) *The Cathode-ray Oscillograph.*

The only device by means of which complete records of lightning surges can be obtained is the cathode-ray oscillograph. The main difficulty in the way of using this instrument for recording lightning surges is that the time of incidence of the surges cannot be predicted. This means that the instrument must be kept in readiness for perhaps an hour or more, during which time the film must be protected from the cathode beam and its stray radiation. If this were not done the rays would blacken the film in a fraction of a second and no trace of a record would be visible. Further, when a record has been taken the film must again be protected against the radiation from the electron beam. The whole operation must be performed within a period of time not exceeding some fraction of a millionth of a second.

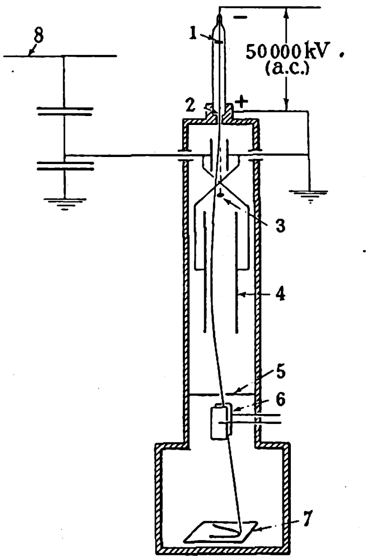

FIG. 1.

This special problem can be solved in two different ways. In each the cathode ray is kept at its normal strength in the instrument during the whole time of exposure. The beam is, in one of the methods, prevented from striking the photographic layer by a special device, comprising an external relay, sometimes composed of a set of electron tubes. If such tubes are used the relay is tripped by the first impulse of the surge and will cause the beam to enter for recording purposes. Such a complicated electron-tube device must, however, give rise to a great deal of trouble and disturbance in recording phenomena of such variable nature as lightning surges.

I have developed another method in which the electron beam itself is used in the oscillograph as a kind of relay. Fig. 1 shows its operation, in which no relay leading to loss of time is used, the whole process being performed by the electron beam of the oscillograph. The electron jet from the cathode (1) passes through the anode hole (2) straight along the central axis of the instrument. The jet is stopped by a small bar of metal (3), the target. This device cannot prevent all stray radiation; therefore in order to prevent the stray rays from blackening the film a diaphragm (5) with a central small hole is arranged. The instrument has a double pair of deviation plates (4) situated above the diaphragm and cross-connected. Below the diaphragm is mounted a second system of deviation plates (6) connected to an oscillator circuit.

The function of the device can easily be explained in the following manner. A surge coming from the line is impressed upon the potentiometer (8), which is connected to the deviation plates (4). These plates above the target bend the beam, let us say, to the left in the figure. The beam is bent back by the lower plates and directed through the hole in the diaphragm. By carefully selecting the length and spacing of the two pairs of deflection plates the beam is made to pass through the hole in the diaphragm. Its deflection is proportional to the voltage applied.

The deviation plates below the diaphragm are so situated that a voltage impressed on them will cause the beam to deviate in a direction at right angles to that produced by the upper plates. The lower plates will thus give a time axis to the record if the plates are connected to an oscillator circuit with a constant and known linear or sinusoidal time variation.

(*c*) *Surge Generators.*

The construction of surge generators gives rise to some difficulty with regard to high-voltage insulation and elimination of superimposed high-frequency currents in the circuits. The voltage at which kenotrons can be operated is limited to about 200 kV, and for a surge generator it will sometimes be necessary to go up to more than 10 times this value. Another inconvenience is the necessity of relatively high effects in the surge generators. Fig. 2 shows how these difficulties can be avoided. This construction has proved to be of great flexibility as a lightning-surge generator device, and has been developed by the Westinghouse Electric and Manufacturing Co., of East Pittsburgh, U.S.A. The generator (see Fig. 2) consists of several groups of condenser banks, spark-gaps and resistances in a special connection. The condensers (C_1 to C_{10}) are charged from a kenotron rectifier (A) over resistances (R_1 to R_{10}) of the order of 1 megohm. One of the spark-gaps (G_2) is set to about 20 per cent lower spark-over voltage than the others. By regulating the voltage of the rectifier a voltage can be reached in the system so high that G_2 breaks down. When this occurs two condenser groups will be charged to a higher voltage than the other groups, and the spark-gaps of all these groups immediately break down. The condensers are con-

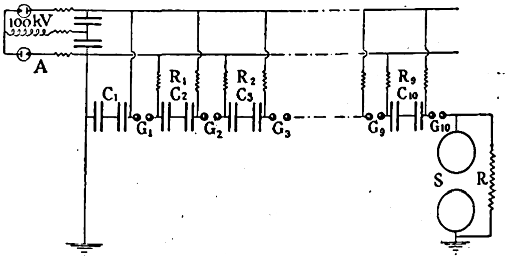

FIG. 2.

nected in series via the spark-gaps. A voltage 10 times as high as the kenotron voltage appears at the terminal gap. Such a generator for 3·5 million volts has been built in the high-tension laboratory of the Westinghouse Co. A portable lightning-surge generator of the Westinghouse Co. for 1 million volts was used last summer for artificial surge generation on a 220-kV line. It might be thought that the generator would give an irregular voltage variation, owing to the spark-lag effect and to other local disturbances, at least in the first micro-seconds of rising voltage; but this is not the case, as may be seen from an inspection of oscillograms.

External Arrangements for Connecting Oscillographs and Klydonographs to Transmission Lines.

One of the predominant advantages of the klydonograph and of the cathode-ray oscillograph is the relatively small effects that are necessary to produce records. The connection to a high-tension line can thus be made by means of condensers, and it is sufficient to use a string of insulators in the form of a capacitative potentiometer. It is obvious that precautions must be taken with regard to natural oscillations in the circuit leading to the oscillograph. The influence of leakage over insulators during rain, and of disturbances by corona, must also be avoided. This can easily be done by using air condensers in series in the circuit. Sometimes we have used strings suspended within the laboratory in combination with air condensers.

One of the difficulties when connecting a cathode-ray oscillograph to a transmission line under full load is the elimination of the normal-load voltage which is impressed on the deviation system of the oscillograph. One method is to use a relatively wide target. The normal voltage in such a case is so regulated that the electron jet will oscillate over the target at normal-load voltage, and only a voltage in excess of the normal will cause the jet to leave the target and impinge on the film.

Sometimes it is convenient to use a non-inductive leakage resistance above the instrument condenser.

The device must be so balanced with regard to the capacity and leakage resistance that it will, without any appreciable disturbance, reproduce impulses of a given wave-form. The action of this resistance may easily be controlled by well-defined impulses from a laboratory circuit.

Electrical Conditions for Lightning Surges.

Lightning surges are supposed to be produced either by direct strokes on the lines or by induced bound charges. From a physical point of view there is a distinct difference between those two kinds of surges.

(a) *Surges by Direct Strokes.*

Let us suppose that a cloud is highly charged and with some of its parts situated vertically above the line. The discharge process is preceded by a slow local accumulation of charge within the cloud itself. This will disturb the equipotential surfaces below the cloud and they will slowly move downwards.

At the commencement of the discharge process we can consider a thunder-cloud as a body with suspended charged particles. From this non-conducting but charged body an electrostatic field radiates out. With increasing accumulation of the charge the field force also will increase and along the lines of forces partial glow-discharge streamers are developed. This will cause certain parts of the cloud and its surroundings to be semi-conducting bodies within which a concentrated lightning path can develop. This path will follow the partial glow-discharge streamers and will thus pass along the general direction of the lines of force, which are emanating from the charged cloud downwards. In this connection the time necessary to break down the insulation between the cloud and the line is of interest. It can sometimes be appreciable, as will be seen later, and it is not surprising that direct strokes to the transmission line will also produce surges in which the peak value is reached within several micro-seconds.

(b) *Surges by Induced Charges.*

Surges caused by bound charges can easily be deduced by theoretical methods. Two factors are of importance when the development of indirect surges is under consideration. Their form is a function both of the distribution of the bound charge along the line before the discharge and of the time function for the release of the charge. This is shown graphically in Fig. 3, which I published earlier.*

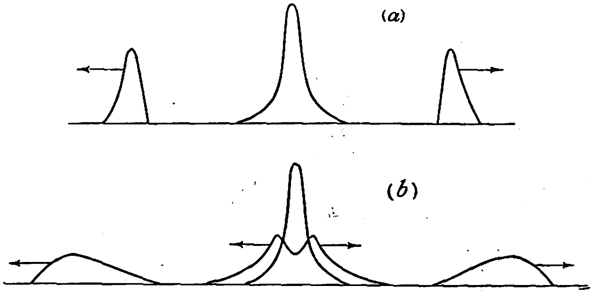

Fig. 3.

A sudden discharge gives rise to two surges with very steep fronts (Fig. 3*a*). On the other hand, a slow discharge results in surges with sloping fronts (Fig. 3*b*). The velocities of the lightning discharges are generally, as we shall see later, relatively slow. The release of the bound charges will thus give rise to indirect lightning surges with very sloping fronts and small amplitudes. They will therefore not be harmful on a transmission-line system. This is in accordance with the views of Dr. G. C. Simpson.†

Experimental Data in Connection with the Rate of Cloud Discharge.

It has been possible to observe the lightning discharges in the atmosphere by aid of the cathode-ray oscillograph in connection with a short antenna circuit. Our first observations along these lines at the Royal

---

* *Teknisk Tidskrift*, 1923, vol. 53; *Elektroteknik*, p. 184.

† "Lightning" (The Twentieth Kelvin Lecture), *Journal I.E.E.*, 1929, vol. 67, p. 395.

Board of Waterfalls Research Station, Uppsala, were carried out in 1921 with an ordinary Braun tube connected to an antenna circuit. The following year we obtained our first records, which have since been much improved upon, by the use of a specially constructed cathode-ray oscillograph. Our observations are of special interest when we have to consider the general physical conditions of lightning surges on transmission lines.

A diagram of the circuit is reproduced in Fig. 4. The antenna capacity was connected to earth through a small non-inductive resistance R_2 of such a value that the time-constant of the circuit was a few micro-seconds. An air condenser of the same value as the capacity of the antenna circuit was shunted across the resistance R_2. Both ends of the resistance R_2 were connected to the deviation system of the oscillograph. The object of the resistance R_1 was to damp the natural oscillations of the circuit.

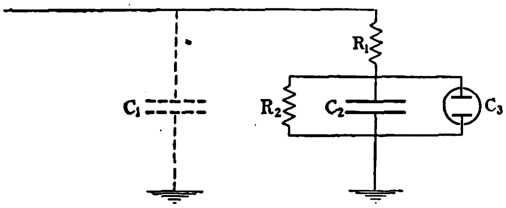

Fig. 4.

The function of the circuit is exemplified by Fig. 5. The voltage of a discharge between two different parts of a cloud in air varies with time, as shown by the curve for *V* in Fig. 5. The variation in the antenna circuit and above the deviation plates of the oscillograph will thus take the form of the curve *dV/dt*.

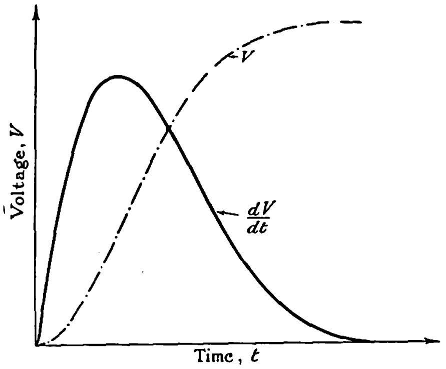

Fig. 5.

I have already pointed out that the discharge in the atmosphere grows, at least in its first stages, relatively slowly. The ordinary lightning stroke is thus generally preceded by partial glow discharges in the form of streamers, which sometimes last for 1 000 to 2 000 micro-seconds.

How the lightning discharge affects the antenna circuit in a given case is exemplified in Fig. 6. The field slowly increases up to the point 1, and is prevented by the leakage resistance of the antenna circuit from giving any charge to the circuit. At this point very rapid glow discharges commence. These are easily absorbed by the antenna circuit, if this is situated near the region of glow discharges. The lightning discharge proper begins at the point 2 and gives a maximum charge to the antenna circuit at the point 3. Superimposed high-frequency variations can be seen at points 4 and 5. Sufficient experimental data are not yet available to permit of an explanation of this superimposed high frequency. It may be caused by some interaction between a partial discharge branch and the main branch of the lightning path, and by some part of the connection taking place over a space filled by partial glow-discharge streamers.

Some Characteristic Records of the Discharge Rate.

In Figs. 7, 8 and 9 are shown some oscillograms of lightning discharges taken in the laboratory of the Royal Board of Waterfalls Research Station during the last two summer seasons. As I have already mentioned, we have, in addition to our work on transmission lines, for several years been occupied with cathode-ray oscillographic studies of the mechanism of lightning discharges. We early discovered that the lightning discharge was itself unidirectional, but our first oscillographs would not allow our investigations to reach the stage to which we have now been able to take them.

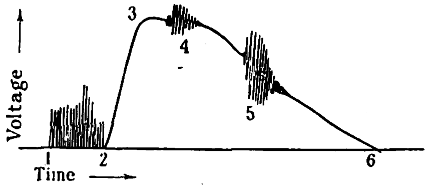

Fig. 6.

Fig. 7 shows four different types of discharge, A, B, C, and D. A and D gave a positive charge to the antenna circuit, B changed the polarity and C gave a pronounced negative charge. The total duration of A was about 1 000 micro-seconds and some pronounced irregularities can be seen at the commencement.

For B the distance between the point at which the lightning stroke occurred and the observation point was about 0·9 km. There is a distinct superimposed high-frequency oscillation which has nothing to do with the production of lightning surges on transmission lines, but it provides the solution of another disturbance problem, viz. the atmospherics in radio receiving sets during thunderstorms. When I have obtained some further experimental data on this subject I hope to revert to this question.

If Figs. 7 and 8 are studied together a remarkable resemblance will be found between curve C of the former and curves A and B of the latter. The lightning discharges, as we shall see later, occur in the same region, and we have here a case of repeated lightning discharges in the same region between cloud and earth. All the discharges show at some point small bands of superimposed high frequency.

Fig. 9 shows two discharges with small amplitudes, but they are quite different in type. For a period of 1 000 micro-seconds discharge B was preceded by a great number of partial discharges.* These partial discharges indicate the period during which a lightning path is built up.

The curves show that the lightning discharges develop slowly and very often indicate single polarity. This provides an explanation of a phenomenon which I have observed for several years when making experiments with the cathode-ray equipment for recording lightning surges. Sometimes very heavy thunderstorms passed near the transmission-line systems without producing any surges at all, whereas one would naturally expect to find induced surges, at least. No doubt such processes took place during the storms, but so slowly and smoothly that no surges above line voltage occurred. I have not yet been able to find any definite evidence of the existence of such indirect surges.

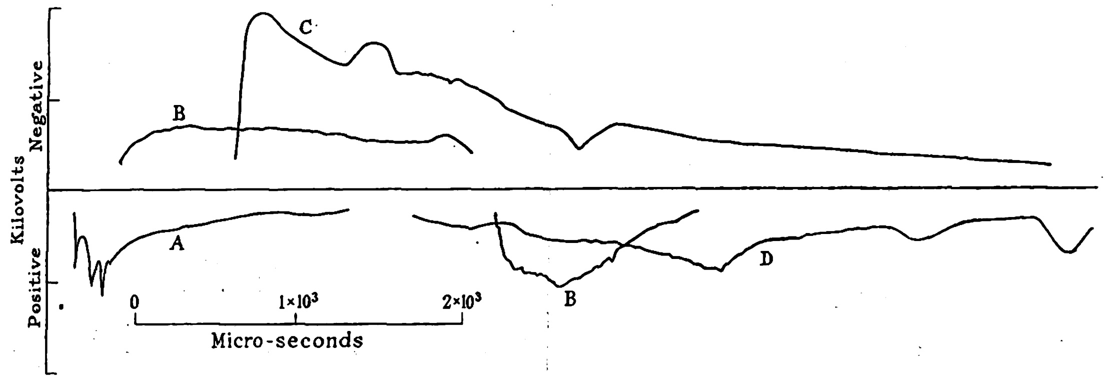

FIG. 7.

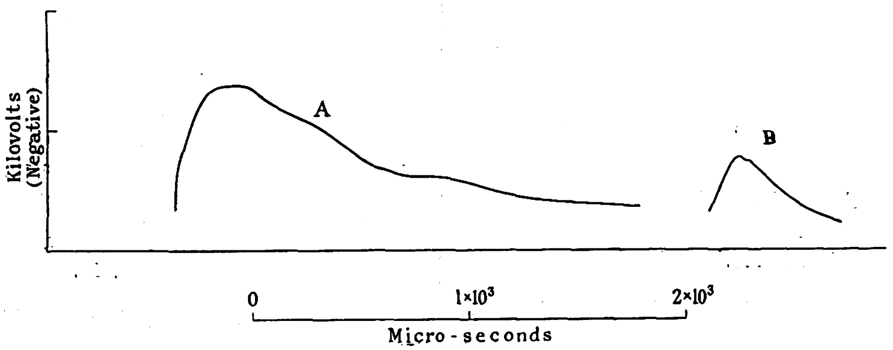

FIG. 8.

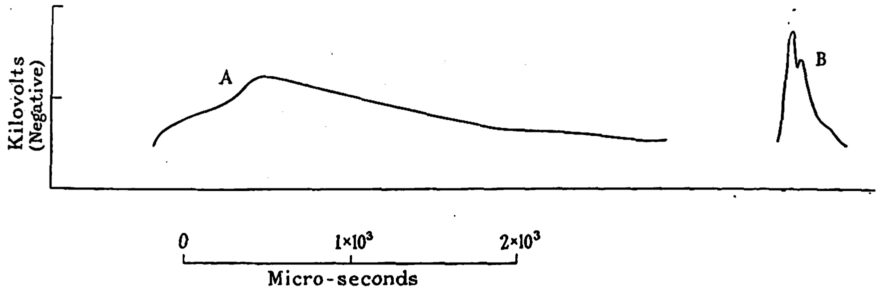

FIG. 9.

We have been able to get some interesting observations on direct lightning strokes to transmission lines. Either discharge C of Fig. 7 or A of Fig. 8 was a direct stroke to transmission lines in the vicinity, a pole of a 3-kV line at 2 km from the laboratory being struck. The 3-kV line was at the time connected by a transformer to a 20-kV line, and this experienced a heavy surge manifested by a short-circuit on the system. The other lightning stroke produced a heavy surge on another 20-kV line at a distance of some 100 m from the former. It must be remembered that a discharge curve similar to the two last-mentioned curves gives an indication that a lightning stroke has occurred between earth and cloud. It seems to be clear that a discharge between a perfect conductor (in this case the earth's surface) and a semi-conductor (a cloud) will give rise to discharge curves similar to those already mentioned.

Only a small proportion of the total number of lightning strokes in any thunderstorm will produce surges on a transmission line in the vicinity of the thunderstorm, and but few of these surges will cause serious damage.

---

* These could be seen in the original oscillogram, but they are not shown in the figure as reproduced.

DIRECT RECORDS OF LIGHTNING SURGES ON TRANSMISSION LINES.

One feature of interest in lightning surges is the time which the surges take to reach their maximum or peak value. Other features are also the peak values of the surges, their total duration and the slope of their tails.

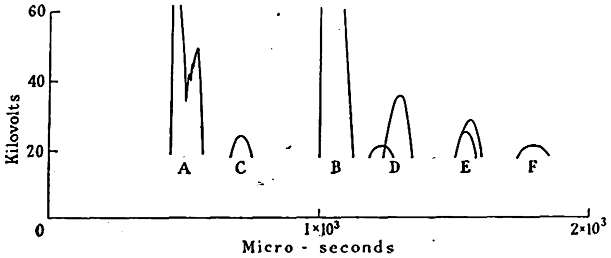

FIG. 10.

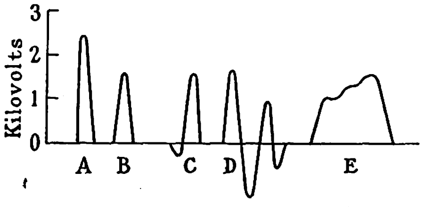

FIG. 11.

The polarity may also be of interest if we consider the problem from a physical point of view.

The maximum value of a surge on a transmission line is limited by the insulation of the line against such a surge, and in this connection the question of time-lag flash-over characteristics has to be taken into account. A surge with a very steep front in which the maximum value is reached within 1 micro-second can pass an insulator string without flashing over, if the value is nearly twice the insulation value at 50 cycles, but if the surge reaches its full value within, say, 10 micro-seconds the insulator will flash over at the value for 50 cycles. It is thus very important to have a knowledge of the surge time-characteristics if we wish to consider the insulation of the line from the point of view of its immunity from surges.

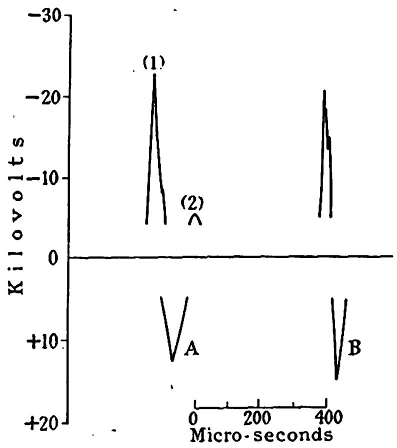

FIG. 12.

Flash-overs on insulators of transmission lines under load make it more difficult to obtain valuable records of the surges. The flash-over from the surge is followed by a short-circuit of the line, and this spoils the film. To avoid this trouble the ideal method would be to run an idle highly-insulated line near to the line conductors.

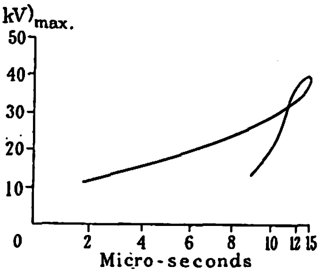

FIG. 13.

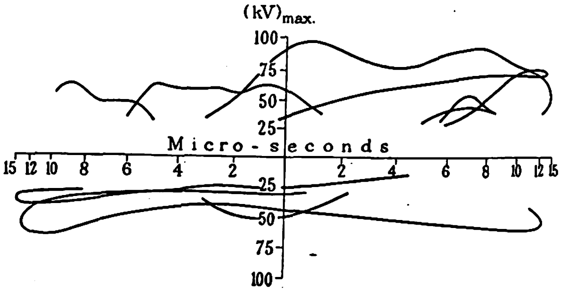

FIG. 14.

THE FIRST LIGHTNING-SURGE RECORDS.

The first lightning-surge record, which was followed three years later by a similar one in another locality, was taken at Uppsala during a severe thunderstorm in July 1925. The record, which is reproduced in Fig. 10, was taken at one end of a 42-km 20-kV line under load.

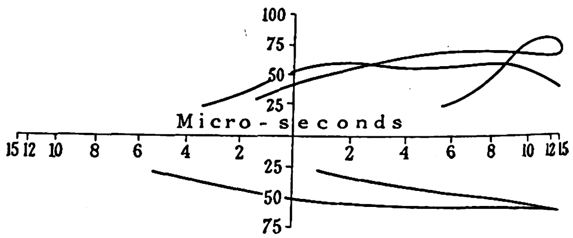

FIG. 15.

In this record it is possible to observe two different primary surges (A and B), both with steep fronts and a peak voltage of about 60 kV. The peak value of one of the surges was considerably beyond the limit of the oscillograph. Surges C and D, and probably E and F, are marked reflections of the primary surges. Surge A, after having travelled to the other end of the 42-km line and returned, shows an attenuation of about 60 per cent. The attenuation for B is also very well marked, with two reflections. The effect of corona attenuation is very pronounced at higher amplitudes of the surges, the slope of the wave-front being especially influenced.

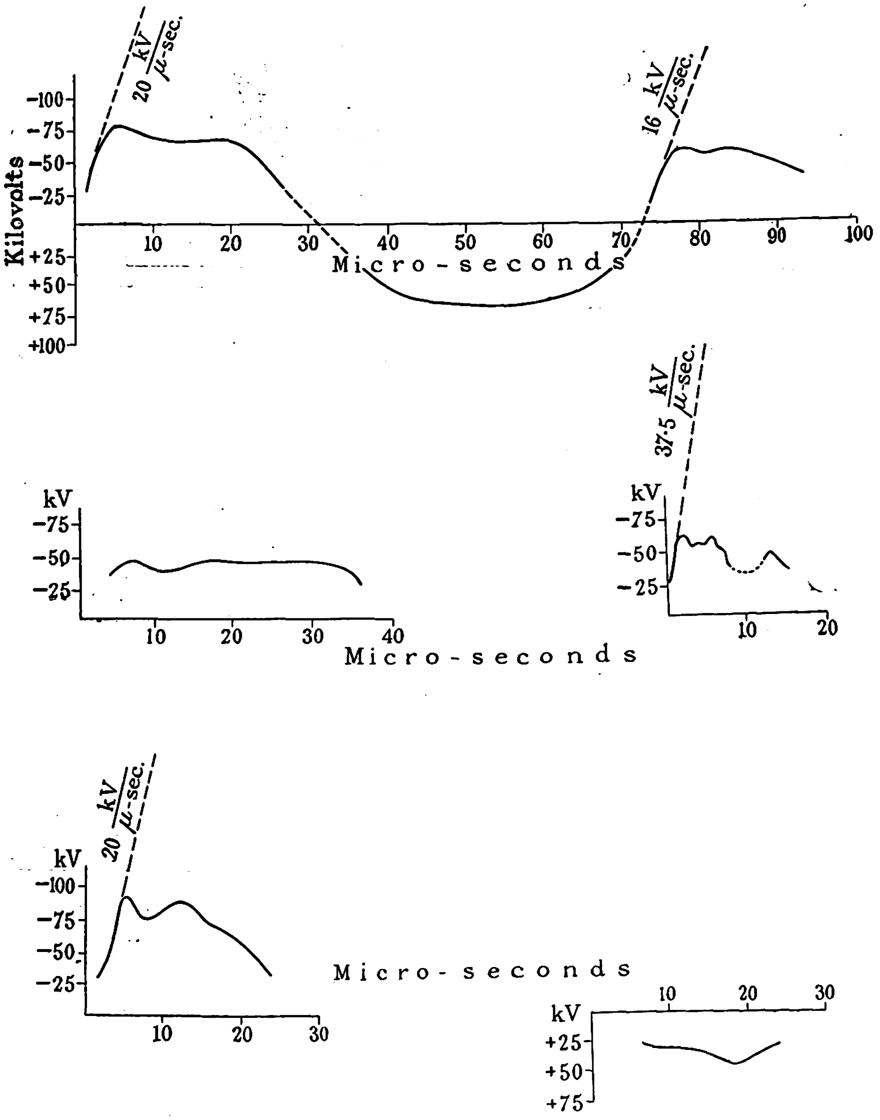

Fig. 16.

During 1926 we had no opportunity of recording lightning surges on transmission lines, but during the summer of 1927 we obtained several records under different conditions. These are shown in Fig. 11. Types A, B and C are pure surges. Type D is probably caused by some kind of natural oscillation of the line, produced by a distant surge. I can give no explanation of type E.

The most frequent surges were of the unipolar type, such as A or B. The slope of the wave-front was sometimes very steep, the peak value in some cases being attained within a few micro-seconds. In other cases the peak value was reached in 50 micro-seconds or more. It must be noted that the steepness of a wave-front depends upon the distance from its origin on the transmission line, and only surges generated quite near to the observation point will show very steep wave-fronts.

During 1928, researches were commenced in the United States with the type of oscillograph used in Uppsala. The Westinghouse Electric and Manufacturing Co. erected, in co-operation with the American Aluminium Co., two research laboratories in Tennessee on a 150-kV line. The first lightning surge recorded on this line had a total duration of 80 micro-seconds. The wave-front was very steep, with a peak value of 750 kV. During the season of 1929 three new stations were operated by the Westinghouse Co., and it is hoped that the results will soon be published. They are in good agreement with our own.

Last summer the Royal Board of Waterfalls Research Station was able to use an improved equipment, and some of the most interesting results are reproduced here in Figs. 12 to 15. Fig. 12 shows two lightning surges which occurred on the same transmission line within a short interval of time. The time scale of the original film on which they were recorded was 1 mm = 24 micro-seconds.

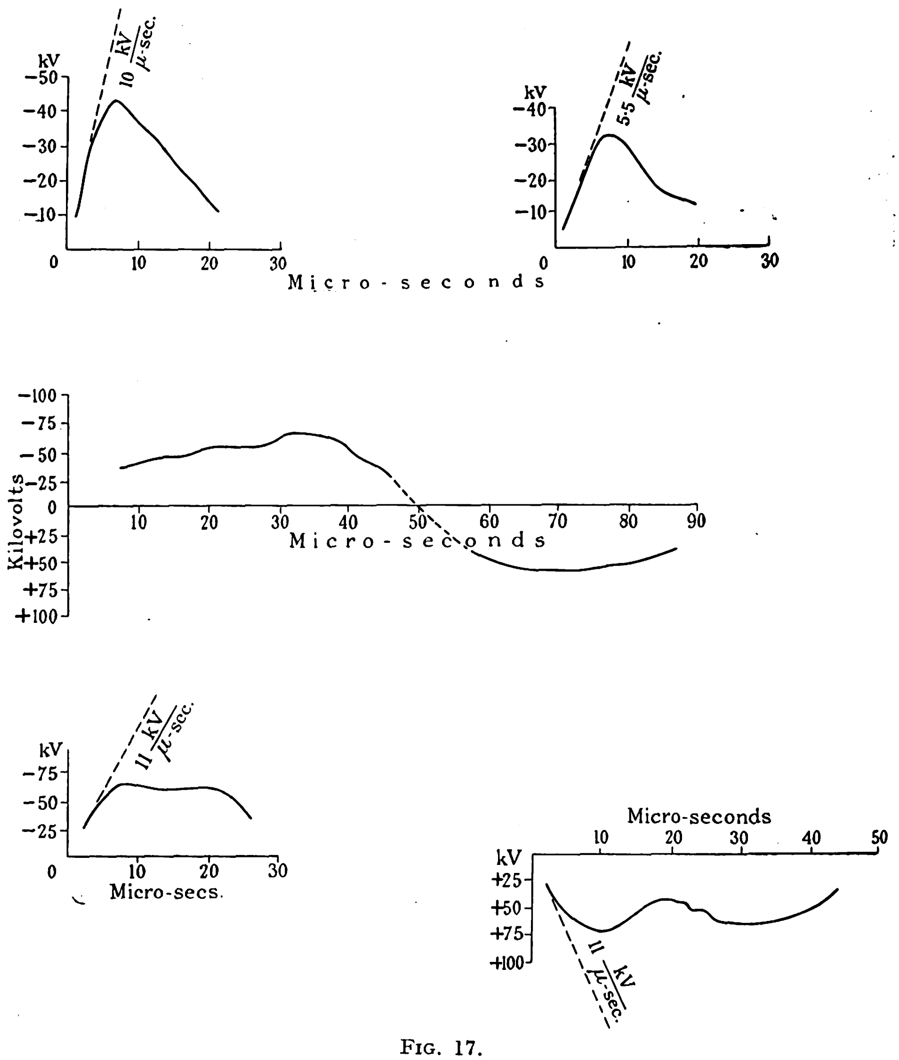

Fig. 17.

The two surges showed a very marked double polarity with a negative charge given to the line at the commencement. Their general character was similar, as can be seen from the records, and they were both produced from the same thunderstorm near the line and at 1 km from the laboratory. The total duration of the surges was about 100 micro-seconds. On the negative side of the surge A in Fig. 12 can be seen the top (2) of the wave reflected from the other end of the line after travelling 84 km, the attenuation thus being about 70 per cent. Some surge records are reproduced in Figs. 13, 14 and 15. For the time scale in these records an oscillator with sinusoidal time variation and with a frequency of 17 000 cycles per sec. was used. It will be seen that the oscillograph gave very sharp records for time intervals of the order of micro-seconds.

Some of the more interesting records have been replotted in Cartesian co-ordinates and are reproduced in Figs. 16 and 17.

For several of the surges the peak value is reached within 2 to 10 micro-seconds, but for others the increase of voltage is much slower. The steepest wave-fronts observed were 38 and 20 kV per micro-second. The total duration of the surges varied between 20 and 100 micro-seconds.

General Conclusions.

The records of lightning surges are hardly sufficient to enable us to obtain definite data, and much caution must therefore be exercised in interpreting the results.

Much work still remains to be done if our knowledge of the subject is to be complete. In the future we are sure to obtain results that are quite as variable in their general aspects as the physical conditions that govern them—the lightning discharges. The investigation of lightning surges will show us how to prevent their effects on transmission lines. The work may be divided into two stages: (1) rational research into the surges under natural conditions in the transmission lines, and (2) the reproduction of surges under controlled conditions in order to study their influence in distribution systems. We shall thus be able to determine the effectiveness or otherwise of protective devices against surges, and we shall also gain information in regard to the best method of constructing such devices.

A DIRECT-READING PHOTO-ELECTRIC PHOTOMETER FOR THE COMMERCIAL MEASUREMENT OF INCANDESCENT ELECTRIC LAMPS.[*]

By G. T. WINCH, Associate Member.

[COMMUNICATION FROM THE STAFF OF THE RESEARCH LABORATORIES OF THE GENERAL ELECTRIC CO., LTD., WEMBLEY.]

(*Paper first received 3rd July, and in final form 8th November, 1929.*)

SUMMARY.

This paper describes the practical difficulties experienced and overcome in the development and construction of a type of photo-electric photometer suitable for measuring incandescent electric lamps of the vacuum and gas-filled 10-watt to 100-watt types. Measurements are made on one direct-reading lumen scale. The apparatus is capable of measuring lamps at commercial speeds under continuous service conditions. The construction is simple and uses mainly standard component parts.

(1) INTRODUCTION.

Experiences in the development and maintenance of a precision photometric standardizing laboratory, coupled with the maintenance of a number of integrating photometers used for initial rating in a factory and measurements on incandescent electric lamps during life test, have shown that it is impracticable by visual means to reduce the probable error of such commercial measurements below ± 2 per cent, and errors up to ± 4 per cent are experienced in such routine work.

The continual improvement in lamp-making has created the need for higher accuracy in commercial photometry, combined with a high speed of measurement. Investigations in this direction were commenced in the summer of 1927 and the following developments have led to the construction of the simple and robust instrument shown in Figs. 1, 2 and 3.

The earlier work carried out in these laboratories,[†] and investigations at the National Physical Laboratory,[‡] had shown that photo-electric methods of measuring light flux and colour temperature can be devised that are far more sensitive and accurate than any visual method. These methods, however, are suitable only when a few observations have to be made by skilled observers. The problem with which this paper is concerned is that of developing photo-electric methods, necessarily of lesser accuracy, suitable for continuous use in the commercial testing of lamps. During the progress of this work important papers have been published describing various photo-electric photometers,[*] sometimes of a form generally similar to that described

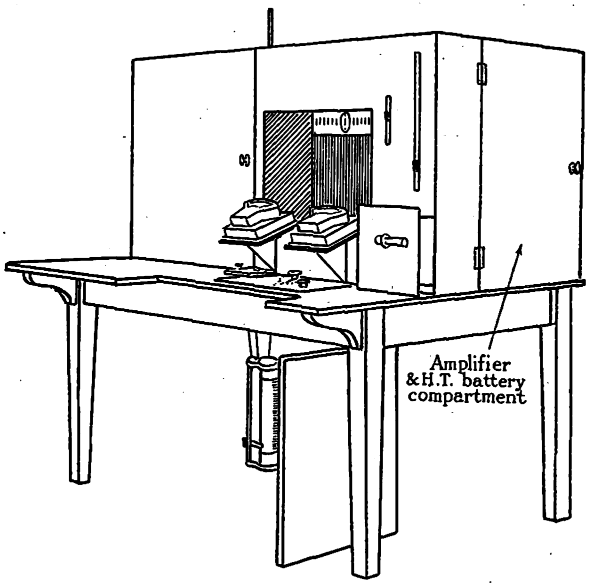

FIG. 1.

(2) DEVELOPMENT.

It was evident from earlier work * using vacuum cells that some revolutionary design was necessary in order to adapt photo-electric photometry to commercial needs. Owing to the small photo-electric current obtainable from the vacuum-type cells (i.e. 10^{-9} ampere) the gas-filled cell † promised greater possibilities for commercial work as it was more robust and gave a considerably greater photo-electric current.

In November 1925 Sharp had published a description of a photo-electric photometer utilizing a method which did not depend on the relation between illumination on the cell and the photo-electric current remaining constant for any appreciable period of time, and it seemed that a development of this method might be suitable for use with the gas-filled ‡ cells as developed up to that time. Such cells could not then be relied on to be sufficiently stable for use in any method depending on a constant relation between illumination and photo-electric current.

(3) THE PHOTOMETRIC INTEGRATOR.

In order to make clear the reasons for adopting certain lines of design of the photometric apparatus, it is desirable to refer to experiences with ordinary visual photometers. The result of careful visual investigations carried out by the author and his colleagues over a period of 3 or 4 years was communicated to the B.E.S.A. Committee on "Photometric Integrators." * These investigations showed the advisability of dispensing with diffusing glass windows in the wall of the integrator as a means of providing a test surface for determining changes of brightness of the inside wall of the integrator.†

† B. P. DUDDING and G. T. WINCH: *Journal of Scientific Instruments*, 1928 vol. 5, p. 312.

Hence in the work hereafter described the opal window has not been used but the cell has been generally arranged in a subsidiary integrator.

The study of the relative behaviour of cubical and spherical integrators had also shown that lamps having fairly uniform polar distributions, such as squirrel-cage vacuum and wreath type gas-filled lamps, when operated at the centre of a cube would produce results in agreement with those obtained in a spherical integrator, within ± ¼ per cent for squirrel-cage vacuum lamps and ± 1 per cent for wreath type gas-filled lamps. As the particular apparatus in course of development was intended for measuring commercially these types of lamp this accuracy was considered satisfactory for this purpose, as gas-filled lamps of normal design are subject to intrinsic light fluctuations of this order.

Throughout this development work on photo-electric photometers cubical integrators have been used for convenience and ease of construction. Substitution of a sphere in all cases herein described would not alter the principle or general structure of the apparatus but would increase the absolute accuracy of measurement on photometric standard lamps designed specially to avoid small variations in light output.

It would be advisable to use spherical integrators even for commercial measurements on lamps and fittings having asymmetric polar distributions.

FIRST EXPERIMENTAL APPARATUS.

The preliminary step was to study the behaviour of apparatus constructed on lines found by the author and his colleagues to be preferable for visual work, but employing the principles involved in apparatus described by Sharp,* in which he used a revolving mirror to illuminate the photo-electric cell alternately with the diffusing window in the integrator wall and the comparison lamp.

As it was not possible to obtain sufficient illumination on the photo-electric cell by adapting the preferred visual method which dispenses with a diffusing window, an arrangement was used in which the light flux received at the screened portion of the wall of the integrator containing the test lamp was allowed to enter a subsidiary integrator from which the cell received diffused illumination. The apparatus is shown diagrammatically in Fig. 4. A revolving shutter was so arranged that the subsidiary integrator received light, through two holes, alternately from the test lamp integrator and the comparison lamp.

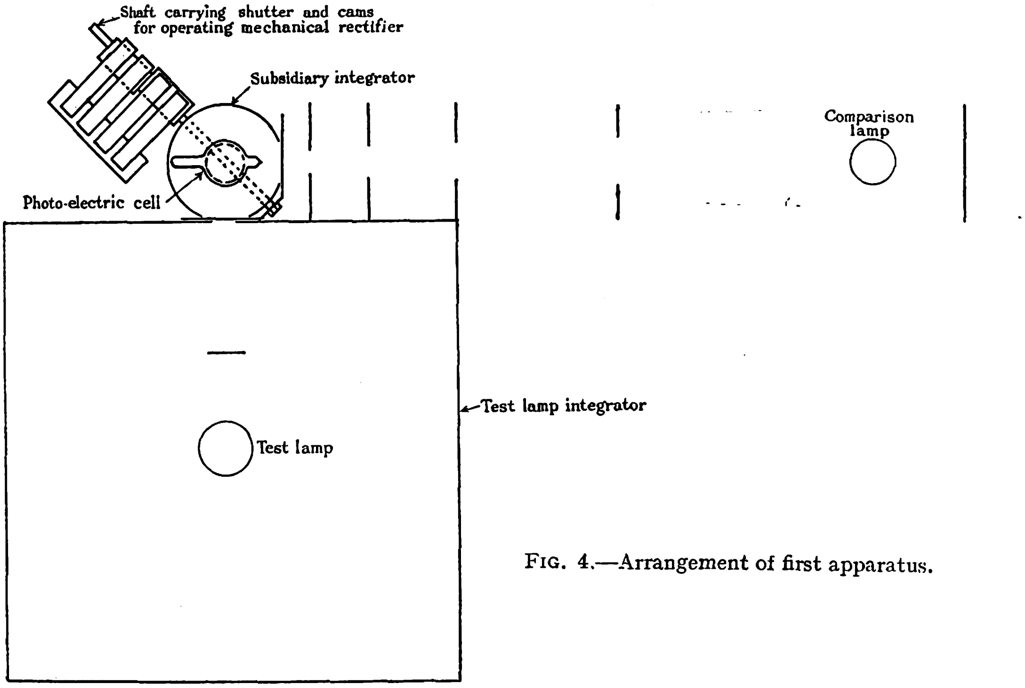

FIG. 4.—Arrangement of first apparatus.

The circuit used for the amplifier is shown in Fig. 5 and is similar to that used by Sharp.* It will be seen that the photo-electric cell is connected to the grid of one valve in the amplifier bridge, and consequently any change in intensity of illumination on the cell due to the alternate shutter positions produced corresponding alternations in an intervalve transformer connected across the valve bridge. The resultant low-frequency alternating current was rectified by a commutator arranged on the same shaft as the shutter and suitably timed. The rectified current operated a galvanometer which deflected to the right or left of zero, depending on the position of the comparison lamp with respect to a photometric balance.

The possibility of using valve rectification was considered but was rejected because with such an arrangement an opposing voltage would be required in order to bring the galvanometer to zero when a photometric balance existed. Also the indications of the galvanometer would always be in one direction irrespective of whether the illumination on the photo-electric cell was higher or lower than that required for photometric balance. This would be very inconvenient on a commercial photometer.

Originally the shutter was driven at a speed of approximately 200 r.p.m. by a small electric motor, but, despite the fact that the valves were in an earthed screened box, the disturbance of the amplifier due to the electric motor resulted in fortuitous kicks of the galvanometer. The motor was, therefore, replaced by a small air turbine.

Subsidiary integrator containing photo-electric cell

Fig. 6.—Arrangement of second apparatus.

The commutator used originally was of normal construction, having segments mounted on a shaft, and stationary brushes, but subsequently it was replaced by butt-ended contacts working from cams on the shutter shaft. This was tried in an endeavour to overcome contact troubles which manifested themselves in unsteadiness of the galvanometer.

The results obtained with this apparatus were rather disappointing as it was only with considerable difficulty that agreement could be obtained to within ± 1½ per cent on a few vacuum lamps (20–100 watts) of the squirrel-cage construction.

Two main difficulties were experienced with this apparatus:—

(*a*) *Electrical.*—Unsteady galvanometer readings due to erratic functioning of the commutating device and the necessary mechanical complications.

(*b*) *Photometric.*—As the result of using the subsidiary integrator to receive illumination from the comparison lamp through a small aperture, the resultant lumen scale did not follow the inverse-square law.

The latter is only a minor objection as it would have been possible to calibrate a scale, but considerable inconvenience was caused during experimental work owing to the impossibility of quickly determining the source of error. This difficulty had been anticipated but it was not thought that it would cause the inconvenience subsequently experienced.

SECOND EXPERIMENTAL APPARATUS.

With the object of overcoming the scale difficulty and improving the commutating arrangements, a new experimental apparatus was built incorporating the improvements shown diagrammatically in the general arrangement in Fig. 6. Pneumatically operated commutating gear was employed and three integrators were arranged so that two thin revolving sectors allowed the central small integrator, containing the photo-electric cell, to receive illumination alternately from the test and comparison integrators arranged on either side. A V shutter was arranged to control the light entering the test lamp integrator so that the lumen scale would be proportional to the movement of this shutter. All the apparatus was electrostatically screened in order to obtain freedom from external electrical disturbances. The best results obtained were with vacuum lamps over a range from 200 to 600 lumens, and the agreement was within ± 1½ per cent of the visual values. The lumen scale was limited in range owing to the lack of perfect integration when large changes were made in the window size by adjustment of the V shutter.

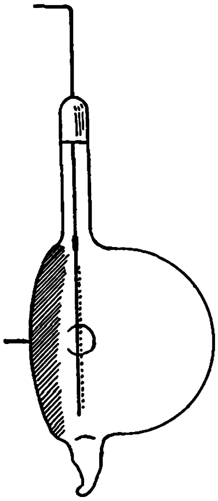

FIG. 7.

These results were not very satisfactory and the apparatus still involved mechanical complications which are always objectionable in an instrument to be used commercially where maintenance attention must be reduced to a minimum.

The inherent difficulties of the alternating light method led to the investigation of the possibilities of other more convenient methods.

THIRD EXPERIMENTAL APPARATUS.

The Red-Sensitive Cell.—At this juncture the red-sensitive photo-electric cell (Fig. 7) was developed,* and its more useful frequency range gave promise of important application to photometry. An investigation of the relation between illumination and photo-electric current indicated the possibility of a much simpler form of apparatus free from moving parts. In order to carry out these measurements an apparatus of the form shown in Fig. 8 was built. The circuit shown in Fig. 9 is a convenient form of amplifier which has been used by Sharp and others and consists of two valves connected in bridge form so that small changes in filament and H.T. voltage do not cause serious changes in the voltage between A_1 and A_2 (Fig. 9). It is clear from the diagram that if the grid bias G.B. is so adjusted, while the cell is dark, that a balance is obtained on the galvanometer, any subsequent change in grid potential due to the photo-electric current can be measured by the extra grid-bias voltage required to restore the bridge to the balanced condition indicated by zero deflection of the galvanometer. This grid-bias voltage, which is applied by means of the potentiometer, was originally measured by a voltmeter as shown in Fig. 9. Several lamps operating at the same colour temperature were put in the integrator in turn and the grid-bias voltage necessary to restore balance was measured. Over a range of 20 to 1 in lumens this method gave a linear relation between grid-bias voltage and lamp lumens.

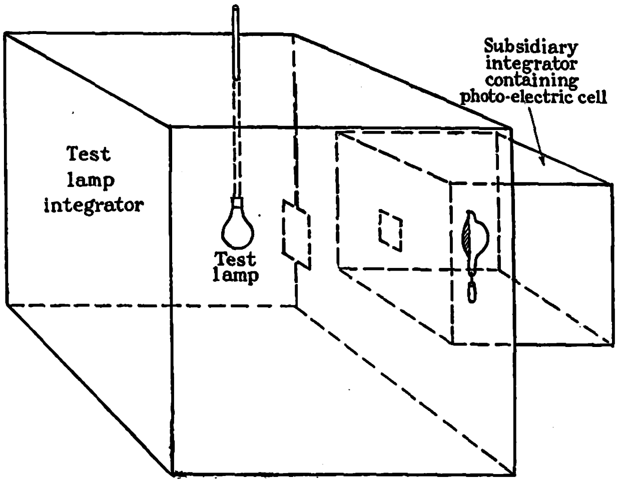

FIG. 8.—Apparatus used to test characteristics of photo-electric cell.

In the light of these promising developments, and owing to the disappointing results obtained from the apparatus involving rectification by commutation, this latter method was abandoned. Publications by Sharp and Smith * indicated that they had been experiencing similar difficulties which, however, they had eventually overcome by employing special, accurately made, commutating gear.

It was clear that some development of the arrangement shown in Fig. 8 would have the advantage of simplicity of design and operation, and it was this apparatus which formed the basis on which the final form of photometer was designed. The difficulties encountered in the perfection of this apparatus will therefore be discussed in detail, as an apparatus working on this principle has been in successful continuous operation for the past 6 months on the industrial measurement of large numbers of lamps.

Valves for the Amplifier.—Since valves were employed in all the apparatus using the commutation system to amplify the low-frequency alternating current produced as the results of the shuttering of the cell, drift of the valve characteristics had been unimportant and therefore great attention had not been given to the amplifier design. With the development of the method involving the measurement of changes of grid potential due to the photo-electric current, several difficulties were encountered, the most serious being that of the choice of suitable valves which would have characteristics sufficiently stable to avoid serious zero drift. This is important in industrial apparatus. Adjusting the zero with the cell dark is an operation which, if it had to be performed before each measurement, would probably outweigh all the advantages of such an apparatus.

D.E.L.610 valves were used in the earlier experiments, but the drift produced apparent changes in calibration of the order of 1 per cent per 10 minutes. Subsequent investigations with this type of valve showed that by operating it at 4 volts instead of 6 volts sufficient amplification could be obtained and the drift reduced to about 1 or 2 per cent per hour after having allowed a period of about 20 hours for them to reach a steady state. Providing the H.T. supply was never disconnected, the filaments could be switched off and when reconnected a period of 3 or 4 hours instead of 20 hours was required to reach the steady state. Drift of this order was still very inconvenient owing to the inevitable breaking of the H.T. supply to permit of battery charging. In an endeavour to overcome this difficulty many types of valves were tried, the most satisfactory being the D.E.5 B type, specially aged and selected for this purpose. These, if operated at 4 volts, were found to be free from serious drift about 1 hour after connection to H.T. and L.T. batteries. About 4½ volts negative grid bias corresponded to the correct working characteristics. Dry batteries used for this purpose need to be very carefully watched as they eventually develop unsteadiness which may at first be attributed to the photo-electric cell or to the lamps being tested. For this reason accumulator grid-bias and H.T. batteries are desirable.

Amplifier Circuit.—Certain minor objections were found to the circuit shown in Fig. 9 which, for the following reasons, was modified to that in Fig. 10. These objections were as follows:—

(*a*) As it would have been necessary to use a potentiometer with very smooth adjustment from about 0 to 0·6 volt, in order to obtain a measure of the light falling on the photo-electric cell (and therefore the lumens of the lamp under test), and furthermore because a voltmeter of this low range would have been required, it was simpler to use a potentiometer with calibrated dial and slide wire. This also had the advantage of being more accurate and easier to read to high precision.

Drum for adjusting calibration shutter

FIG. 11.—Arrangement of final form of photometer.

(*b*) When D.E.L.610 valves were used which would operate satisfactorily with their grids at earth potential, it was more convenient to adjust the galvanometer to zero by using a sliding resistance in series with one of the anode resistances of the valves so that the galvanometer tapping could be adjusted to obtain a balance (see G.T., Fig. 10). This avoided the necessity at the time for an extra accumulator and potentiometer, but as in the later experiments D.E.5 B valves were used which required a permanent grid bias of $4\frac{1}{2}$ volts, preferably from secondary cells, an adjustable grid bias would be equally convenient.

COLOUR CORRECTION.

The red-sensitive cell employed in this apparatus was found to give linear response with changes in illumination at constant colour temperature and to depart slightly from this relation with lamps operating at colour temperatures varying from about 2 350° (vacuum lamp colour) to 2 700° C.[*] (small-wattage gas-filled lamp colour). There also appears to be a slight drift in the response to such changes of temperature. Hence a suitable variable colour filter was needed to correct this error if it were required to measure lamps operating at various colour temperatures within the range mentioned above, without the application of a correction for colour. The requirement was met by the use of a Wratten colour filter (colour not critical but dependent on particular integrator paint and cell used) arranged to slide vertically over the aperture between the two integrators W.F. (Fig. 11). The area of aperture covered by this filter is adjustable by the knurled nut K which raises or lowers the filter.

The final form of the apparatus is shown in Figs. 1, 2 and 3.

LUMEN SCALE CALIBRATION.

There are two methods of adjusting the potentiometer P (Fig. 10) to read direct in lumens:—

(*a*) By varying the value of the grid leak G (Fig. 10) and thus varying the sensitivity of the amplifier.

(*b*) By varying the amount of light entering the photo-electric cell.

A compromise between these two methods was found to give the most satisfactory results. The grid leak had a total value of about 60 megohms [*] which could be tapped at approximately 40, 50, 55 and 60 megohms. This gave a suitable sensitivity with the colour filter in its normal position.

In order to obtain fine adjustment so that the potentiometer could be made to read correct values, a thin aluminium shutter was arranged between the two integrators S (Fig. 11) moving at right angles to the colour filter. This could be varied without altering the ratio of filtered to unfiltered light entering the photo-electric cell integrator.

It was found possible by use of this shutter to halve the normal working lumen scale and so make possible the measurement of lamps having lumen values in excess of the normal full-scale value (1 500 lumens).

THE APPARATUS IN USE.

The photometer is very simple to use and for routine measurements is capable, with one operator, of handling 150 lamps per hour. It is found convenient to leave the valve filaments and H.T. batteries connected day and night as this reduces the time wasted when waiting for the batteries and valves to reach the steady state. Filament batteries are charged at week-ends and the H.T. and potentiometer batteries need charging only about once a month, so that inconvenience of charging is not great. Automatic charging equipment to operate during the night or week-ends is scarcely necessary but could be installed if necessary.

METHOD OF CALIBRATION.

Calibration of the apparatus is carried out in the following manner:—

(*a*) The colour sensitivity is conveniently checked by using two standard lamps calibrated at voltages such that they both have the same or closely similar values

---

of lumens but operate at temperatures of about 2 350° K. and 2 700° K. respectively. These lamps represent the limits of the working range of colour temperature of lamps normally measured on this photometer. The colour filter is then adjusted until the two lamps balance at their nominal value on the potentiometer.

(*b*) The potentiometer is next set to zero and the galvanometer balanced by adjusting the position of the bridge arm tapping G.T. on the sliding resistance (Fig. 10) while the cell is dark.

(*c*) A standard lamp is then put in the photometer, the potentiometer scale adjusted to the value of lumens of the standard lamp and the galvanometer balanced by adjusting the sliding shutter S (Fig. 11). The photometer is then ready to measure lamps of vacuum and gas-filled types from about 80 to 1 500 lumens.

The vacuum lamps were of squirrel-cage construction free from internal contact variations.

The gas-filled lamps had a special construction which rendered them free from momentary small fluctuations. They also had a symmetrical polar distribution in order that the effect of imperfect integration of the cubical integrator might be reduced to a minimum.

(5) VISUAL CALIBRATION OF STANDARD LAMPS.

These specially prepared lamps were calibrated visually in the photometric standards laboratory, where electrical measurements are to an accuracy of 2 parts in 10 000. Photometric measurements were then made in a 1-metre sphere against 110-volt, 20-, 40- and 60-watt vacuum lamps which had been standardized by the National Physical Laboratory.

TABLE 2.

(*d*) Measurements can now be made by substituting test lamps in the integrator and balancing the galvanometer by adjusting the potentiometer, which will then indicate the lumen value of the lamp.

(*e*) By suitably closing the sliding shutter the photometer can conveniently be made to read double the actual scale values, thus extending the lumen range to 3 000 lumens.

(4) COMPARISON OF PHOTO-ELECTRIC AND VISUAL MEASUREMENTS.

From the experience gained with this apparatus it has been found useless to compare the relative accuracy of visual and photo-electric measurements by individual results obtained on normal commercial lamps. This is because of the continual small changes inside the lamps, which cause lumen fluctuations. For such comparisons a special set of light standards was made.

The vacuum lamps were measured by two observers on four separate occasions and the gas-filled lamps by six observers on two separate occasions so as to minimize the error introduced by the colour difference.

Each observer's reading on any one occasion is the mean of six settings.

(6) RESULTS OF VISUAL AND PHOTO-ELECTRIC MEASUREMENTS.

The results of the visual measurements on vacuum lamps are given in Table 1, together with values obtained on the photo-electric photometer. The means of the visual observations are given in col. 8. Col. 9 contains two sets of observations measured photo-electrically, using a large sub-standard voltmeter to set up the lamps.

Col. 11 contains results obtained by using a normal sub-standard precision voltmeter with which the apparatus is ordinarily equipped to set up the lamps, the observations being representative of the normal accuracy obtained.

Table 2 contains the individual observers' visual values for the gas-filled lamps together with the photo-electric measurements, the voltage being measured to the same degree of accuracy.

(7) Discussion of Results.

It will be seen from the tables that when a large sub-standard voltmeter was used to set up the lamps the accuracy of repetition was better than ± 0·5 per cent. The deviation from the mean visual value in several cases is greater than ± 0·5 per cent, but it is obvious from the individual visual values that the mean value of this deviation for individual lamps may possibly be as great as 1 per cent in a few cases, and it seems probable that the mean of the photo-electric values given in col. 10 of Table 1 are more nearly the correct values than the mean of the visual values. This seems highly probable when it is realized that the mean error of all results given in col. 10 of Table 1 is − 0·1 per cent from the mean visual values for all lamps.

In the case of the measurements given in col. 11 of Tables 1 and 2, where a normal sub-standard voltmeter was used for setting up the lamps, the photo-electric values are in agreement with the mean visual values within ± 1 per cent and the mean deviation from the visual values is + 0·37 per cent.

(8) General Survey of Experiences Gained During Six Months' Daily Use of the Photo-Electric Photometer for Commercial Measurements.

The existing apparatus, shown in Figs. 1 to 3, has given general satisfaction in regular service and the following points cannot be over-emphasized in connection with the design of such apparatus for commercial use.

In order to ensure trouble-free working the apparatus should be designed as a complete unit and attention to the following details is essential.

(*a*) The whole of the photo-electric cell circuit, amplifier, potentiometer, batteries and wiring, must be thoroughly screened from electrical disturbance.

(*b*) The highest insulation is desirable in the photo-electric cell and grid circuits. Stiff wire, mainly air-insulated and held at intervals in sulphur bushes, is very satisfactory.

(*c*) All batteries should be of secondary cell type, as sooner or later dry cells will give inconsistent results even when used as grid bias.

(*d*) All component parts should be rigidly fixed in relation to the surrounding screening, as movement of apparatus due to vibration may result in variable charges being impressed on the grid of the amplifying valves. In this connection it is found that the valves themselves are sensitive to heavy vibration of the apparatus even when mounted in holders on sorbo rubber, and it is desirable to "nest" them in cotton-wool in order to overcome this trouble. It might be wise, in a design required for use under factory conditions, to mount the whole of the cell and amplifier equipment on a mounting separate from the photometric integrator equipment in order to insulate the valves from shock.

(*e*) The potentiometer, whilst being electrostatically screened, should be easily accessible as it is submitted to very strenuous treatment. It should, therefore, be designed accordingly.

(*f*) It is essential that suitable valves should be used for the amplifier, otherwise very serious inconvenience may be suffered and spurious results obtained. The valves at present found most suitable for this work are specially selected D.E.5.B type with the filaments operated at 4 volts. In cases where the highest precision is required it is advisable to use the valves uncapped in order to secure the best insulation. For commercial work, valves carefully capped with caps slotted between the contact pins in order to reduce surface leakage have given satisfaction.

(*g*) Best-quality grid leaks and anode resistances should be used in order to ensure freedom from amplifier variations.

The results of this development work have suggested many possibilities in photometric technique. Whilst the eye must, of necessity, be the ultimate source of reference there seems every reason to hope that in the near future commercial and sub-standard photometry will nearly always be carried out photo-electrically. This should result in increased accuracy and speed, and at the same time it should decrease eye fatigue in the laborious task of visual photometry.

As an instance of the saving of time without loss of accuracy, the measurements given in Tables 1 and 2 occupied the equivalent of 5 observers for 4 days, apart from the time taken to calculate the results. This same series of measurements was carried out photo-electrically by one observer in about 4 hours and no calculations were involved. There is every reason to believe that if an apparatus were built for precision work, incorporating spherical integrators and further improved electrical arrangements for setting up the lamps, still higher accuracy could be obtained.

THE DEVELOPMENT OF A PRECISION AMMETER FOR VERY HIGH FREQUENCIES.[*]

By E. B. MOULLIN, M.A., Associate Member.

(*Paper first received* 6*th November*, 1929, *and in final form* 15*th January*, 1930.)

SUMMARY.

This paper describes the principles and development of an ammeter which has been made for measuring current of very high frequencies, such as 30 000 kilocycles per sec. The instrument is of the dynamometer type and has a geometrical form for which all the changes of current distribution can be calculated. The correcting factors approach a limiting value and do not increase continuously with frequency as they do in thermal instruments. A special feature of the design is that an instrument can be made to carry unshunted a current of any magnitude. This removes all uncertainty about shunting ratio and so the instrument should be more reliable than one in which the current is supposed to divide evenly among a number of resistance wires in parallel.

Methods are described for checking the calculated correction factors and there are also some calibrations at frequencies round about 1 000 kilocycles per sec. In addition, measurements are described of the high-frequency resistance and of the inductance and terminal capacity.

(1) INTRODUCTION.

The difficulty of measuring currents of very high frequency has again been made prominent by the development of short-wave telegraphy. The instruments in use at present are no doubt relatively correct at any one frequency, but possibly they may have an appreciable frequency error. Thermal instruments, with or without a current transformer, have been used almost exclusively for measuring radio-frequency currents, and, since the resistance of all conductors increases continuously with frequency, all such instruments must become progressively more sensitive as the frequency rises. The heated element is made from a wire the diameter and material of which are such as to make the probable increase of resistance small at the highest frequency required, but when frequencies of the order of 10^8 cycles per sec. are contemplated the wire must be so fine that it can scarcely carry a current of 1 ampere. Many wires must be placed in parallel, and then it is difficult to ensure that the fraction carried by each one is independent of frequency. To this end, usually the wires are arranged as generators of a surface of revolution, for example a cylinder, hyperboloid or double cone. Given perfection of manufacture this device must achieve the required result in respect of the effect of one wire on the others, but it affords no protection from a magnetic field penetrating the whole cage. If the cage is placed concentrically within a long and thick screen tube of copper, then the current will divide evenly between all the wires at all frequencies and in all circumstances. The instrument will still have a frequency error due to the increase of resistance of each wire, but this should be calculable with a high degree of accuracy. It will have a further frequency error due to capacity effects, and this may not be readily calculable.

The author has been concerned in making an ammeter which can carry a current of any magnitude unshunted and which has a geometrical form for which the various frequency corrections can be calculated exactly. Uncertainty in respect of unconstant shunting ratio is then removed entirely and the frequency corrections are known and are, in fact, very small. This ammeter has been described already [*] and the analysis of the various correction factors developed in great detail. Since then considerable experience has been gained in the construction and use of the instrument, and this paper is concerned chiefly with such recent developments. It will be necessary first to describe briefly the principle of the instrument and to enumerate the cause and magnitude of the three separate frequency corrections, after which the constructional details and methods of testing will be given.

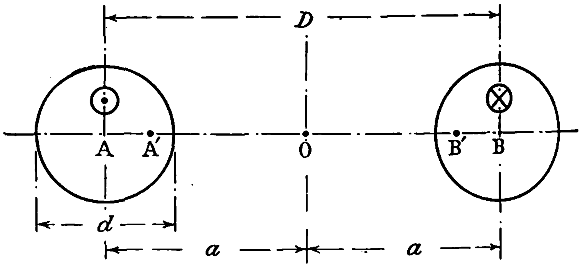

FIG. 1.

(2) ELEMENTARY SYSTEM OF THE AMMETER.

Consider two long, straight, solid circular cylinders of diameter d, placed parallel to one another at a distance D apart, and let them carry the same current in opposite directions; the system is shown diagrammatically in section in Fig. 1. The two cylinders will repel one another with a force $F = 2i^2/D$ per unit length if the current i is distributed uniformly over the cross-section. If the current is alternating and of R.M.S. value I, the mean value of the repulsive force is $F = 2I^2/D$. If the force can be measured in any convenient manner the system becomes an ammeter which can be calibrated with steady current and used to measure alternating current. But an alternating current is not distributed uniformly over the cross-section, and the force is no longer given accurately by the equation $F = 2I^2/D$ and the instrument requires a frequency correction. In the limiting condition of infinite frequency or perfect conductivity there is no magnetic field within the cylinders and then each circumference must coincide with a line of force. It is well known that each circumference would coincide with a line of force of two line currents situated at the points A′ and B′ which are mutually inverse points for the circles centred at A and B. So ultimately we have

---

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[*] *Proceedings of the Royal Society*, A, 1928, vol. 121, p. 41.

$$F = \frac{2I^2}{\mathrm{A'B'}} = \frac{2I^2}{\sqrt{(D^2 - d^2)}} \quad . \quad . \quad . \quad (1)$$

We see that the ultimate increase of force is small so long as D is considerably greater than d.

A frequency correction which comes to a limiting value is in striking contrast with the frequency correction for thermal ammeters, which does not come to a limiting value but increases continuously. Furthermore, the limiting correction is sensibly attained at finite frequencies. Very complicated analysis is required to express the force as a function of frequency, but the result is expressed by the following series:—

TABLE 1.

D/d	F_0	F	F/F_0
1½	1·296	1·340	1·032
2	1·13	1·15	1·02
3	1·048	1·06	1·01
4	1·026	1·031	1·005

$$F = \frac{2I^2}{D}\left\{1 + \frac{1}{2}\frac{d^2}{D^2} + \frac{3}{8}\frac{d^4}{D^4} - \frac{1}{\sqrt{2z}}\cdot\frac{d^2}{D^2}\left(1 + \frac{d^2}{D^2}\right) + \ldots\right\} \text{with } z > 3\cdot5 \ldots \quad (2)$$

where we have the well-known parameter $z^2 = \pi\omega d^2/\rho$, in which $\omega = 2\pi f$ and ρ is the resistivity of the material. Substitution in (2) will show that the limiting value has sensibly been attained when z is, say, greater than 10, and this is illustrated by Table 1, in which F_0 is the force for zero frequency.

So if $D/d = 3$ the limiting increase is less than 6 per cent and this has been attained within about 1 per cent of itself when $z = 10$. This will occur at frequencies less than 300 kilocycles per sec. for all copper wires larger than No. 16 S.W.G.

But the two cylinders, as depicted in Fig. 1, will inevitably be situated in a magnetic field arising from the remainder of the circuit, and this field will produce an additional force. Therefore the wires must be shielded from external fields by placing them within a thick copper tube in the manner shown diagrammatically by Fig. 2. This tube will prevent the penetration of any external field, but the currents situated at A and B will induce in the screen tube eddy currents whose field will modify the force on the wires. The screen tube is comparable with the short-circuited secondary of a transformer, and so the currents in it are substantially in antiphase with the currents at A and B. The field between A and B due to the eddy currents in the screen is therefore opposed to the field created by the currents at A and B and consequently lessens the force on each. If the small non-uniformity of current density round the circumferences of the cylinders at A and B is now ignored, it follows readily that in the limit the field of the eddy currents within the screen tube is the same as would be the field of image currents placed at A′ and B′, the inverse points of A and B with respect to the circle of radius r centred at O. It follows from this that

$$F = \frac{2I^2}{D}\left(1 - \frac{4\mathrm{OA}\,.\,\mathrm{OA'}}{\mathrm{A'B}\,.\,\mathrm{B'B}}\right)$$
$$= \frac{2I^2}{D}\left(1 - \frac{4r^2a^2}{r^4 - a^4}\right) \quad . \quad . \quad . \quad . \quad (3)$$

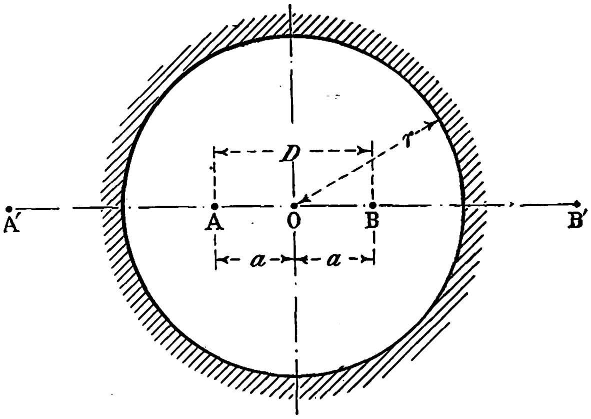

FIG. 2.

Since the eddy currents in the screen reduce the force between the cylinders, they tend to counteract the increase of force due to non-uniform current distribution round the cylinders. We may superpose the two effects without sensible error (see Appendix), and since $r >> a$ and $D > d$ the two effects will neutralize each other approximately when a, r, etc., are so chosen that $D^2 = rd/\sqrt{2}$. If $r/a = 8$ (approx.), then in the limit either effect by itself would change the force due to a specified current by about 6 per cent, or the current required for a given force would differ by 3 per cent from that required at zero frequency, since the force varies as the current squared. The difference between two approximately equal effects, each comparatively small in value, must be a quantity of negligible magnitude. The effect of the screen approaches close to its limiting value at a frequency of a few hundred cycles per second, but this may be considered more appropriately later.

We now have to consider the effect of longitudinal distribution, which is important only when the length of the system is comparable with the wavelength. Two parallel cylinders which are not in a screen tube may be represented by the circuit system shown diagrammatically by Fig. 3, which represents a uniform short-circuited line of length l and having a capacity and inductance per unit length of C and L respectively. If the current entering at A is $-I\cos\omega t$, and that leaving at B is $I\cos\omega t$, it is well known that the current i at a distance x along the line is given by the equation

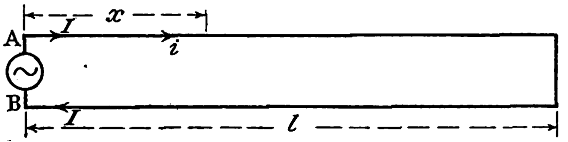

FIG. 3.

$$i=-I\frac{\cos\omega a(l-x)}{\cos\omega al}\cos\omega t$$

where $a=\sqrt{(LC)}$. The voltage between the ends of the line is expressed by the equation

$$v=\frac{I}{2}\sqrt{\frac{L}{C}}\frac{\sin\omega a(l-x)}{\cos\omega al}\sin\omega t$$

(The resistance of the line is ignored, but this makes only a second-order difference to the current distribution.)

If the surrounding medium has unit permeability and dielectric constant ϵ, and if c is the ratio of the electromagnetic to the electrostatic absolute unit of current or charge, then for a parallel-wire system we have $LC=\epsilon/c^2$. The force per unit length between the cylinders is a repulsion of value $2i^2/\sqrt{(D^2-d^2)}$ due to the magnetic field and an attraction of value $2q^2/\epsilon\sqrt{(D^2-d^2)}$ due to the electrostatic field. Hence for the electrostatic attraction F_e we have

$$F_e=2\cdot\frac{4C^2v^2C^2}{\epsilon\sqrt{(D^2-d^2)}}=\frac{2I^2}{\sqrt{(D^2-d^2)}}\frac{\sin^2\omega a(l-x)}{\cos\omega al}\sin^2\omega t$$

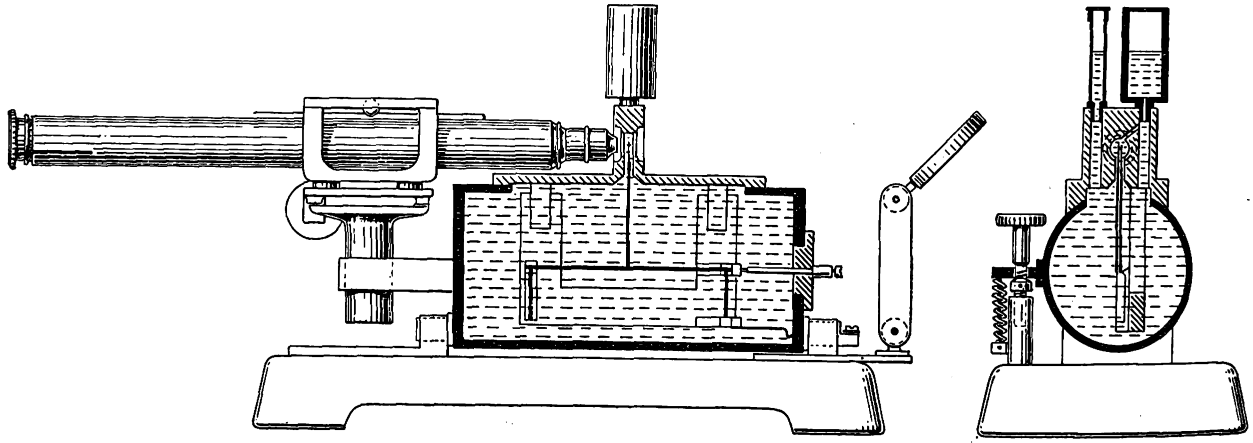

FIG. 4.

and so for the mean total force we have

$$F=\frac{I^2}{\sqrt{(D^2-d^2)}}\int_0^l\frac{\cos^2\omega a(l-x)-\sin^2\omega a(l-x)}{\cos^2\omega al}dx$$

$$=\frac{I^2}{\sqrt{(D^2-d^2)}}l\frac{\tan\omega al}{\omega al}\quad .\quad .\quad .\quad .\quad .\quad (4)$$

$$=\frac{I^2l}{\sqrt{(D^2-d^2)}}(1+\tfrac{1}{3}\omega^2a^2l^2+\tfrac{2}{15}\omega^4a^4l^4)$$

$$\text{approximately, if } \omega al<<1\quad .\quad (4a)$$

Equation (4a) may be interpreted more readily in terms of wavelength than of frequency. When $\pi al=\frac{1}{2}\pi$ the length of the system equals a quarter wavelength of current; since the system is immersed in a dielectric of constant ϵ the length of the current waves on it are thereby made $1/\sqrt{\epsilon}$ of the length they would have in a dielectric of constant unity. Let the wavelength in free space, corresponding to a frequency $f=\omega/(2\pi)$, be λ. Then we may rewrite (4a) as follows:—

$$F=\frac{I^2l}{\sqrt{(D^2-d^2)}}\left(1+\frac{4}{3}\cdot\frac{\pi^2\epsilon l^2}{\lambda^2}+\frac{32}{15}\cdot\frac{\pi^4\epsilon^2l^4}{\lambda^4}\right)\quad .\ (5)$$

So if $\epsilon=2$ and $l/\lambda=1/25$ the force is 4·5 per cent greater for a given current than it is at zero frequency. We are contemplating a system in which l is about 20 cm, and then a given current will produce 2·2 per cent more deflection at a wavelength of 5 m than it did at zero frequency. The correction term is therefore quite definite and calculable but it is so small as to be unimportant for the wavelengths in use at present.

This analysis is incorrect for a system enclosed in a screen tube. The correct analysis has been developed,* but it is very complicated and it is unnecessary to reproduce it in this paper. When the system is in a screen tube the point B in Fig. 3 will be connected to the screen, and then the complete analysis shows that the correcting factor within the screen differs insensibly from that calculated from (5), provided l is replaced by $2l$. So if the instrument has been arranged with $D^2=rd/\sqrt{2}$, the only resultant correcting factor is that due to longitudinal distribution of current: for a system 20 cm long this will not have reached 2·5 per cent even when the wavelength is reduced to 10 m.

---

* *Proceedings of the Royal Society*, loc. cit.

(3) CONSTRUCTIONAL DETAILS OF THE AMMETER.

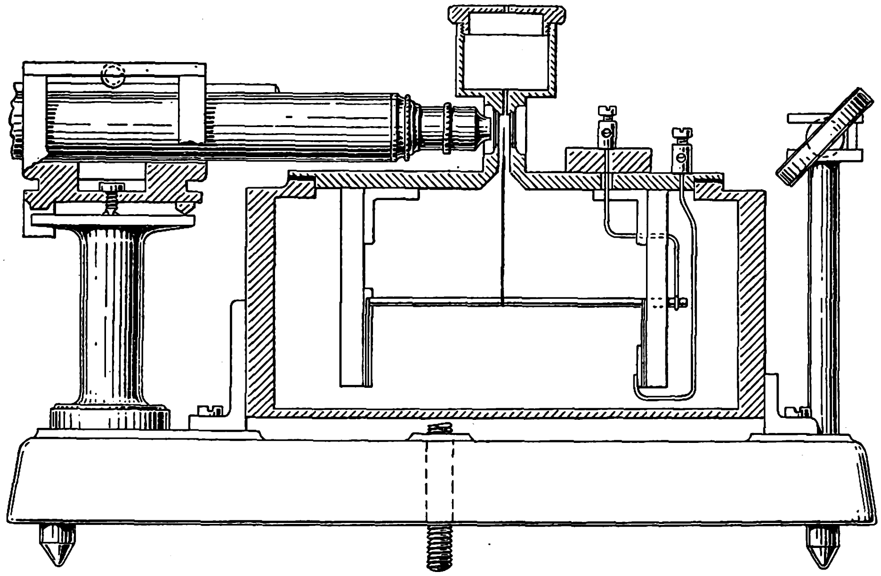

FIG. 5A.

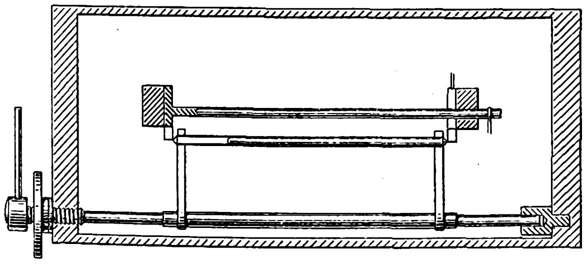

FIG. 5B.

So far only two of these ammeters have been made, the first for currents up to about 2 amperes and the second for currents up to about 25 amperes. A longitudinal and transverse section of the first instrument is shown in Fig. 4 and two longitudinal sections of the second instrument in Figs. 5A and 5B. These drawings show clearly the arrangement of the cylindrical copper screen tube, which in both instruments is 3 mm thick and 77 mm internal diameter and 190 mm long. One cylinder is fixed rigidly to an ebonite frame attached to the under side of the thick copper cover-plate of the screen tube. The other cylinder stands on spring legs which conduct the current to it and also provide most of the elastic constraint to resist the repulsive force between the two cylinders. The repulsive force of the current moves the two cylinders further apart and it is this spread which provides the indication of the ammeter. The repulsive force is very small, about $2I^2/10^4$ grammes weight in the instrument of Fig. 5, and this necessitates the spring legs being weak and the total spread very small. The spread is measured by observing with a microscope the movement of a thin quartz pointer attached to the middle of the moving cylinder. This pointer passes through a hole in the cover plate of the screen and is viewed through a glass window in a small chamber. The arrangement of pointer, window and microscope may be seen in Figs. 4 and 5 and requires no further explanation. The pointer tip magnifies the movement of the cylinder about five times; the microscope has a 1-inch objective with a 10-inch tube length and an eyepiece scale 1 cm long divided into 100 parts. Consequently the maximum spread of the cylinders is about 0·2 mm, and this is 2 per cent of their central distance for the instrument of Fig. 5. If the spread is x, then the law relating x to the current I is

$$I = A\sqrt{x}(1 - \tfrac{1}{2}x/D),$$

and this differs inappreciably from a simple square law since the greatest value of x/D is only 2/100. Also it is clear from equations (1) and (3) that if D increases by 2 per cent there is a negligible change in the correction factor. In the instrument of Fig. 5 the correction factor would change from zero at no deflection factor to + 0·25 per cent at full scale. The spring legs are made from standard cadmium-copper alloy, and this is a great improvement on the phosphor-bronze used originally in the small instrument. The cadmium-copper strip is 3 mm wide and 0·08 mm thick in the 25-ampere instrument and 0·5 × 0·035 mm in the 2-ampere instrument. The current density in the strips is very high, about 11×10^3 amperes per cm^2, and for this reason the whole screen tube is filled with a high-grade oil. Besides helping to cool the strips, the oil damps the movement and makes the instrument dead-beat and at the same time makes a cushion for the movement when the instrument is carried about. The 2-ampere instrument would be very fragile without the oil; but with the oil it is perfectly portable and has withstood several long journeys standing unpacked on the floor of a light motor-car. The 25-ampere instrument is thoroughly robust and would not need oil to make it portable; the comparatively heavy cylinder renders a clamp desirable and its arrangement is shown in Fig. 5B. Two light phosphor-bronze fingers are fixed to the clamp rod, and a quarter-turn of this lifts the fingers so that the cylinder is cradled in forks at their ends. It will be noticed that the end bearing of the clamp rod is of ebonite, and this prevents a flow of induced current along the rod and back by the screen.

The terminal arrangement differs from that illustrated in Fig. 4 and will be discussed later.

The oil immersion is useful also for reducing the load carried by the spring legs, and in the 2-ampere instrument these are in tension. At the same time it reduces sensitivity as it reduces the gravity control, which control is negative when the net weight is positive.

In the small-current instrument the moving cylinder is an aluminium tube 10 cm long and having an external diameter of 1·1 mm with walls 0·025 mm thick. In the large-current instrument it is a tube of copper-alloy (verging on brass) 10 cm long, 3·19 mm external diameter and having walls 0·4 mm thick and weighing about 2·5 grammes in oil.

The force of gravity is used to place the cylinders at the exact central distance obtaining at the time of testing and calibration. A fixed fiducial pointer is mounted inside the pointer chamber, and the microscope, which has a short cross-traverse, is placed so as to bring the fixed pointer exactly at one end of the eyepiece scale. The levelling screw, shown in Figs. 4 and 5, is then turned until the gravity control brings the moving pointer to the other end of the scale; this setting is taken as standard. Having set the pointers, the microscope is further cross-traversed until the fixed pointer has moved out of the field of view and the moving pointer stands at the zero of the eyepiece scale. The width of the pointer chamber is such that the central distance of the cylinders cannot change by more than 0·6 mm in 10 mm, and experiment with the larger instrument shows that a given current can produce an extreme range of deflection of ± 5 per cent above and below the mean and ± 1 per cent in the smaller instrument. The setting-up process therefore does not require to be done with very great care.

It was found that a deflection due to heating was present in the 25-ampere instrument (but not in the 2-ampere instrument). This was traced to imperfect parallelism of the spring legs. The mounting has been fitted with an adjustment which twists slightly the bottom of one spring. The slow drift deflection due to heat effect can be made positive or negative by this adjustment, which is so set as to make it zero before the instrument is sealed up. Experience shows that this adjustment remains permanent. In addition to this there may possibly be a slow drift of about 2 mm due to convection currents in the oil. Apparently this can often be neutralized by slight adjustment of the levelling screw. However, searching tests show that if the deflection is observed and the zero is read at the instant of switching off, a given current produces the same deflection consistently to within less than ± 0·3 mm in 100 mm. This means that full-scale deflection represents a given current to within ± 0·15 per cent, and so the instrument justifies the correction factors which are to be applied to it.

The pointer chamber is fitted to take a condensing lens so that the image of the pointer may readily be thrown on a screen. The instrument is perhaps more convenient to use in this manner and there is a large gain in the obtainable accuracy of reading.

The pointer chamber is surmounted by a cylindrical reservoir to form a breathing chamber for the oil.

(4) CALIBRATING AND TESTING THE AMMETER.

It is not easy to set up the system on its spring legs so that the cylinders are at precisely the desired distance apart, and it is desirable to check this distance after the ammeter has been sealed up in its case. This may be done by placing parallel currents at external points such as A′ and B′ in Fig. 2. Thus, referring to Fig. 2, let there be a winding of N turns with its sides at A′ and B′ and connected in series with the ammeter in the sense to reduce the deflection. By a suitable choice of N and the distances AA′, BB′ it is easy to make the deflection almost zero for any current. A permanent magnet should be placed near the ammeter to neutralize the vertical component of the earth's magnetic field. The method of adjustment is to approach the magnet until there is no change of deflection on reversing the direction of a steady current of given value. (Note that during this adjustment the external winding is cut out.) If this adjustment is imperfect, so that a small remaining field V produces a difference of deflection which is a fraction y of the mean deflection due to a current I, then we have $VD/(2I) = y$. Now let the external winding be put in series with the ammeter, having one coil side at a distance b from A, in Fig. 2, and the other at a distance b'. Also let the deflection due to I be now a fraction x of its value without the external winding, then it follows readily that

$$D = \frac{(1 + x)\,(1 + y)bb'}{N(b + b')}$$

$$= \frac{bb'(1 + x + y)}{N(b + b')}$$

since both x and y are very small. So by measuring b and b', D may be deduced. Naturally the system will be arranged with b nearly equal to b', and then it is worthy of notice that a given fractional error in measuring b makes a very much smaller fractional error in the value deduced for D. So D may be deduced to about the same accuracy that $(b + b')$ can be measured. As an example of such a test in the 25-ampere instrument, $x = 2\cdot9$ per cent, $y = 0\cdot8$ per cent, $bb' = 18\cdot4$ cm, $b = 6\cdot8$ cm and $N = 4$, whence we find $D = 1\cdot11$ cm. The internal diameter of the screen tube was 77 mm, and so it follows from (3) that the limiting reduction of deflection due to the presence of the screen should be $4(11\cdot1/77)^2 \times 1/100$ per cent = 8 per cent. The cylinders are a little too far apart for perfect compensation, since the relation $D^2 = \frac{1}{2}Rd$ would require that $D = 0\cdot935$ cm. So the two limiting correcting factors do not balance by 4·15 per cent and in the limit the ammeter would read 2·07 per cent lower than the steady-current calibration.

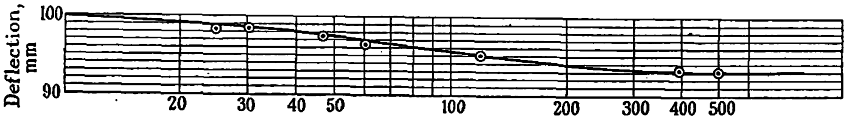

FIG. 6.

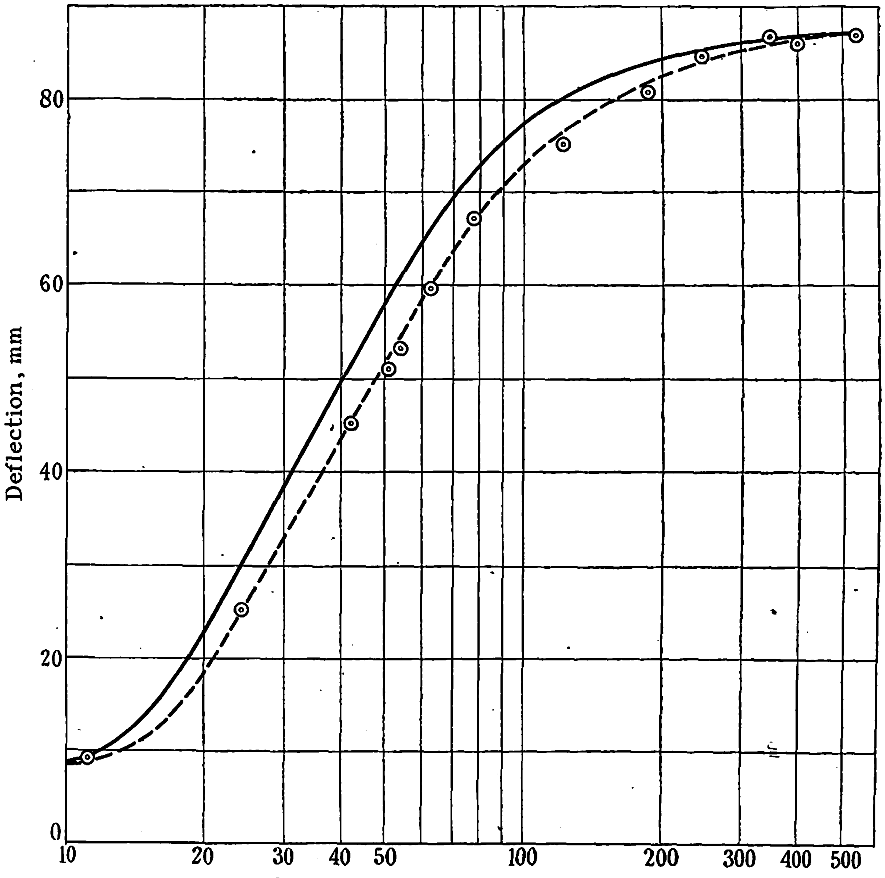

FIG. 7.

Let us now consider the rate at which the effect of the screen approaches the limiting value. If the non-uniformity of current density across the thickness t of the screen tube is ignored, it may be shown * that equation (3) should be written

$$F = \frac{2I^2}{D}\left\{1 - 4\sum_1^\infty\left(\frac{a^2}{r^2}\right)\frac{qm^2}{m^2 + q^2}\right\} \quad . \quad . \quad (6)$$

$$\doteqdot \frac{2I^2}{D}\left\{1 - 4\frac{a^2}{r^2}\cdot\frac{m^2}{m^2+1}\right\} \text{ since } \frac{a^2}{r^2} << 1$$

where $m = 2\pi t\omega r/\rho$, in which $\omega = 2\pi \times$ frequency, ρ is the resistivity of the tube whose mean radius is r, and q is every odd integer. Taking $t = 0{\cdot}3$ cm, $r = 4$ cm and $\rho = 1{\cdot}68$ microhms per cm^3, we find $m = 0{\cdot}028\,f$. On substitution it will be found that $m^2 = 197$ when the frequency is 500 cycles per sec., so that at this frequency the screen correction will have reached its limiting value to within 0·5 per cent. Over this range it is a simple matter to plot experimentally a curve connecting the deflection due to a given current and the frequency; in this way the accuracy of the predicted correcting factor can be tested. This has been done for the 25-ampere instrument and the result is illustrated in Fig. 6, and from this the limiting reduction appears to be 6·6 per cent, which is 1·7 per cent less than was anticipated. These tests took a considerable time to make and are obviously very difficult since the differences are so small. It was thought that a more reliable method of making the test would be to switch over instantly from steady

---

* *Proceedings of the Royal Society*, loc. cit., p. 53; also F. W. CARTER: *Proceedings of the Cambridge Philosophical Society*, 1927, vol. 23, p. 902.

current to 500 cycles per sec. Three readings were taken with the steady current in each direction and with current at 500 cycles per sec., and the greatest departure from the mean was 0·5 mm. The deflections are as follows: steady current 97·5 mm, steady current reverse 96·8 mm, mean 97·15 mm; at 500 cycles 89·5 mm. According to this the reduction of sensitivity is 7·9 per cent, and this agrees with the predicted value of 8·3 per cent to well within the limits of experimental error.

The calculated correcting factor might be inexact because the analysis assumes that the cylinders and the screen tube are infinitely long, whereas the length of the cylinders is in reality only $2\frac{1}{2}$ times the radius of the screen. A large portion of the screen tube, at its ends, is not acted on by magnetic field and this might well be expected to reduce the eddy currents flowing. An indirect method of checking the correction factor is to see whether the deflection with the external coil in use varies in the correct manner with frequency. With steady current the external field neutralizes the deflection, but as the frequency increases less and less of this field penetrates the screen and the deflection will tend to the value it has with no external coil. This experiment will surely be an exacting test of the applicability of analysis appropriate to very long cylinders. If, in the previous notation, we take $b = b'$ it may be shown that

$$F\Big/\frac{2I^2}{D} = \frac{m^2}{m^2+1}\left[\frac{x}{m^2} + \left(1 - \frac{4a^2}{r^2}\right)\right]$$

A certain current was found to give a deflection of 87·2 mm at 560 cycles per sec. and 2·5 mm at zero frequency. The curve of Fig. 7 has been drawn from values calculated from the above equation, in which $[1 - (4a^2/r^2)]$ has been given the value 87·2 and x the value 0·03; the observed deflections at various frequencies are shown by observation points near the dotted curve. Experiment shows that the external field which penetrates the screen is a little more than the calculated value; this is doubtless due to the resistance of the copper end-pieces. However, the observed and calculated deflections are in substantial agreement, and the fractional difference between the two curves must represent very closely the fractional error in the calculated correction factor at a given frequency. Fig. 7 is surely good evidence to prove that the calculated limiting values of the correction factors are substantially accurate, and that if the two factors are arranged to neutralize approximately then the error in the calculated value of their small difference must be quite unimportant. If a curve corresponding to Fig. 7 could be obtained for the cylinders, presumably it would fit the calculated values still more closely, for there the end effect is relatively much less important. That one of the correcting factors can readily be measured experimentally, as shown by Fig. 6, is perhaps a feature of the instrument.

The central distance between the cylinders of the smaller instrument was deduced in the same manner. With a compensating winding of 6 turns the net deflection was negative and with 5 turns it was positive, and from the observed values of these deflections the central distance was calculated to be 8·7 mm and 8·65 mm respectively. For this distance the screen should reduce the deflection by 4·7 per cent. The steady-current deflection was deduced from the mean of three readings between three-quarters and full scale, and likewise the deflection for currents at 500 cycles per sec. The reduction of deflection at 500 cycles per sec. was thus found to be 4·9 per cent, and this again verifies the method of calculating the correction factor. The correction factor for cylinders 1·1 mm diam. and 8·7 mm apart has a limiting value of 0·7 per cent, and will have approached closely to this value at a frequency of 1 megacycle per sec.*

(5) RESISTANCE, INDUCTANCE AND CAPACITANCE OF THE AMMETER.

(a) *Estimated values.*

The steady-current resistance of the larger instrument is 14·0 milliohms, which is composed as follows:—

	mΩ
Lead from earth terminal to moving cylinder ..	1·0
Lead from fixed cylinder to terminal	0·6
Moving cylinder	1·6
Fixed cylinder	0·2
The two spring-legs	10
	13·4

The fixed cylinder is solid copper and the moving cylinder is a tube of resistivity 6·2 microhms per cm³. The total length of circuit from terminal to terminal is 43 cm. The power input at full scale is about 7·5 watts at low frequencies. About 70 per cent of the total resistance is in the spring legs, which are too thin for their resistance to increase appreciably at any frequency likely to be used. Thus, supposing the current to penetrate into them as though they were plates of infinite width, then the current density at mid-thickness is still 10 per cent of its surface value at a frequency of 3×10^7 cycles per sec. ($\lambda = 10$ m) and 47 per cent at $\lambda = 50$ m. The increase of total resistance should, therefore, be mainly due to the cylinders and leads.

It may be shown that the resistance per unit length of each cylinder enclosed in a screen tube, as depicted in Fig. 2, may be calculated from the equation

$$R_n/R_0 = \frac{\sqrt{2z}}{4}\left\{\frac{D}{\sqrt{(D^2-d^2)}} + \frac{D^2rd}{2(r^4-a^4)}\right\}$$

$$\doteqdot \frac{\sqrt{2z}}{4}\left(1 + \frac{1}{2}\frac{d^2}{D^2} + \frac{1}{2}\frac{d}{r}\cdot\frac{D^2}{r^2}\right)$$

This equation shows that the presence of the screen and the proximity of one cylinder to the other cause a negligible increase of resistance; accordingly these effects will be ignored. Assuming that the resistance of the strips does not increase appreciably, then the resistance of the ammeter should be about 42 milliohms at $\lambda = 50$ m and 64 milliohms at $\lambda = 15$ m. At this wavelength the case will have to radiate about 0·4 watt per square inch of cooling surface.

---

* *Proceedings of the Royal Society*, loc. cit., Table 3.

The steady-current resistance of the smaller instrument is 83 mΩ and is composed as follows:—

	mΩ
Moving cylinder	33
Fixed cylinder	1·5
The two spring-legs	47

The fixed cylinder is solid No. 18 S.W.G. copper, and the moving cylinder is an aluminium tube 1·1 mm diameter and 0·025 mm thick. The total length of the circuit is about 43 cm and the power input at full scale is about 0·4 watt at low frequencies.

If the effect of the screen is ignored, the limiting value of the inductance of the cylinders is

$$L = 4 \log_e \frac{D + \sqrt{(D^2 - d^2)}}{d} \text{ per unit length.}$$

If the effect of non-uniform current distribution round the circumferences of the cylinders is ignored, then the inductance in the screen is

$$L \doteqdot 4 \log_e \frac{2D}{d}\left(1 - \frac{a^2}{r^2}\right)$$

Combining these two we have as a first approximation

$$L = 4 \log_e \frac{2D}{d}\left(1 - \frac{1}{4}\frac{d^2}{D^2} - \frac{a^2}{r^2}\right)$$

and the correction term, as part of a logarithm, is evidently negligible. Taking $D = 1$ and $d = 0\cdot3$ we have $L = 7\cdot28 \times 10^{-3}$ μH per cm, or, taking $D = 0\cdot5$, then $L = 5 \times 10^{-3}$ μH per cm, so L is insensitive to the ratio D/d. At low frequencies, when the current is distributed uniformly, we should have respectively $8\cdot28 \times 10^{-3}$ and $6\cdot28 \times 10^{-3}$ μH per cm. Thus for any ammeter of this type the inductance will be roughly 7×10^{-3} μH per cm of cylinder. The change from cylinder to spring leg or terminal lead will evidently make very little difference and we shall estimate the inductance at 7×10^{-3} μH per cm of the system. Accordingly either instrument should have an inductance somewhere between 0·15 and 0·17 μH. Similarly the capacity of the system, if on open circuit at the far end of the loop, would be about 3·2 μμF, and twice this amount when immersed in oil.

Reduction from the exact equation * shows that the apparent input impedance is

$$Z \doteqdot \omega Ll\left\{1 + \frac{8\pi^2 l^2}{3\lambda^2} \cdot \frac{2\alpha - 1}{\alpha - 1}\right\}$$

where l is the length of the loop, λ is $1/\sqrt{\epsilon}$ times the wavelength in the ether and α is a constant such that $\alpha = (\log_e 2r/d)/(\log_e r/D)$, numerical substitution will show that α has a value not far removed from 2. Alternatively this equation may be interpreted as showing the apparent input impedance to be due to the inductance shunted by a capacitance of value $\frac{1}{3}Cl(2\alpha - 1)/(2\alpha + 1)$, where C is the capacity per unit length in oil. Accordingly we must consider the ammeter to be shunted by a capacity of about 2·5 μμF, and in parallel with this capacity is the capacity due to the terminals external to the case.

(b) *Measured values.*

The resistance of both ammeters has been measured at various wavelengths between 50 and 150 m. The process was to connect a coil, whose apparent inductance was either 1 μH or 2 μH, in parallel with a variable condenser and to deduce the effective resistance of this system by plotting a resonance curve. The ammeter was then added to the circuit and the effective resistance again determined, the difference being ascribed to the ammeter. The earth terminal of the ammeter was in both measurements connected to the earth terminal of the condenser, and the ammeter was included by moving one end of the inductance from this terminal to the other terminal of the ammeter. The inherent resistance of the circuit was about 0·2 ohm over the range of wavelength used. Though the operation of including the ammeter makes a negligible disturbance to the coil, yet it is not necessarily correct to ascribe the difference of resistance to the ammeter because the capacity has to be reduced to compensate for the inductance of the ammeter. When the ammeter is not included, then R_1, the total apparent resistance, is composed of R_c, the effective resistance of the condenser, and R_L, the effective resistance of the coil. After including the ammeter we have

$$R_2 = R_c' + R_L' + R_A$$

It is fair to assume $R_L' = R_L$, but it is probable that R_c' is greater than R_c because the capacity has been decreased. So R_A is probably less than $R_2 - R_1$. Some values determined with the 2-μH coil are shown collected in Table 1.

TABLE 1.

λ	165 m	115 m	80 m	50 m
	ohm	ohm	ohm	ohm
R_1	0·153	0·18	0·285	0·344
R_2	0·213	0·266	0·373	0·444
$R_2 - R_1$	0·06	0·086	0·088	0·10

Now though these differences increase roughly as $\sqrt{f}$, yet they are much larger than the estimated resistances of the ammeter. For example, at $\lambda = 50$ m the apparent resistance is 100 milliohms instead of about 42 milliohms.

Measurements with the 1-μH coil are given in Table 2.

TABLE 2.

λ	80 m	50 m
	ohm	ohm
R_1	0·194	0·258
R_2	0·31	0·342
$R_2 - R_1$	0·116	0·084

The values by difference are in rough agreement with those found with the 2-μH coil, but consistency of repetition in the measurements showed that the agreement ought to be closer if the difference does represent the resistance of the ammeter.

---

* *Proceedings of the Royal Society*, loc. cit., equation (15).

From a different set of experiments, to be described at some future time, there was very strong reason to suppose that the condenser had an effective resistance of 0·16 ohm and 0·12 ohm at wavelengths of 50 m and 80 m respectively, at the capacity in use, with the 1-μH coil, before adding the ammeter. After adding the ammeter the capacity had to be reduced to 82 per cent of its former value; if the condenser had a constant power factor its effective resistance would then be 0·19 ohm and 0·145 ohm respectively. On this assumption the ammeter resistance would be respectively 0·06 ohm and 0·09 ohm at 50-m and 80-m wavelengths. It is clear, therefore, that the condenser can make a large effect on the value deduced for the resistance. But probably we can say that the high-frequency resistance is certainly not more than twice the estimated value. The resistance of the small ammeter was measured at 50-m and at 80-m wavelengths, using the 2-μH coil, and found to be 0·187 ohm and 0·193 ohm respectively, showing an apparent increase of about 2·3 times the steady-current value.

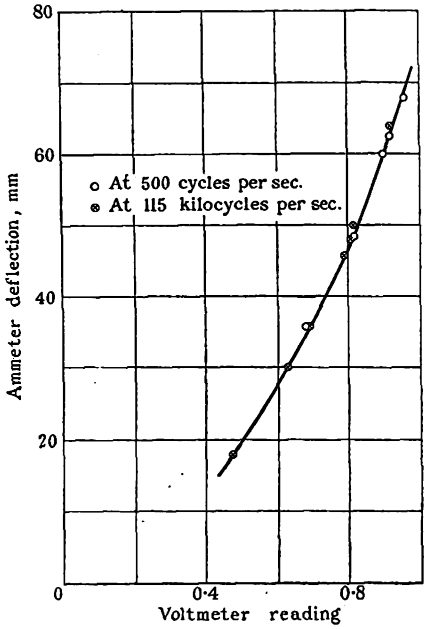

FIG. 8.

The inductance of both instruments has been measured by difference, using the same two coils. With a given coil the inductance values by difference are consistent over a wide range of wavelength, but depend slightly on the coil used. The large ammeter has an inductance of 0·18 μH when measured by difference with the 1-μH coil, and 0·22 μH when measured with the 2-μH coil; these values are about 20 per cent greater than the estimated value. The inductance of the small instrument appeared to be 0·2 μH.

The capacity of the system has not been measured, because to do so would entail opening the system at the far end. The terminal capacity of both forms of terminal system has been measured. When measuring the capacity of the axial terminal, as in Fig. 4, the movement had been removed, but 4 cm of lead protruded into the case from the terminal. The capacity was measured by noting the necessary decrease of a variable condenser required to compensate for joining a neighbouring wire to the axial terminal, the capacity formed between the terminal and its lead and the case then being in parallel with the variable condenser. With the case full of oil, this capacity was found to be 3·6 $\mu\mu$F over a range of wavelengths, and 2·9 $\mu\mu$F with the case empty of oil. The capacity of the lead, considered as a piece of concentric cylinder, is 0·6 $\mu\mu$F in air and 1·2 $\mu\mu$F in oil. Subtracting these values we find the true terminal capacity to be 2·4 or 2·3 $\mu\mu$F.

The capacity of the terminal system shown in Fig. 5 was measured when the terminal lead was just freed from the fixed cylinder. The capacity in oil was found to be 4·1 $\mu\mu$F and this includes the capacity of 6 cm of terminal lead whose capacity belongs to the system. Again estimating this capacity as for a concentric cylinder, we must subtract 1·8 $\mu\mu$F and again find a residue of 2·3 $\mu\mu$F due to the terminal proper. It therefore seems safe to assume that the true terminal capacity, shunting the system, is less than 3 $\mu\mu$F.

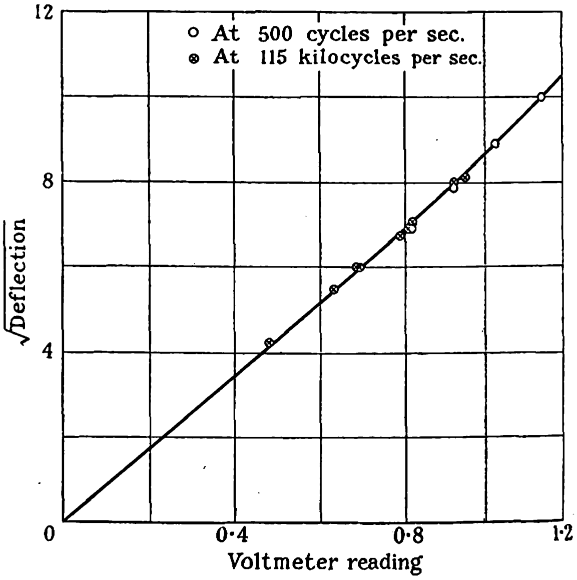

FIG. 9.

(6) TESTS AT HIGH FREQUENCY AND TEMPERATURE-RISE.

The smaller instrument has been checked very carefully at various frequencies up to 3×10^6 cycles per sec. Three 1-ampere hot-wire instruments (with 8-in. dials) were joined in parallel and then connected in series with the ammeter being tested. The relation between deflection and the sum of the three ammeter readings at 500 cycles per sec. was obtained with great care, and this has been compared with the relation obtained at radio frequencies. Also the voltage-drop across 0·39 ohm of No. 26 S.W.G. Eureka wire was measured by means of a thermionic voltmeter. The silk-covered Eureka wire was twisted on itself, making a very narrow loop 7 cm long, and the calculated inductance of this loop to steady currents is 0·03 μH. At 115 kilocycles per sec. the resistance will have increased by less than 1 part in 1 million and the reactance will increase the voltage-drop by 0·17 per cent. Tests were made with the voltmeter at 115 ($\lambda = 2\,600$ m), and with the hot-wire ammeters at 1 850 ($\lambda = 160$ m), 2 300 ($\lambda = 130$ m) and 2 830 ($\lambda = 106$ m) kilocycles per sec. Fig. 8 shows the comparison between voltmeter reading and deflection: the points marked with a circle were obtained at 500 cycles per sec. and the points marked with a cross in a circle were obtained at 115 kilocycles per sec. Fig. 9 shows the voltmeter reading plotted against the square root of the deflection, and the average agreement between the points obtained at 500 cycles per sec. and those at 115 kilocycles per sec. is certainly closer than 1 per cent. Fig. 10 shows the sum of the three ammeter readings plotted against the deflection: the points marked with a dot in a circle were obtained at 500 cycles per sec. These high-frequency observations could not be made in very ideal circumstances, both because conditions were not perfectly steady at the very high frequencies, and also because sufficient current for full-scale deflection could not be obtained. At the frequencies to which Fig. 10 relates the proximity of the cylinders should increase the deflection for a given current by 0·7 per cent. Fig. 10 is satisfactory in showing that a given deflection always corresponds to a larger reading of the hot-wire ammeters at very high frequencies than at low frequencies, and so shows that the hot-wire instruments are consistently reading high: their error is, however, small and is of the order of 3 per cent round about $\lambda = 100$ m.

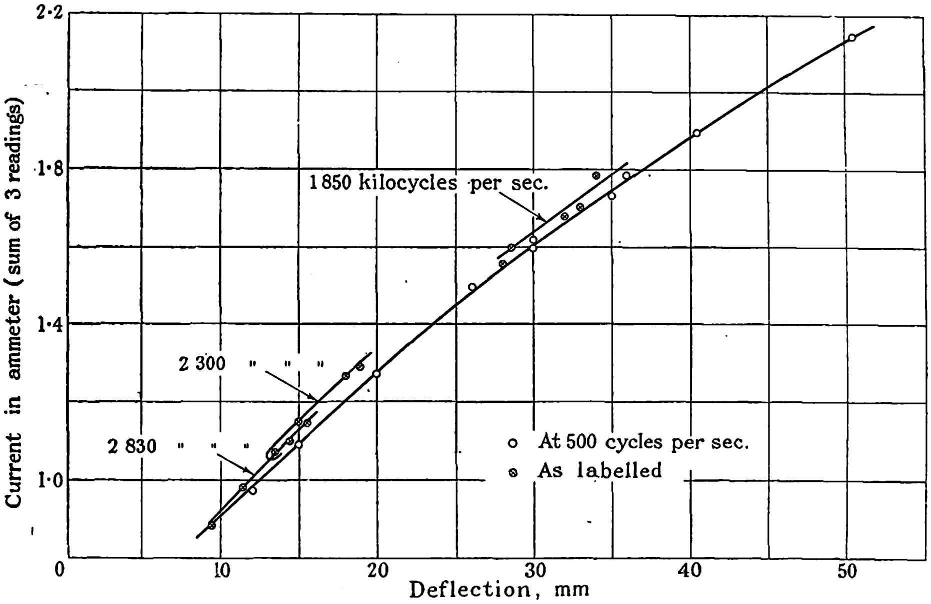

FIG. 10.

The large ammeter has been calibrated at 500 cycles per sec. against a Weston model 425 radio-frequency thermo-ammeter (0 to 20 amperes) and the two instruments again compared at 3 000 kilocycles per sec. ($\lambda = 100$ m). The result of the comparison is exhibited in Fig. 11, the points marked with a cross being obtained at 3 000 kilocycles per sec. Here again it was difficult to obtain perfectly steady conditions at the high frequency, and the current could be adjusted only in fixed steps which did not correspond to the most desirable parts of the scale. Since both instruments had a square-law scale, the four readings between 17 and 18 amperes should be the most reliable, and according to these a current at 3 000 kilocycles per sec. produces 5·6 per cent more deflection than it did at 500 cycles per sec. But now we have to allow for the proximity effect of two cylinders, 3·19 mm diam., placed 11·1 mm apart, and from formula (1) this will increase the deflection by 4·1 per cent. We have accordingly to account for a residue of only 1·5 per cent, and thus the scale reading of the Weston instrument is only 0·75 per cent high at a wavelength of 100 m—surely a very satisfactory performance for so small a thermal instrument of 20-ampere capacity.

Curves of temperature-rise for the large instrument are shown in Fig. 12, and by means of a cooling curve the thermal time-constant of the ammeter was found to be about 3 000 seconds. The heat capacity is about 4 600 joules and the cooling coefficient 1·5 watts per deg. C.

From the two heating curves of Fig. 12 we deduce that the resistance at $\lambda = 100$ m is 72 milliohms, and this value is in fair agreement with the values collected in Table 1.

(7) CALCULATED CORRECTION TABLES FOR THE LARGE AMMETER.

These factors are expressed as a correction to be applied after the proximity effect has attained its limiting value. Thus we suppose the calibration has been made at some convenient frequency such as 200 cycles per sec.

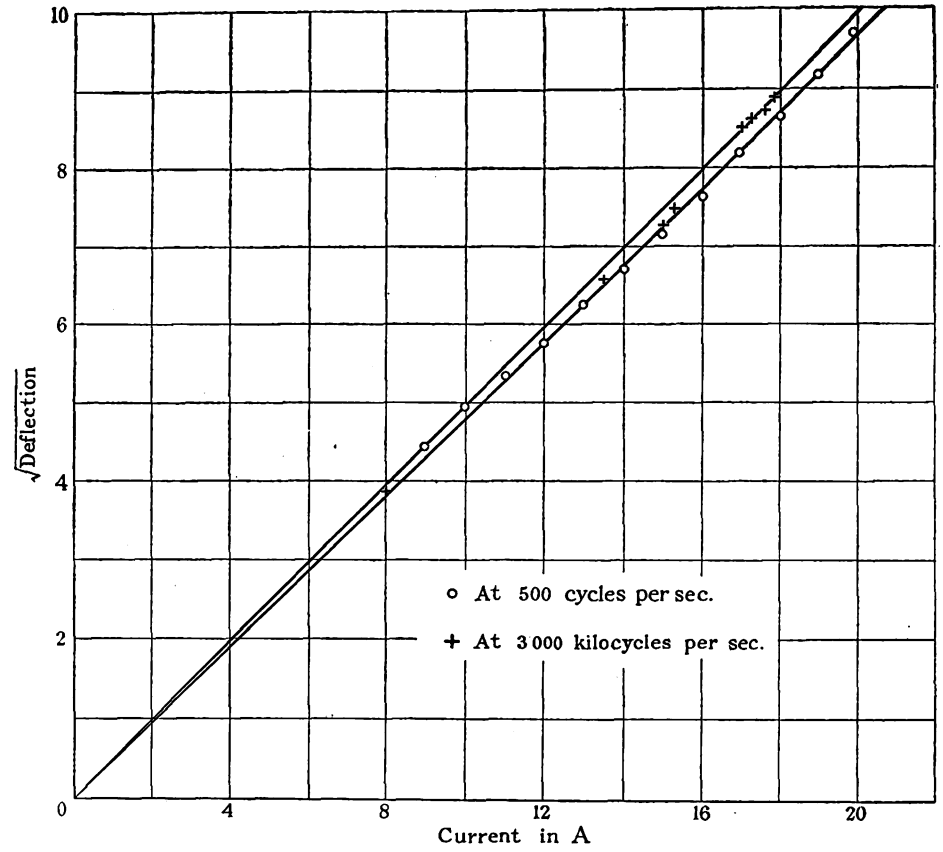

FIG. 11.

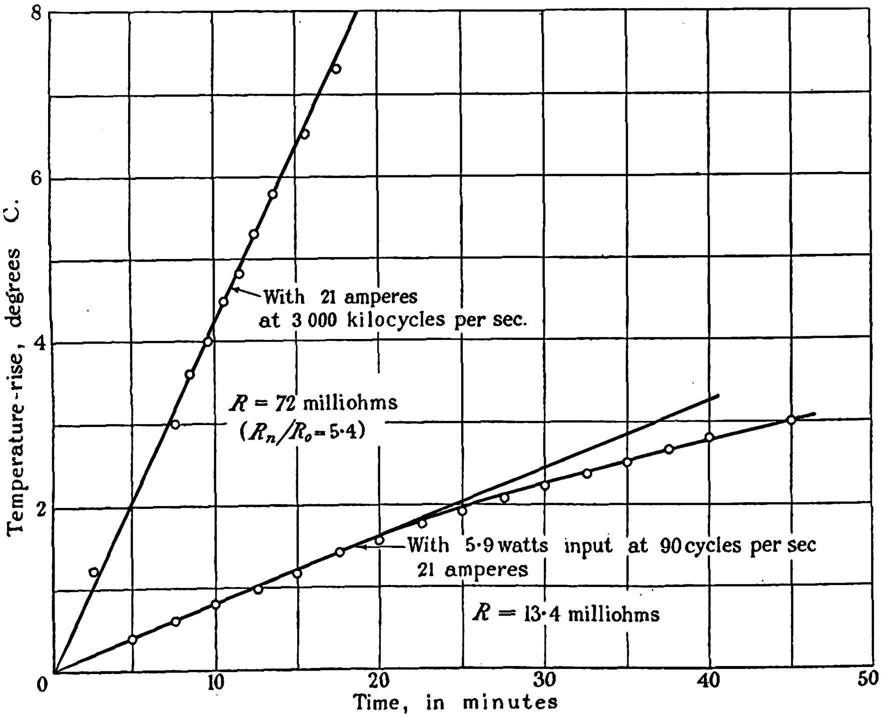

FIG. 12.—Heating curves of large ammeter.

and that the deflections then observed have been increased by 4·1 per cent to render the calibration valid for frequencies greater than 100 kilocycles per sec. (Note that at 40 kilocycles per sec. the addition is 3 per cent.) This calibration will then hold without further adjustment between 100 and 6 000 kilocycles per sec. ($\lambda = 3\,000$ m to 50 m). In calculating the factors collected in Table 3, the inductance has been taken as 0·2 μH and the terminal capacity as 3 $\mu\mu$F. The correction for longitudinal distribution of current has been calculated from formula (5) and in this k has been taken as 2 and l as 40 cm. The current corresponding to the observed deflection is to be read from the calibration curve, and then this current is to be reduced by the amount shown in the last column of Table 3.

TABLE 3.

λ	f (kilocycles per sec.)	Correction for current distribution	Correction for terminal capacity	Net reduction factor for current
m		per cent	per cent	per cent
50	6 000	0·085	0·02	0·1
20	15 000	0·504	0·5	1·0
10	30 000	2·15	2·0	4·1
5	60 000	8·2	8·5	16·7

It will be seen that the correction factor is small, and perhaps unimportant, until the wavelength is less than 15 m, but when it is less than 10 m the factor rapidly becomes large. The non-uniformity of the complete system may possibly make the factor slightly different from that calculated by equation (5), and perhaps that analysis should be interpreted as showing that the factor will not reach 1 per cent until the wavelength is less than about 15 m, and should thereafter be used for estimating roughly the correction for much shorter waves. Possibly future experience with instruments having systems of different lengths may substantiate the applicability of equation (5) to bent systems. Also the correction for terminal capacity becomes very appreciable, and this factor cannot well be more than an approximate estimate.

If and when it becomes necessary to make accurate current measurements at wavelengths shorter than 10 m it will be necessary to use an ammeter with a shorter system; in other words the ammeter must constitute a smaller fraction of the total length of the circuit in use.

(8) FUTURE DEVELOPMENTS.

The mechanical development and testing of these two instruments has shown up certain difficulties and drawbacks. The chief mechanical difficulty is to provide supports for the moving cylinder which are heavy enough to carry the current and yet do not impose too great a control. The convenience of calibrating at, say, 500 cycles per sec. has shown that a steady-current calibration is both unnecessary and troublesome. Accordingly it is proposed to abandon the possibility of steady-current calibration, for then the instrument can be built in a way which possesses very great advantages both in construction and use. In future it is proposed to use only one cylinder, which will be placed eccentrically within the screen tube, and to measure the repulsive force between the current in the cylinder and the eddy currents induced in the screen tube.* The cylinder will then be fixed and the screen tube will become the moving member. Since all the current in the screen tube is induced in it by the field of the cylinder, no means are required for leading this current in and out. This avoids the difficulty of carrying current through thin strips, and oil immersion is no longer required: the absence of the strips will reduce the resistance of the instrument at least 10-fold. It is proposed to carry the screen tube on knife edges and the whole control will be by gravity. The whole system is uniform as the right-angle bends, necessitated by the control springs, are no longer present; and the whole length is operative in producing repulsive force. Also the relevant value of l to be substituted in equation (5) is the length of the screen tube instead of the whole length of the complete loop. Thus had the 20-ampere instrument been made with one cylinder and a moving screen tube, its effective length would have been 10 cm instead of 40 cm. It may be calculated from (5) that the correction for current distribution would then have been only 1·7 per cent at $\lambda = 2$ m. With such an instrument we could therefore ignore the effect of current distribution entirely. In addition the inductance of the system would be halved, because now the screen tube is equivalent to placing a thick copper plate in the median plane of Fig. 1 and then obliterating one cylinder. It will further be reduced because the length of the system has been shortened by the length of the control springs. Probably the inductance would be reduced from 0·2 μH to 0·07 μH. The presence of the ammeter would then make less disturbance to the circuit, and the small inductance would render the terminal capacity much less effective. Assuming an inductance of 0·07 μH and a terminal capacity of 3 $\mu\mu$F, it may be calculated that the correction for terminal capacity would be 0·6 per cent at $\lambda = 10$ m and 2·4 per cent at $\lambda = 5$ m. The calibration of such an instrument would therefore be independent of frequency between 100 cycles and 30 000 kilocycles per sec.

---

AN AMMETER FOR VERY HIGH FREQUENCIES.

By Professor C. L. **Fortescue**, O.B.E., M.A., Member, and L. A. **Moxon**.

(*Paper first received* 18*th September, and in final form* 20*th December*, 1929; *read before the* Wireless Section 5*th February*, 1930.)

Summary.

This paper describes the construction and theory of a simple form of hot-wire ammeter intended for use at any frequency up to 100 million cycles per sec. A cylindrical form is adopted in order that the correction factors for various frequencies may be calculated with certainty, and figures are given for an instrument as actually constructed.

(1) Introduction.

An ammeter for measuring currents up to about 1·2 amperes at frequencies between 10^7 and 10^8 cycles per sec. has been described by E. B. Moullin.[*] It consists of two parallel conductors mounted on elastic supports, the deflection of these supports under the electrodynamic forces arising from the mutual action of the currents being used to measure the magnitude of the current. The corrections for the capacity effects and the distribution of the current over the cross-sections of the conductors are somewhat difficult to calculate. The impedance would appear to be rather high and is to some extent dependent upon the magnitude of the current being measured. Finally, the measurement of the movement of the conductors is made by means of a microscope, with the result that the instrument is rather expensive, inconvenient to use and by no means robust.

Several alternative proposals have been made. P. R. Coursey and others have proposed to use capacity dividers and thermo-junctions. Hot-wire ammeters of the ordinary type are commonly used in practice without correction. The measurement of the voltage across either a single-turn loop of wire or other calculable form of inductance by means of a rectifying valve has also been suggested.

The ammeter described in this paper is a hot-wire instrument so arranged that the correction can be calculated easily. The impedance is relatively low and the R.M.S. value of the current is given directly by the movement of a pointer over a scale.

(2) The Difficulties of Measuring Very High-Frequency Currents.

These arise from:—

(*a*) The capacity effects in consequence of which the current in the measuring device is different from that entering the instrument.

(*b*) The high inductive reactance of even very short conductors, and the consequent difficulty of using parallel circuits.

(*c*) The disturbance of the circuit in which the measurement is being made, owing to the relatively high impedance of the measuring device.

With regard to (*a*), at a frequency of 10^8 the reactance of a capacity as low as 10 $\mu\mu$F is only 160 ohms, and where thorough screening is adopted—as it must always be—it is by no means easy to keep the parallel capacities down to so low a figure. Moreover, the distribution of the current along the conductors employed for its measurement is dependent upon the distributed inductance and capacity. It is not always permissible to assume that the distribution is uniform, and where a high degree of accuracy is necessary a correction must be made for this effect.

The high value of the inductive reactance makes it difficult to adjust any instrument depending upon the subdivision of the current in unequal arms. At a frequency of 10^8 the reactance of a lead having an inductance of only 0·1 μH is already 62·8 ohms. The circuits must either be so adjusted that the impedances are identical, or the inductive reactance must be swamped by resistance or capacity reactance. In the latter cases the resultant instrument would have far too high an impedance for general use.

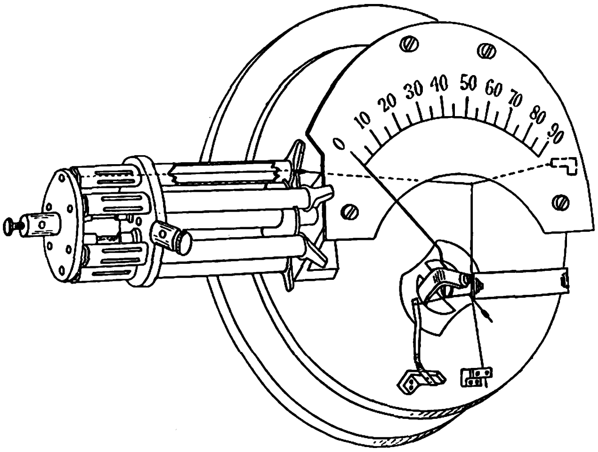

Fig. 1.

As to the permissible impedance, this depends upon the current for which the instrument is designed. The admittance should, if possible, be not less than 1 reciprocal ohm per ampere to be measured, since the total inductive reactance of resonant circuits at these high frequencies is usually low.

(3) Principle of the New Hot-Wire Instrument.

The simplest case for which all corrections can be applied with certainty is that of a wire of small diameter mounted co-axially with a cylindrical screen. Russell[*] has given a full treatment of this case. The high-frequency resistance of the wire and cylinder are easily calculable; the varying distribution of the current is easily found from the dimensions and a correction for the capacity of the terminal blocks can easily be made.

---

[*] See page 544; also *Proceedings of the Royal Society*, A, 1928, vol. 121, p. 41.

[*] *Philosophical Magazine*, 1909, vol. 17, p. 524.

The passage of the current heats the wire and causes it to expand, and this expansion is used to measure the currents. The instrument is calibrated by direct current and the corrections for the high-frequency currents are calculated and applied either by reference to correction curves or by the use of curved scale divisions.

(4) The Construction of the Instrument.

This is shown in Figs. 1 and 2, where provision is made for six parallel wires each carrying a maximum direct current of about 1·2 amperes at full scale deflection.

Each current-carrying wire is kept in its central position on the axis of a screening tube by means of a flat spring at the end. One of these wires is directly attached to what is normally the heated wire of an ordinary hot-wire ammeter. As the wire in the tube expands and contracts, the pointer of the instrument moves to and fro over the scale and this movement thus becomes a measure of the current in the heating wires within the screening tubes.

A symmetrical arrangement of the terminal connections ensures uniform distribution of current between the heated wires.

For some experimental work this first instrument has been used with only one screened heating wire. This is quite satisfactory for the experiments, but the terminal capacity is much greater than need be the case with a simple wire, and consequently the corrections are abnormally large.

A second heating unit having only a single wire is now under construction. The terminal capacity is estimated to be only about one-fifth of that of the 6-wire heater, with the result that the corrections will be more normal.

(5) Calibration and Correction.

The initial calibration is by direct current in the ordinary way, and the scale is marked from this calibration.

The capacity between the terminal blocks and the screening tubes is measured before the wires are inserted. This and the dimensions enable the corrections to be made, the actual value of the alternating current entering the input terminal for each scale division being thus found and plotted for use as a correction curve. Alternatively, curved scale divisions as shown in Fig. 3 may be used.

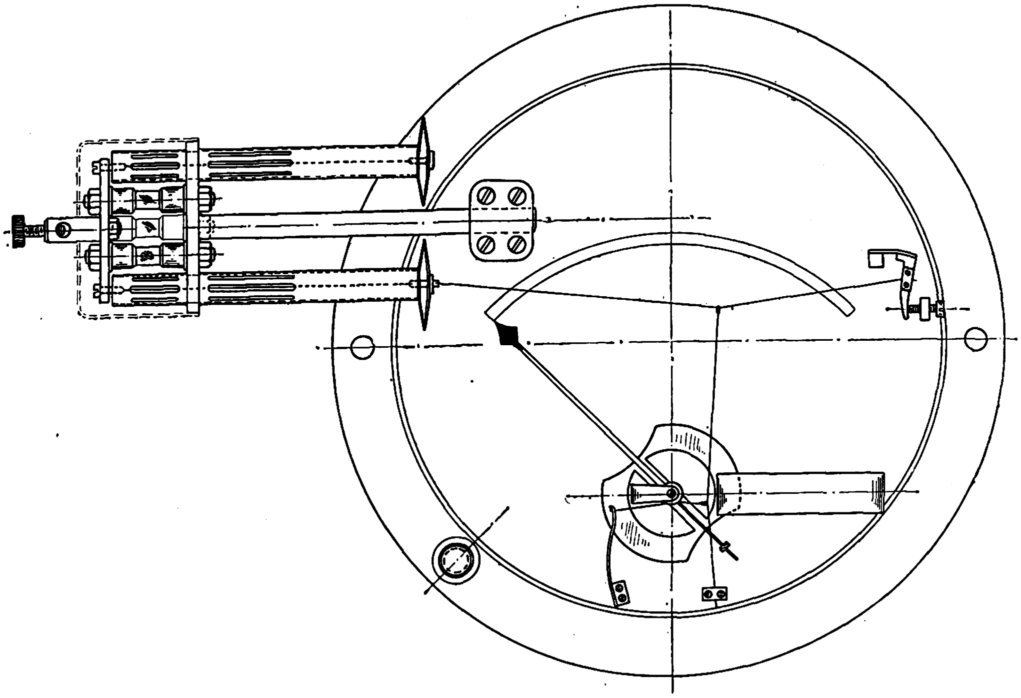

Fig. 2.—High-frequency hot-wire ammeter

Scale: $\frac{3}{5}$ full size.

(6) Calculations of the Corrections.

Notation :—Terminal block capacity	C_t
Capacity per cm length of heating wire	C
Inductance per cm length of heating wire	L
High-frequency resistance per cm length of heating wire	R
Total current (R.M.S. amperes) entering input terminal	I_0
Current (R.M.S. amperes) in the terminal capacity	I_t
Current (instantaneous or vector amperes) in wire at distance x cm from input terminal	i
Ditto (maximum value)	$\mathfrak{I}$
Ditto (R.M.S. value)	I
Current (instantaneous, maximum and R.M.S. amperes) in wire at input-terminal end	i_w, $\mathfrak{I}_w$, I_w

Voltage (instantaneous or vector volts) between wire and cylinder at distance x from input terminal	v
Ditto (at input terminal)	v_w
Number of parallel heating wires	N
Length (cm) of each wire	l

Considering firstly the distribution of current along the wire, the conditions are as usual; viz.

$$\left.\begin{aligned} -\frac{\partial i}{\partial x} &= C\frac{\partial v}{\partial t} \\ -\frac{\partial v}{\partial x} &= iR + L\frac{\partial i}{\partial t} \end{aligned}\right\} \quad . \ . \ . \ . \ . \quad (1)$$

The terminal conditions are that when $x = 0$, $i = i_w$, and when $x = l$, $v = 0$, it being assumed that the screening tube is equivalent to a short-circuit. The methods given by Russell * must be adopted if this is not the case.

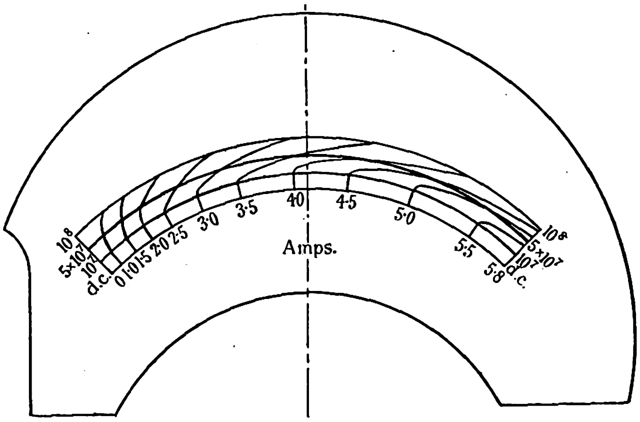

Fig. 3.—Scale for high-frequency ammeter.

Equation (1) and the terminal conditions give:—

$$i = i_w\,(\cosh mx - \tanh ml \sinh mx) \quad . \ . \quad (2)$$

$$v_w = i_w\frac{m}{j\omega C}\tanh ml \quad . \ . \ . \ . \quad (3)$$

where $\quad m = a + j\beta = (-\omega^2LC + j\omega CR)^{\frac{1}{2}} \quad . \ . \quad (4)$

The mean power input is equal to the real component of the multiplier of i_w in (3) multiplied by I_w^2. If $I_{d.c.}$ is the calibrating direct current for the whole N wires, the current in one wire is $I_{d.c.}/N$ and the power expended is $(I_{d.c.}/N)^2lR_{d.c.}$, where $R_{d.c.}$ is the d.c. resistance per cm length of the wire.

If this power expenditure causes the same deflection as the alternating current, then

$$\frac{I_{d.c.}^2}{N^2}lR_{d.c.} = I_w^2\left(\text{Real component of } \frac{m \tanh ml}{j\omega C}\right) \quad (5)$$

Turning now to the current in the terminal capacity, this will be

$$i_t = i_w m\frac{C_t}{C}\tanh ml \quad . \ . \ . \ . \ . \quad (6)$$

The input current to the input terminal will be the sum of the capacity current given by (6) and N times the current in each wire; viz.

$$i_w\left(N + m\frac{C_t}{C}\tanh ml\right)$$

whence the value of the mean-square input current, I_0^2, can be found. Then, with the aid of (5), I_0^2 is connected with $I_{d.c.}^2$ and the correction factor determined.

From (4),

$$a = \omega\sqrt{(LC)}\left[\frac{1}{2}\left\{\sqrt{\left(1 + \frac{R^2}{\omega^2L^2}\right)} - 1\right\}\right]^{\frac{1}{2}}$$

and

$$\beta = \omega\sqrt{(LC)}\left[\frac{1}{2}\left\{\sqrt{\left(1 + \frac{R^2}{\omega^2L^2}\right)} + 1\right\}\right]^{\frac{1}{2}}$$

When $\omega\sqrt{(LC)}$ is small, both a and β are small and

$$m \tanh ml = m^2l = (-\omega^2LC + j\omega CR)l$$

Also the real component of $m \tanh ml/(j\omega C)$ is then lR and, from (5),

$$I_w^2 = \frac{I_{d.c.}^2}{N^2}\cdot\frac{R_{d.c.}}{R} \quad . \ . \ . \ . \ . \quad (7)$$

With the same approximations, the input current is

$$i_0 = i_w\{(N - l\omega^2LC_t) + jlR\omega C_t\}$$

and $\quad I_0^2 = I_w^2\{(N - l\omega^2LC_t)^2 + l^2R^2\omega^2C_t^2\}$

$$= I_w^2(N - l\omega^2LC_t)^2$$

in most cases.

Substituting for I_w^2 in (7) gives

$$I_0^2 = I_{d.c.}^2\frac{R_{d.c.}}{R}\left(1 - \frac{l\omega^2LC_t}{N}\right)^2$$

or $\quad I_0 = I_{d.c.}\left(1 - \frac{\omega^2lLC_t}{N}\right)\sqrt{\left(\frac{R_{d.c.}}{R}\right)} \quad . \ . \quad (8)$

The effective impedance of the instrument is

$$Z_0 = \frac{v_w}{i_0} = \frac{m \tanh ml}{j\omega(NC + mC_t \tanh ml)}$$

With small values of a and β this becomes

$$Z_0 = \frac{l(R + j\omega L)}{(N - l\omega^2LC_t) + jlR\omega C_t} \quad . \ . \ . \quad (9)$$

which at relatively low frequencies becomes

$$Z_0 = lR/N$$

as it should be for steady currents.

(7) CALCULATIONS FOR THE FIRST INSTRUMENT MADE.

Number of heating wires	6
Length of each wire	9·5 cm
Internal diameter of screening cylinder	0·80 cm
Diameter of wire	0·0140 cm
D.C. resistance of wire per cm length at 15° C.	0·1562 ohm
Specific resistance of wire at 15° C.	24·2 × 10⁻⁶ ohm per cm per cm²
Observed terminal capacity	14·6 μμF

---

* *Loc. cit.*

The capacity per cm length of wire is

$$\tfrac{1}{2}\log_\epsilon \frac{0\cdot 80}{0\cdot 0140} \text{ electrostatic units}$$
$$= 0\cdot 1373 \times 10^{-12} \text{ farad.}$$

The inductance per cm length of wire is

$$2\log_\epsilon \frac{0\cdot 80}{0\cdot 0140} \text{ electromagnetic units}$$
$$= 8\cdot 093 \times 10^{-9} \text{ henry.}$$

The ratio $R/R_{d.c.}$ when computed from the usual tables is as follows:—

Frequency ..	10^6	10^7	5×10^7	10^8
$R/R_{d.c.}$ ..	1·000	1·015	1·268	1·678

The approximations made in the previous section are permissible for all except the last case, which must be calculated from the complete formulæ.

The results are:—

Frequency	10^6	10^7	5×10^7	10^8
$\frac{I_0}{I_{d.c.}}$	1·000	0·992	0·874	0·706
Impedance of instrument, in ohms ..	0·261	0·840	4·11	8·84

(8) Comments on These Results.

(*a*) The corrections are very small for frequencies below 10^7, and from this frequency downwards the direct-current calibration can be used with errors not greater than 1 per cent. Above that frequency, however, the correction increases rapidly owing to the relatively quick increase of the resistance, and also because of the increasing current in the terminal capacity.

(*b*) The impedance of the instrument increases with the frequency, and the reactance is inductive up to frequencies considerably above 10^8.

(*c*) The magnitude of the correction due to the capacity is mainly dependent upon the term $\omega\sqrt{(LC)}$, which in this case is ω/c^2, where c is the ratio of the electromagnetic to the electrostatic absolute units of quantity. With the cylindrical construction, therefore, the dimensions will have little influence on this correction. There is consequently a fairly free choice of dimensions, which enables the design to be adapted to the other requirements of the hot-wire instrument.

(*d*) The results given in the previous section are only calculated to a moderate degree of accuracy because sufficient experience of either the construction or use of these instruments has not yet been obtained to justify more exact computations. These will be made later if it is found desirable.

(9) Programme of Further Work.

There is now in progress a lengthy research which includes both the design of the instrument, and the method of comparing the results with other similar ammeters or indirect methods of measuring current. This research is being carried out under the auspices of the Department of Scientific and Industrial Research, by whose permission this paper is now published.

The authors wish to thank Mr. D. W. Hopkin for assistance in preparing drawings for the illustrations.

A METHOD OF MEASURING MECHANICAL IMPEDANCE.

By Professor E. MALLETT, D.Sc. (Eng.), Member, and R. C. G. WILLIAMS, B.Sc. (Eng.), Graduate.

(*Paper first received 2nd December, and in final form 20th December,* 1929; *read before the* WIRELESS SECTION *5th February,* 1930.)

SUMMARY.

The device the mechanical impedance of which at a given frequency is to be measured is driven by one prong of an electrically-driven tuning fork, and the other prong is loaded to restore balance, the load required being the mechanical impedance to be determined. The balance condition is indicated by the absence of vibration of the fork support.

An improvement depends upon the experimentally determined fact that mechanical resistance out-of-balance does not appreciably affect the support vibration. If the prongs are balanced for mass, the total resistance can be found from a decay-factor determination or by a single measurement of amplitude with a known current, and the resistance of the device estimated.

A measurement is made of the mechanical impedance at 100 cycles per sec. of a certain gramophone pick-up.

LIST OF SYMBOLS.

m = equivalent mass of each prong of a tuning fork (grammes).

s = equivalent stiffness of each prong of a tuning fork (dynes/cm).

r = equivalent mechanical resistance of each prong of a tuning fork (dynes/cm/sec.).

a = decay factor of each prong $\left\{= r/(2m)\right\}$.

m' = mass added to one prong of tuning fork (grammes).

r' = total mechanical resistance added to two prongs (dynes/cm/sec.).

r_1 = resultant mechanical resistance of each prong when loaded $(= r + \frac{1}{2}r')$.

f_0 = resonant frequency of tuning fork (cycles/sec.).

$\omega_0 = 2\pi f_0$ (radians/sec.).

C_0 = capacity (μF) in oscillatory circuit of valve oscillator to produce a frequency f_0.

x = amplitude of displacement of prong from mean position (cm).

u_m = maximum value of velocity of prong (cm/sec.).

$\left.\begin{matrix} x_0 \\ u_0 \end{matrix}\right\}$ values of x and u_m at resonance.

i = R.M.S. value of alternating current in driving coil of fork (mA).

i_m = maximum value of alternating current in driving coil of fork (absolute electromagnetic units, called " abamps ").

A = force factor of driving system (dynes/abamp) $(= NB/S)$.

N = number of turns on driving coil.

B = flux density of permanent magnetism in the air-gaps (lines/cm^2).

S = total reluctance of the magnetic circuit of the driving system.

SECTION (1).

The resonant frequency of an electrically-driven tuning fork depends upon the length and thickness of the prongs and upon the material of which they are made, but referred to the point of drive an equivalent mass m and an equivalent stiffness s can be found for each prong, so that the resonant frequency is given by

$$f_0 = \frac{1}{2\pi}\sqrt{\left(\frac{s}{m}\right)} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

This applies accurately for small amplitudes only. At large amplitudes the frequency of maximum response decreases as the amplitude is increased, according to a square law.*

The decay factor of each prong of the tuning fork can also be expressed in terms of an equivalent mechanical resistance r, as

$$a = \frac{r}{2m} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Here again only small amplitudes are intended, as the decay factor increases with amplitude.

If a mass m' is added to each prong at the point of drive the resonant frequency will be lowered to

$$f_0 = \frac{1}{2\pi}\sqrt{\left[\frac{s}{m + m'}\right]} \quad . \quad . \quad . \quad . \quad (3)$$

and if a mechanical resistance r' is added to each prong at the point of drive the decay factor will be altered to

$$a = \frac{r + r'}{2(m + m')} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

If the two prongs of the fork are perfectly balanced there will be little or no tendency for the support to vibrate, but if they are not balanced the support will tend to vibrate in order that the centre line of the mass of the two prongs may remain stationary. Suppose now that one prong is made to drive a gramophone pick-up. Its constants will on that account be altered to $(m + m')$ and $(r + r')$, and the fork will be thrown out of balance and the support caused to vibrate. But if the other prong can be loaded with a known mass and a known resistance to restore the balance, the effective mass and resistance of the pick-up are determined. The case where the pick-up reactance is effectively a stiffness can be dealt with by loading each prong initially with a known mass m' sufficient to cause a greater reduction of frequency than the increase caused by the pick-up stiffness.

SECTION (2).

The obvious indication that balance has been obtained is the absence of vibration in the support, and many experiments were made in this direction.

The fork used was a laboratory model consisting of two bars of hard steel mounted on a bracket to form a tuning fork. The effective length of the prongs could be varied by altering the position of a massive steel clamping block, the frequency range being from 80 to 500 cycles per sec. The fork was magnetized and between its prongs was mounted a small low-resistance coil with a core of a bundle of soft-iron wires to complete the magnetic circuit of the prongs.

---

* *Proceedings of the Physical Society of London*, 1926–7, vol. 39, p. 338.

In order to leave the support fairly free to vibrate, the bracket at the stationary end of the prongs was removed, the only support being a long bolt clamping the steel block to the base. The unused portion of the prongs was then available for mounting the vibration detector as in Fig. 1.

After trying several types of detectors the one found to be most useful was a set of 22 single reeds rigidly clamped into two brass blocks and of various lengths covering a frequency range of about 80 to 100 cycles per sec., the free ends being viewed from above through a low-power microscope. A button microphone and vibration galvanometer was much more sensitive but somewhat unstable, and the tuning of the galvanometer had to be adjusted with every alteration of balancing load, making the measurement very laborious.

The oscillator used had an L.S.6A output valve working from the 400-volt d.c. mains through a filter circuit, this large power output being necessary to drive the heavily loaded fork through a high-value swamping resistance necessary for stability.*

The balancing impedances used were (*a*) reactive, and (*b*) resistive, as follows:—

(*a*) A set of weights each shaped to clamp on to the prongs by means of a small set-screw.

(*b*) A 3-bladed copper paddle dipping into a bath of thick machine oil. The direction of motion of the paddles was in their own plane, this scheme allowing rigid construction consistent with lightness to be used.

The pick-up was driven from the fork by fixing a small piece of gramophone record to the top of the prongs by means of hot shellac and resting on this the needle of the pick-up. This coupling has the advantage of simplicity and, moreover, very nearly reproduces the forces between needle and record under actual playing conditions. Back-coupling due to vibrations passing along the pick-up arm and hence to the fork support was prevented by mounting the arm on a massive cast-iron base independent of the fork mounting.

The practical difficulties encountered with this apparatus are summarized below:—

(1) Resistance could not be added without also adding effective mass.

(2) Resistance out-of-balance produced an inappreciable vibration of the support.

(3) An out-of-balance of mass produced a considerable increase of effective resistance, which caused a decrease in the prong and support vibrations although balance conditions were being departed from.*

(4) Every change of added mass necessitated a change of frequency of drive. Unless the fork were driven at the resonant frequency corresponding to the load of the moment, it was impossible to say whether balance conditions were being approached.

It then appeared to be possible [from (2)] that with the order of resistances encountered the additional effective resistance of each prong would be one-half the total added resistance, irrespective of whether it was added to one prong only or divided between the two. In other words, a determination of the decay factor of the fork by any method,† provided of course that the mass of each prong was balanced, would give the resistance of the pick-up. In Appendix 2 it is shown that this idea is justified. The use of the support vibration as an indication in balancing the mass was possible but tedious for the reasons given above. A simpler method was found to be as follows: A curve of resonant frequency/added mass (equal mass to each prong) was drawn. Then the pick-up was added to one prong and mass added to the other prong until the resonant frequency of the fork for the mass added agreed with the value read from the curve. The effective mass of the pick-up was then equal to the mass added. Alternatively, equal known masses (greater than the pick-up mass) were added to each prong, and one of these was subsequently replaced by the pick-up and a variable mass, the latter being adjusted to bring the resonant frequency back to its previous value.

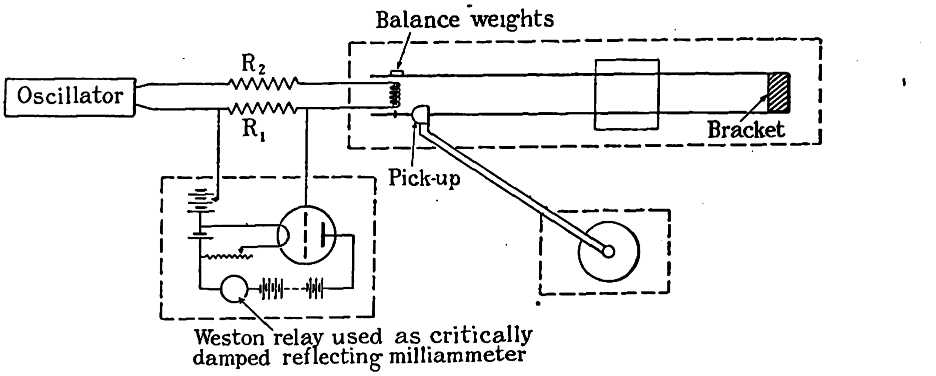
SECTION (3).

Details will now be given of an experimental determination of the impedance of a certain gramophone pick-up.

The skeleton circuit used is given in Fig. 2. The fork amplitudes were measured by viewing some illuminated mercury globules on the prong tips through a high-power travelling microscope with a scale in the eye-piece, and the current was determined by the valve voltmeter and known resistance R_1, using a Weston relay as a critically damped reflecting galvanometer.* R_2 was a series controlling resistance for keeping the current constant while taking the resonance curve, the smallest value to which R_2 was reduced being sufficiently large to prevent unstable effects.



Balance weights

R2
R1
Bracket
Pick-up
Weston relay used as critically damped reflecting milliammeter

FIG. 2.

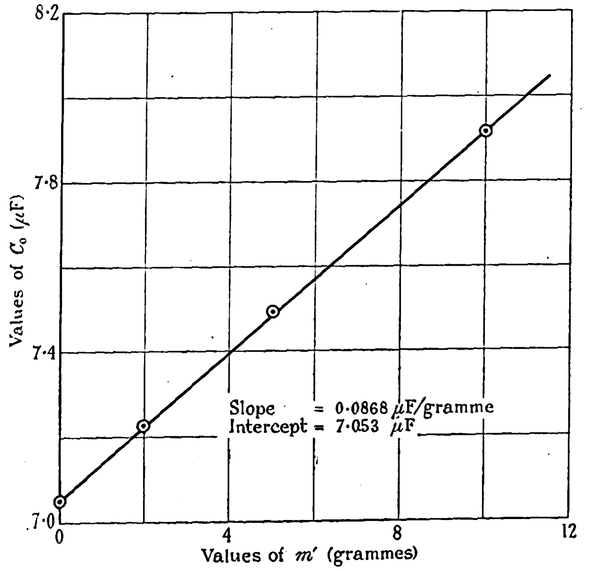

FIG. 3.

The equivalent mass and resistance of the fork prong required in equations (3) and (4) were found by the following method:—

$$\text{From (3)} \qquad \frac{1}{f_0^2} = 4\pi^2\frac{m}{s} + 4\pi^2\frac{m'}{s} \quad . \quad . \quad . \quad . \quad (5)$$

and if C_0 is the capacity in the oscillatory circuit of the oscillator corresponding to a frequency f_0

$$f_0^2 C_0 = K$$

where K is some constant determined from the oscillator calibration.

$$\text{Hence} \qquad C_0 = 4\pi^2K\frac{m}{s} + 4\pi^2K\frac{m'}{s} \quad . \quad . \quad . \quad . \quad (6)$$

If, therefore, equal masses m' are added to the prongs at the point of drive, C_0 found for resonance, and m' plotted against C_0, the graph should be a straight line of slope $4\pi^2K/s$ and intercept $4\pi^2Km/s$, and from these two quantities m and s are determined.

This experiment was carried out, the graph obtained being shown in Fig. 3. This checks the theory and provides a rapid method of finding m and s for any fork.

K, from the oscillator calibration, was

$$10^5 \text{ (cycles/sec.}^2)^2 \ \mu\text{F}$$

and from the graph the slope is 0·0868 μF/gramme and the intercept is 7·053 μF.

$$\text{Hence} \qquad m = 81 \cdot 3 \text{ grammes, and}$$
$$s = 45 \cdot 5 \times 10^6 \text{ dynes/cm}$$

A resonance curve of the unloaded fork at constant current was taken and by the circle construction the decay factor was found to be 0·096, giving

$$r = 2ma = 15 \cdot 6 \text{ dynes per cm per sec.}$$

where r is the mechanical resistance of one prong of the fork.

The pick-up was now coupled to one prong and at a frequency of 117 cycles per sec. it was found that the reactive load of the pick-up and 16 grammes was balanced by 4·3 grammes on the other prong.

Thus the pick-up has an apparent negative mass of 16 − 4·3 = 11·7 grammes, corresponding to a stiffness, at this frequency, of

$$s_0 = \omega_0^2 m_0 = 4\pi^2 \times 117^2 \times 11 \cdot 7 \text{ dynes per cm}$$
$$= 6 \cdot 36 \times 10^6 \text{ dynes per cm}$$

A resonance curve taken of this balanced system gave

$$a = \frac{r + \frac{1}{2}r'}{2(m + m')} = 14 \cdot 3$$

$$\text{hence} \qquad r + \tfrac{1}{2}r' = 2\,450$$

$$\text{giving} \qquad r' = 4\,870 \text{ dynes per cm per sec.}$$

---

* *Journal I.E.E.*, 1925, vol. 63, p. 401; also *Proceedings of the Physical Society of London*, 1927-8, vol. 40, p. 14.

In order to test the sensitivity of the method for the balancing of mechanical reactance, a graph was taken showing resonant capacity C_0 plotted against mass added to one prong only (Fig. 4). The steepness of the curve for small values of mass out-of-balance is very apparent, and a measurement can be obtained without any difficulty with an accuracy of 2 or 3 per cent.

The determination of the decay factor from the graphical construction, however, is laborious and not so accurate, and the advantages of a single-reading method for determining the resistance from the points of view of increased accuracy and rapidity of measurement are apparent.

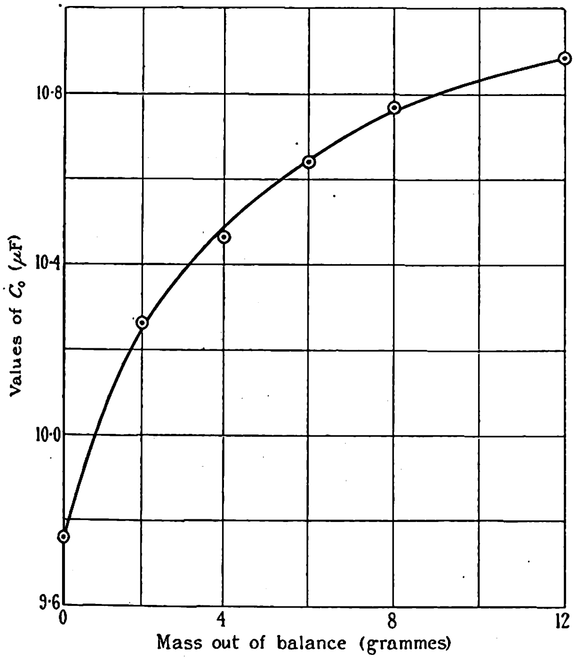

FIG. 4.

Such a method can be obtained by making use of the equation

$$u_0 = \frac{Ai_m}{r_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where x_0 = amplitude at resonance,
u_0 = max. velocity at resonance,
$= \omega_0 x_0$,
i_m = current in abamps (max. value),
A = force factor of driving system in dynes per abamp, and
r_1 = total mechanical resistance of one prong.

Hence if A is known, measurement of x_0, C_0 and i_m will determine the mechanical resistance $\frac{1}{2}r' + r$.

It is well known that

$$A = NB/S \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

where N = number of turns on driving coil,
B = flux density, in lines per cm^2, of permanent magnetism in the air-gaps, and
S = reluctance of magnetic circuit,

so that from theoretical considerations A should be independent of the external load on the fork. The accuracy of this assumption is discussed in Appendix 4.

The experimental details for determining the force factor are given in Appendix 3, the result being $A = 5{\cdot}06 \times 10^6$ dynes per abamp.

The resonance curve giving the pick-up impedance was taken at a constant current of 26·0 mA and the maximum deflection at resonance was 0·0102 cm, so that, using the shorter method,

$$\tfrac{1}{2}r' + r = \frac{Ai_m}{\omega_0 x} = \frac{5{\cdot}06 \times 10^6 \times 26 \times 10^{-4} \times \sqrt{2}}{2\pi \times 117 \times 0{\cdot}0102}$$
$$= 2\,470 \text{ dynes per cm per sec.}$$

This gives

$$r' = 4\,910 \text{ dynes per cm per sec.}$$

which agrees with the result obtained by the graphical construction.

CONCLUSION.

The method has so far been tried only at the low frequency of about 100 cycles per sec., but no difficulty is anticipated in obtaining results at frequencies up to, say, 500 cycles per sec. with forks of higher pitch. It is hoped to extend the frequency range still further by employing the higher modes of vibration of the fork.

The experimental work described in this paper was carried out in the Telegraphy and Telephony Laboratories of the City and Guilds (Engineering) College, and the thanks of the authors are due to Mr. F. W. Andrews and the staff of the departmental workshop for assistance in the construction of the special apparatus used.

APPENDIX 1.

INCREASE OF EFFECTIVE MECHANICAL RESISTANCE OF FORK WITH A MASS OUT OF BALANCE.

In the first attempt made to measure mechanical impedance by a tuning-fork method,* the pick-up was driven by one prong of the fork, and the influence on the decay factor and frequency of the fork was used to estimate the mass and resistance of the pick-up. The mass was determined from a curve such as Fig. 4. To estimate the resistance, resonance curves were drawn with various masses added to one prong only of the fork and the decay factor as determined from these curves was plotted against the mass added, to obtain a curve such as Fig. 5. From this curve the increase in the effective mechanical resistance of the fork itself resulting from out-of-balance of mass can be estimated and subtracted from the total increase obtained with the fork driving the pick-up. To obtain an idea of the correction involved, reference may be made to Section (3). With the mass balanced the pick-up introduces a decay factor of 14·3, whereas the reactive load of the pick-up, being 11·7 grammes, would itself introduce, if unbalanced, a decay factor of 10·1.

This correction is of the same order as the resistance to be measured, and the scheme was therefore abandoned in favour of a balance method.

---

* The first experiments in which were carried out by Mr. R. Toombs.

APPENDIX 2.

CONSTANCY OF FORK RESISTANCE WITH AN UNBALANCED RESISTIVE LOAD, AND MEASUREMENT OF POWER FACTOR OF OIL DAMPING.

For this experiment, matched, 3-bladed copper paddles could be attached to each prong at equal distances from the support, and glass containers so arranged that either or both paddles could be immersed to the same level in thick machine oil. By this means oil damping could be applied to either or both prongs while leaving balanced the reactive load due to the mass of the paddles.

The equivalent mass and stiffness of each prong with paddle attached was found as described in Section (3), and the decay factors under the various resistive loads were found by plotting resonance curves. With only one paddle immersed there was an out-of-balance of reactive load due to the oil carried along with the paddle. This was indicated by a change in the resonant frequency, and was corrected as described above by the addition of a small mass to the prong carrying the free paddle.

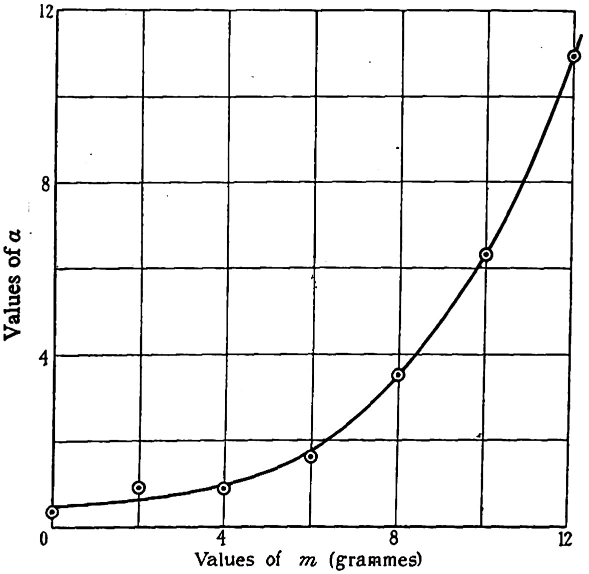

FIG. 5.

The results, giving the total mechanical resistance of the two prongs (as determined from the resonance curve multiplied by 2) under different loads, are given below, the resonant frequency being constant at $103\cdot 2$ cycles per sec.

	Resistance, in dynes/cm/sec.
(1) Thick oil round left-hand paddle with right-hand paddle free	2 776
(2) Thick oil round right-hand paddle with left-hand paddle free	3 320
Sum	6 096
(3) Thick oil round both paddles	5 980
(4) Both paddles free	136
Sum	6 116

Assuming no increase of prong resistance with unbalanced resistive load, the two sums should agree as they are each equal to the mechanical resistance of 4 prongs plus 2 immersed paddles plus 2 free paddles, and from the results it is clear that the assumption is justified.

From the balancing mass required with only one paddle immersed, a figure may be obtained expressing the " mechanical power factor " of the damping. With the right-hand paddle immersed, $1\cdot 0$ gramme had to be added to the left-hand paddle to restore the mass balance.

The mechanical resistance of the oil damping with the right-hand paddle

$$= 3\,320 - 136 = 3\,184 \text{ dynes/cm/sec.}$$

Hence " power factor " of the oil damping

$$= \frac{r'}{\sqrt{[(r')^2+\omega_0^2(m')^2]}} = \frac{3\,184}{\sqrt{[3\,184^2+(2\pi\times 103\cdot 2\times 1)^2]}}$$
$$= 0\cdot 98$$

This result shows that oil damping, at any rate under the conditions used, acts practically as a pure resistance.

APPENDIX 3.

DETERMINATION OF THE FORCE FACTOR A.

The force factor was determined in the first instance in the well-known manner by drawing curves of vibration amplitude against frequency and of coil impedance against frequency. The decay factor a is determined from either; the former gives, in addition, the amplitude x_0 at resonance and the latter the diameter OD in ohms of the motional impedance circle.

From (7), $$\omega_0 x_0 = \frac{A i_m}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and $$\text{OD} = \frac{2A^2}{r} \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

whence $$A = \frac{\text{OD}}{2\omega_0 x_0} i_m \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

Subsequently, however, the determination of m and s from a curve such as Fig. 3, and a from a resonance curve of amplitude against frequency, enabled r to be found as

$$r = 2ma$$

and a quicker determination of A from equation (9) as

$$A = \frac{\omega_0 x_0 r}{i_m} \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

For the experiments described in Section (3),

$$\omega_0 = 2\pi \times 119 \text{ radians per sec.}$$
$$x_0 = 0\cdot 0108 \text{ cm}$$
$$r = 15\cdot 6 \text{ dynes per cm per sec.}$$
$$i = 0\cdot 176 \text{ mA (R.M.S. value)}$$

giving $A = 5\cdot 06 \times 10^6$ dynes per abamp.

APPENDIX 4.

CHECK ON CONSTANCY OF FORCE FACTOR WITH UNBALANCED RESISTIVE LOADS.

Using the equation (12) derived above, the force factor A was determined for the unbalanced resistive loads used in Appendix 3, giving the results tabulated below.

From the figures in the last column of the table it is clear that A is sensibly independent of the load on the fork, provided that there is mass balance.

SOME NOTES ON THE DESIGN OF A GRAMOPHONE PICK-UP.

By G. W. Sutton, B.Sc.

(Paper first received 29th November, and in final form 20th December, 1929; *read before the* Wireless Section *5th February,* 1930.)

Summary.

It is a matter of common experience that the performance of the large majority of commercial pick-ups leaves much to be desired. The following notes describe an experimental investigation of the performance of certain types.

Further experiments are then described on the mode of vibration of a pick-up armature and on other factors affecting the performance of the instrument.

A theoretical treatment based on the results of these experiments is given and finally a new design is evolved.

Table of Contents.

(1) Classification of types of pick-up.
(2) Results of preliminary tests.
(3) Experiments on mode of vibration of a pick-up armature.
(4) Parasitic vibrations in the pick-up support.
(5) Lamination of armature and pole-shoes.
(6) Distribution of alternating component of the magnetic field at different frequencies.
(7) Effect of annealing armature and pole-shoes.
(8) Damping the vibrating system.
(9) Acoustical damping.
(10) Résumé of theory of operation.
(11) Method of design.
(12) Regulation of voltage output.
Appendix 1. Measurement of voltage output over a wide range of frequency.
Appendix 2. Theory of the pick-up.
Appendix 3. Tendency of the pick-up needle to leave the record groove.

(1) Classification of Types of Pick-up.

It would appear that there is a demand for three types of pick-up:—

(1) A type, frequently called a "play-back," which is used to reproduce directly from the "wax" immediately after an impression has been made, in order to ascertain whether the recording is satisfactory. In this device voltage output is of relatively little importance compared with the necessity for an absolute minimum of wear by the needle.

(2) An instrument which is intended to be used with its own special amplifier, where again the voltage output is of minor importance since it can be so readily augmented in the amplifier.

(3) A type which can be used with a standard broadcast receiving set. This should provide an output of the order of 0·15 volt/mm/cycle/sec.* in order to comply with the present tendency in receiver design.

It is with type (3) that the present paper is primarily concerned.

It may be accepted at the outset that the technique of recording has advanced to a very high standard. The frequency range covered is such as to call for reproducing apparatus capable of dealing properly with frequencies down at least to 50 cycles per sec., and up to the region of 8 000 cycles per sec. In the author's opinion the importance of the lower frequency limit is still not fully appreciated.

Not only has the useful frequency band been very considerably widened, but the amplitude of the groove has been increased, at least in the better-class records. This means that the ratio of recorded note amplitude to that of those unavoidable irregularities which give rise to surface noise or "scratch" has been increased. Full advantage of this can only be taken by the use of electrical pick-ups, since some control of volume of the output becomes necessary. In fact there have been many protests from musically inclined listeners who use mechanical sound-boxes, at the excessive volume given by good modern records.

Considerations of voltage output and of cost of production led the author to conclude that the moving-iron electromagnetic type of generator was the only one likely to prove satisfactory in class (3). In designing this type we have to choose between the methods of construction which are generally known as the "attracted reed" and the "balanced armature." Of these the latter appears to possess two distinct advantages. Firstly, the resultant forces of magnetic attraction on the armature are smaller, and therefore do not necessitate the use of such a high order of stiffness in the armature suspension. Secondly, a comparatively much larger amplitude of armature vibration can be allowed without introducing "rectification" effects in the voltage output. These two points allow a very useful margin of freedom in deciding the dimensions of the armature and pole-pieces and of the constants of the principal vibrating system.

(2) Results of Preliminary Tests.

The results of some preliminary tests, using the method outlined in Appendix 1, on various commercial pick-ups, brought out the following points:—

(1) The existence, in every case, of one or more "resonant" points in the voltage characteristics. The prominence of these peaks varied considerably, and in some cases so affected the output that when the instrument was used for the reproduction of speech and music a clearly noticeable distortion resulted. It appeared probable that corresponding damage was

---

* Measured from + peak to − peak of the amplitude of needle-point displacement.

caused to the record. Such a case is illustrated in Fig. 1.

(2) A tendency, with some pick-ups, for the needle to jump out of the groove at frequencies below about 100 cycles per sec. In all cases a distinct vibration of the tone-arm or supporting lever could be felt at low frequencies.

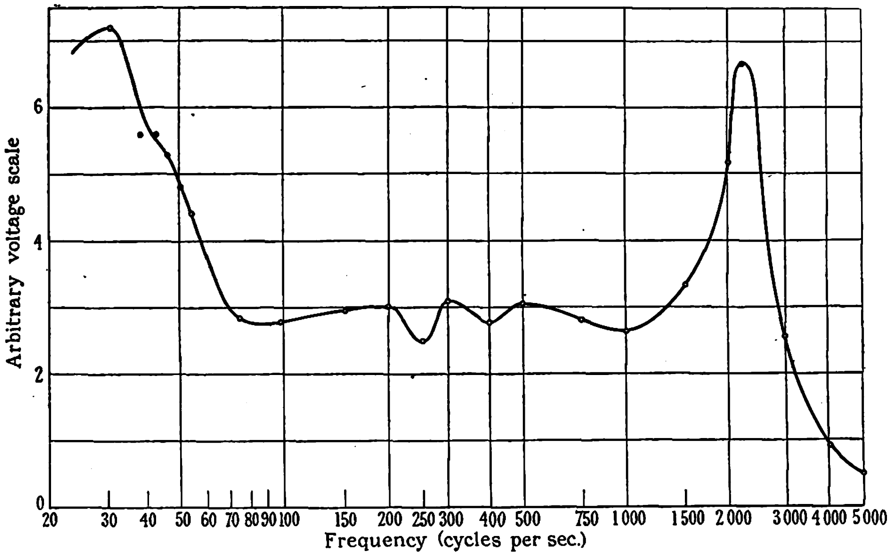

Fig. 1.—Voltage output characteristic of commercial pick-up using "loud" tone H.M.V. needle, showing two principal resonances.

(3) A comparatively poor voltage output at frequencies of 5 000, 4 000 and sometimes even 3 000 cycles per sec. This leads to a distinct lack of "brilliance" in speech and music reproduction.

(3) Experiments on Mode of Vibration of a Pick-up Armature.

The reason for the peak in the characteristic in Fig. 1 at 2 200 cycles is not at first clear. It is true that at a certain frequency the reaction force due to the moment of inertia of the vibrating armature is balanced by that due to its method of suspension, leaving only frictional or damping forces at play. This, however, should only increase the amplitude of vibration at that frequency *for a constant deflecting force*. When the needle-point rests in the groove of a record the amplitude of excursion of the point is governed, however, by the record, and the deflecting force adjusts itself accordingly. Consequently, providing the armature is rigid and the needle-point does not leave the groove there is no reason why there should be a peak in the voltage characteristic at this frequency. To explain the existence of the peak, therefore, it is necessary to assume either that the armature is not rigid or that the needle itself bends very considerably. It was thought worth while to investigate this point experimentally, and the following simple test was devised. The commercial pick-up of Fig. 1 was mounted in an inverted position in a heavy clamp. A certain measure of flexibility (to simulate that existing when the instrument is fitted to a tone-arm) was provided by blocks of rubber (R in Fig. 2). A mirror, about 2 mm square, stuck to the armature as close to the air-gap as possible, reflected a clearly defined spot of light on to a scale at a distance of about 3 m. By this means vibrations of so small a total amplitude as 0·00005 radian could be observed, and 0·0001 radian and upwards could be fairly accurately measured. A constant-amplitude variable-frequency current was passed through the pick-up windings by placing it in the anode circuit of a power valve excited by a heterodyne oscillator. The valve was of the "pentode" class, having a differential resistance of 30 000 ohms. This ensured a sufficient degree of constancy of the current with frequency (for constant voltage input to the grid) up to about 3 000 cycles per sec. Curve A in Fig. 3 shows the result of a test carried out under these conditions. One clearly defined resonance is noticed at 715 cycles per sec. The armature of this generator was of simple shape and its moment of inertia could readily be calculated. The value was $1 \cdot 52$ gramme-cm^2. The stiffness of the suspension was measured by hanging weights on a short length of steel wire clamped in the needle holder and observing the deflection. The mean value obtained was 23×10^6 dyne-cm per radian. From this and the moment of

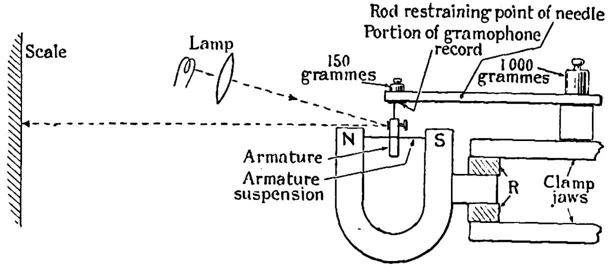

Fig. 2.—Method used for examining the mode of vibration of the armature.

inertia the resonant frequency is found to be 620 cycles per sec.; a result in fair agreement * with the value obtained from Fig. 3.

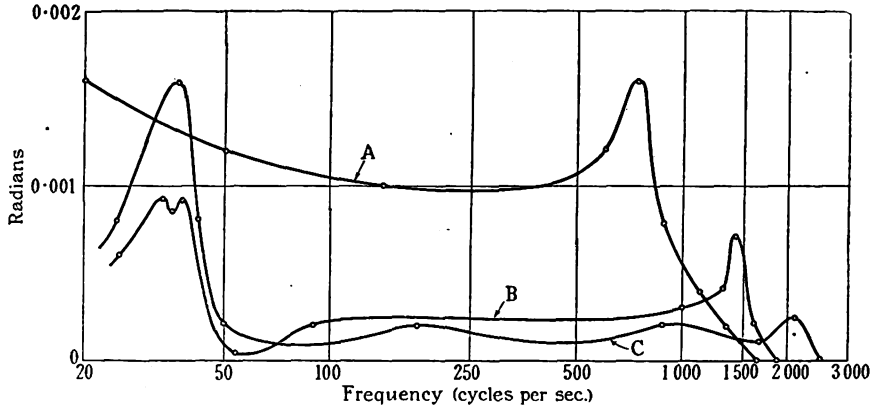

FIG. 3.—Amplitude of armature vibration of commercial pick-up. Vibrations produced electrically; constant input current.
A.—Armature free. B.—Needle-point restrained, "soft" needle. C.—Needle-point restrained, "loud" needle.

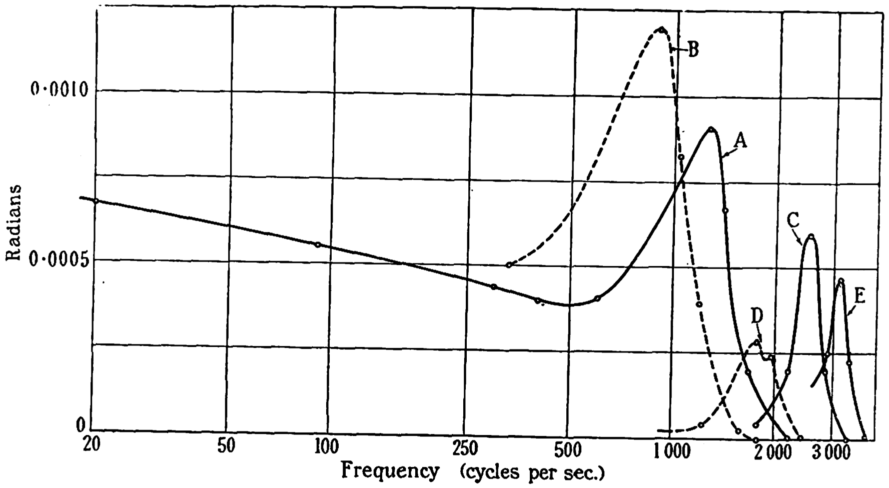

FIG. 4.—Amplitude of armature vibration of experimental pick-up.
A.—Armature free. B.—Armature free, moment of inertia artificially increased. C.—Needle-point restrained, "soft" needle. D.—Needle-point restrained, "soft" needle. E.—Needle-point restrained, "loud" needle.

It will be noted that there is no appreciable peak in the voltage characteristic (Fig. 1) at this frequency.

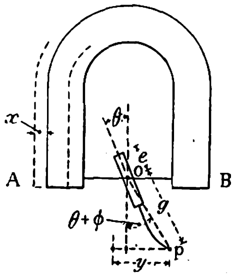

FIG. 5.

The test illustrated in Fig. 2 was than extended by restraining the point of the needle in a manner which reproduced, as closely as possible, the conditions under which the pick-up normally operates. A small portion of gramophone record was firmly stuck to a square-section rod which was then placed in position as illustrated in Fig. 2. The 150-gramme weight corresponded to the weight of the pick-up when in its normal operating position. The readings obtained with the same operating current as before are shown in Fig. 3, curves B and C.

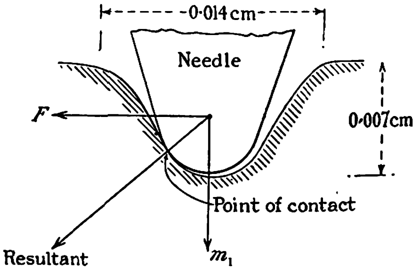

FIG. 6.

It will be seen that the general level of amplitude is

* Compare similar calculation on page 574.

much reduced in curves B and C and that there is no sign of the peak at 620 cycles per sec. Instead, prominent peaks are introduced at 40 cycles and at 1 450 and 2 100 cycles for the "soft" and "loud" needles respectively. The two peaks in curve C correspond almost exactly to those in Fig. 1, and the test demonstrates fairly conclusively that the bending of the needle plays an important part in the performance of the amplifier, particularly at the higher frequencies.

(4) Parasitic Vibrations in the Pick-up Support.

With a simple and rigid construction no complications will arise from parasitic vibrations in the armature itself, except at quite high frequencies, i.e. above 5 000 cycles per sec. On the other hand, trouble may readily arise at lower and more important frequencies from vibrations of the pick-up support or of some part of it. Evidence of this was apparent in several of the output characteristics taken in the course of the work, and the most striking example is illustrated in Fig. 7. In the characteristic A a peculiar irregularity occurs between 200 and 500 cycles per sec. The shape resembles that of the impedance/frequency curve of a coil to which a tuned circuit is coupled, in the neighbourhood of the resonant frequency of the latter. It suggests, therefore, that energy is being absorbed by some system coupled to the pick-up. It was noticed also that the counterbalance weight vibrated appreciably at about 300 cycles per sec. When damping oil was put into the pick-up the effect was very considerably intensified (see curve B).

The counterbalance weight was a sliding fit on the supporting lever and was held in position by a clamping screw. It was thought that by insulating this weight from the rod instead of clamping it rigidly to it the vibrations transmitted by the pick-up along the lever would be absorbed instead of being reflected. The hole through the weight was therefore bored out to a larger diameter and the space so formed between it and the rod was packed with felt. This was sufficient to reduce the irregularity in the characteristic to the negligible proportions illustrated in curve C.

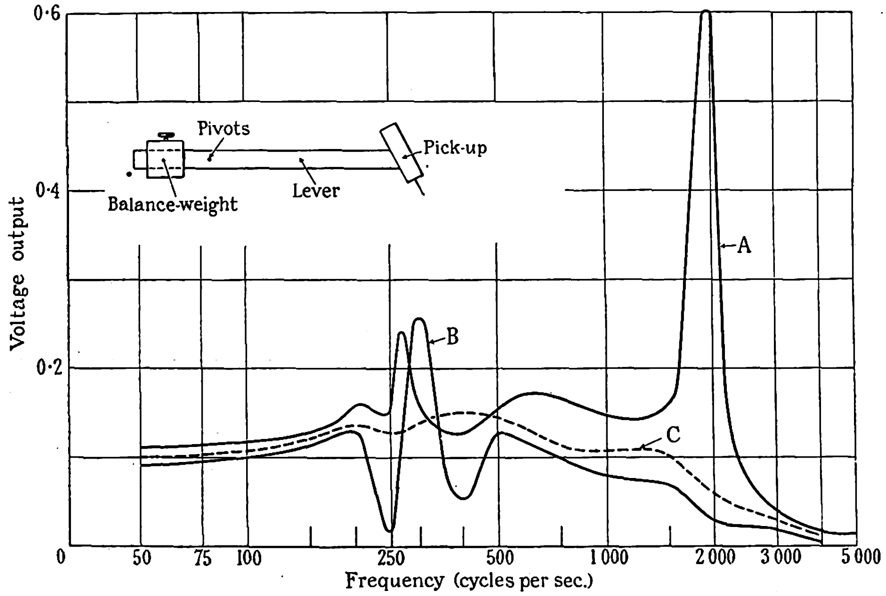

Fig. 7.—Effect of vibration in supporting lever. Balanced-armature pick-up; armature mounted on 0·0085 in. disc.

A.—No added damping. B.—Heavy oil damping. C.—Medium oil damping; balance-weight insulated from lever with felt.

(5) Lamination of Armature and Pole-Shoes.

In all apparatus designed for alternating fields, particularly of high frequency, care is taken to laminate the iron core. It is a matter of some difficulty to do this in the present case owing to the limitations of size.

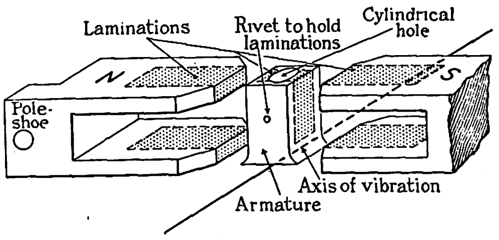

Fig. 8.

Experiments were, however, made to ascertain whether improved performance at 3 000, 4 000 and 5 000 cycles per sec. could be obtained by this means.

The shape of the armature and pole-shoes of the model upon which the experiment was conducted is shown in Fig. 8. The armature consisted in the first place of a short length of annealed mild-steel rod, hollowed out by drilling as shown. A voltage characteristic of this instrument was taken, after which it was disassembled and the portions shown dotted were cut away and replaced by thin stalloy laminations. After reassembling a fresh characteristic was taken. It was found that only slight improvements in voltage and output resulted and that this was more pronounced for frequencies *below* 200 cycles than for those above it. In any case it was not sufficient to justify the complications of construction, and it appeared that improvements at the higher frequencies were more likely to be obtained from reduction in the inertia of the armature. The apparent anomaly of a greater improvement at lower than at higher frequencies may indicate insufficient insulation between laminations; in the author's opinion, however, it is more likely to be due to the difficulty of reassembling such a small instrument to exactly the same gap dimensions and motional constants of the armature as it previously possessed.

TABLE 1.

Cycles per sec.	50	100	250	500	1 000	5 000
V_a volts	0·061	0·071	0·094	0·091	0·075	0·029

* No additional damping was introduced for this experiment, and 3 000 cycles was the principal resonant frequency.

(6) DISTRIBUTION OF ALTERNATING COMPONENT OF THE MAGNETIC FIELD AT DIFFERENT FREQUENCIES.

The experiment just mentioned suggested that the falling off at high frequencies was not due in such large measure as had previously been supposed to the effect of eddy currents on the alternating flux distribution. A further experiment to check this point was carried out.

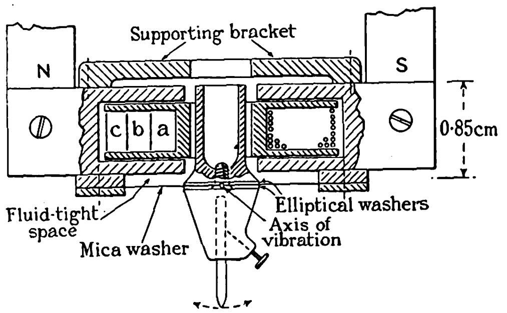

FIG. 9.—Calculated moment of inertia of vibrating system:

Armature (above axis)	0·08	(mass 0·55 gramme)
Needle-clamp	0·08	(mass 0·87 gramme)
Clamping screw	0·17	(mass 0·35 gramme)
Needle	0·12	(mass 0·19 gramme)
	0·45 gramme-cm	

A coil was wound in three sections (a, b and c, Fig. 9) of 2 000 turns each, and the voltage outputs from the three sections were measured and compared. As will be seen from the diagram, the changes in flux distribution due to the motion of the armature will be greatest at the pole-tips. Consequently a given amplitude of vibration will induce a larger voltage in "a" than in "c"; and the higher the frequency the greater will be the ratio of V_a to V_c. In fact it had previously occurred to the author to make use of this by backing-off V_c against V_a and V_b in series, with the object of levelling up the voltage characteristic of the pick-up. Measurement showed, however, that the difference was not actually as great as was anticipated. The figures in Table 1 illustrate the point.

(7) EFFECT OF ANNEALING ARMATURE AND POLE-SHOES.

The opportunity was taken when constructing one model to ascertain the extent of the improvement in output which might be expected from annealing the mild-steel portions of the magnetic circuit. The difficulty in making the experiment was to reconstruct the instrument after annealing to the same dimensions as it possessed originally. In order to reduce as much as possible the uncertainty due to this, the model selected was one which had been constructed with comparatively long air-gaps.

The armature was a short length of mild-steel rod and the pole-shoes were machined from a sheet of the same material. The annealing process consisted of heating the portions in a gas flame to a pale yellow colour and then allowing them to cool slowly by gradually reducing the flame. The operation was spread over a period of about ½ hour.

The results are given in Table 2.

(8) DAMPING THE VIBRATING SYSTEM.

When the reaction force due to the inertia of the armature is balanced by that due to the stiffness of the needle and the armature suspension, the damping alone controls the extent of the vibration. As the frictional forces are ordinarily much smaller than the reaction forces, both voltage output and record wear become excessive at this resonant frequency. Some method of increasing the damping is therefore essential. The means available may be classed as follows:—

(1) To raise the resonant frequency to the neighbourhood of 4 000 or 5 000 cycles.

(2) To couple to the armature a second vibrating system which absorbs energy, either electrically or mechanically.

(3) To increase artificially the damping factor by mechanical means.

(1) If this can be achieved by a reduction of the moment of inertia of the armature it is the most satisfactory way of dealing with the problem. Both the damping "constant" itself, for a given construction, and the force corresponding to a given damping constant, increase with frequency. Consequently, if the resonant frequency is raised to, say, 5 000 cycles per sec., additional damping becomes unnecessary, that inherent in the suspension being sufficient. A sufficient reduction in the inertia of the armature can only be achieved, however, at such a sacrifice of voltage output as to remove the pick-up from the present class as regards sensitivity.

It is much more common to attempt to get the same result by inserting small pieces of rubber between the armature and pole-faces. This is usually spoken of as "damping" the system with rubber. Actually, however, the stiffness of the system is increased to a far greater extent than the damping factor, and this has an undesirable effect on the performance of the pick-up at low frequencies (see equations 8 and 11).

(2) Unfortunately, the degree of coupling between the mechanical vibrating system of the pick-up and the electrical circuit is not sufficiently close to make it feasible to damp the former with a tuned-circuit shunt. It is necessary, therefore, to employ a second mechanical system and to couple it mechanically with the first. A form of construction which makes this possible is described later. Preliminary experiments with the method have given promising results.

(3) It is most commonly attempted to employ rubber for this purpose, as mentioned above. The difficulty of devising a satisfactory construction to this end is considerable. In the case of an electromechanical recorder* it was found necessary to use a rod of gum rubber 25 cm long to provide a non-reactive load sufficient to swamp the reactive forces set up in the vibrating system during operation. The rod was attached to the armature in such a manner that torsional vibrations were set up in it. These were transmitted axially from end to end, and were absorbed by the time they had travelled along the rod and back again. It is apparent, therefore, that if vulcanized rubber, which is presumably far less viscous in nature than gum rubber, is to be employed, its dimensions and disposal must be exceedingly carefully worked out.

The use of viscous liquid, such as a heavy oil, offers a simpler solution to the problem. The difficulty which immediately arises, however, is to design a suitable liquid-tight container.

At least one good commercial pick-up has been constructed on these lines and one of the designs described later employs the same method.

The author has also used the friction set up between two small oily mica surfaces, one carried by the armature and one attached to the pole-shoes. This has proved satisfactory, but suffers from the drawback of needing very careful and frequent adjustment.

"Book" damping has also been tried. This consists of a number of small sheets of tissue paper which are alternatively compressed and released by the motion of the armature. In the author's experience this method also needs frequent adjustment owing to the liability of the paper to become "packed."

(9) Damping Due to Acoustical Output from a Mechanical Sound-Box.

It is well known that the performance, as judged by ear, of a modern mechanical sound-box connected to a well designed tone-arm and horn is remarkably good, despite the somewhat complicated nature of the lever system by which the needle operates the diaphragm, and the fact that the only damping incorporated is that due to the acoustic load. It was thought worth while, therefore, to study the vibration of the operating lever of a sound-box with and without its acoustic load.

The method employed was to mount the permanent magnet, pole-tips and coils of a telephone ear-piece on the outer face of the sound-box. A very small piece of annealed mild steel was firmly attached to the sound-box lever close to the centre of the diaphragm, and the ear-piece was clamped in such a position that the piece of steel formed its armature. Thus the vibration of the lever produced proportional voltages in the ear-piece coils, and these were measured on the valve voltmeter as before. The instrument became, in fact, a combined sound-box and pick-up. As such it was useful for the comparison by ear or microphone of the acoustical output from the gramophone itself with that from the amplifier and moving-coil loud-speaker. By means of a switch in the pick-up circuit, the loud-speaker reproduction from a record could be superimposed on the direct gramophone reproduction, or removed, at will.

In Fig. 10, curve A shows the voltage generated by the sound-box pick-up when operating under normal conditions. Over the frequency range employed it will represent fairly closely the amplitude of vibration of the centre of the sound-box diaphragm. Curve B was taken after the narrow end of the tone-arm had been tightly plugged with cotton-wool, thus preventing sound output through the horn. A prominent resonance point is apparent, under these conditions, at about 1 300 cycles per sec. The effect of the acoustical load in obliterating this resonance is apparent from comparison of the curves. If impedance/frequency characteristics of a horn-type moving-iron loud-speaker are plotted with and without the horn in place, it is seen that the resonance effect of the armature is smothered by the acoustical damping in just the same way.

The curves of Fig. 10 also indicate how closely the mechanical and acoustical systems of a well designed gramophone are coupled, since the numerous horn resonance points impress themselves upon the vibrations of the lever system. When the same tone-arm and horn were used in conjunction with a different sound-box, the cavities in which were not so well adjusted to the aperture in the tone-arm, this effect was not nearly so pronounced, although a useful degree of damping was provided by the acoustical load. The results of a measurement under these conditions are given in Fig. 11.

---

* *Bell Telephone Laboratories Reprint*, B—377, 3, p. 5.

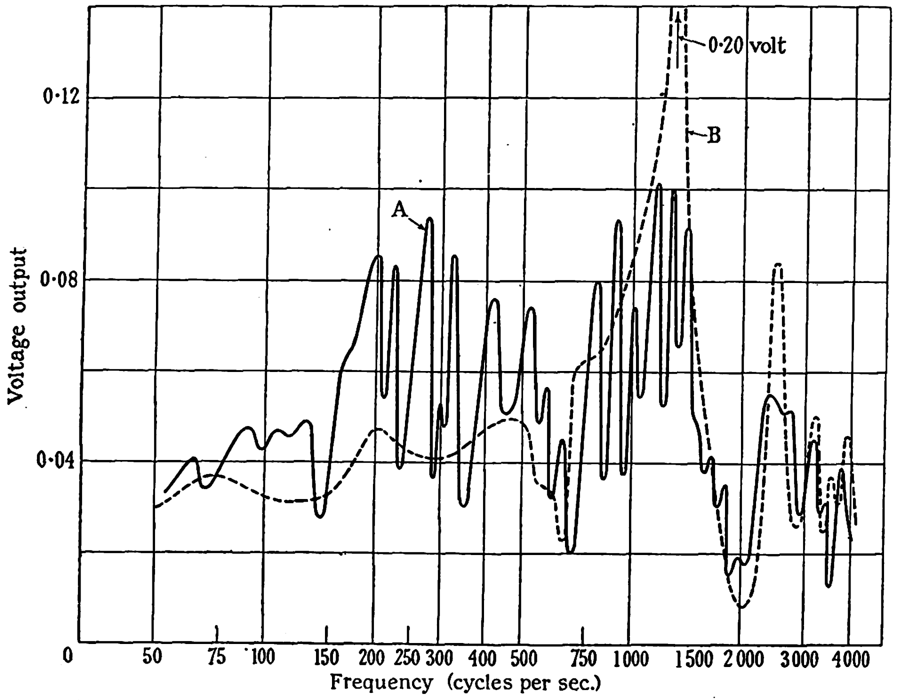

FIG. 10.—Sound-box lever as armature of electromagnetic generator.

A.—Sound-box, tone-arm and horn in normal operation. B.—Acoustic output prevented by plugging tone-arm with cotton-wool.

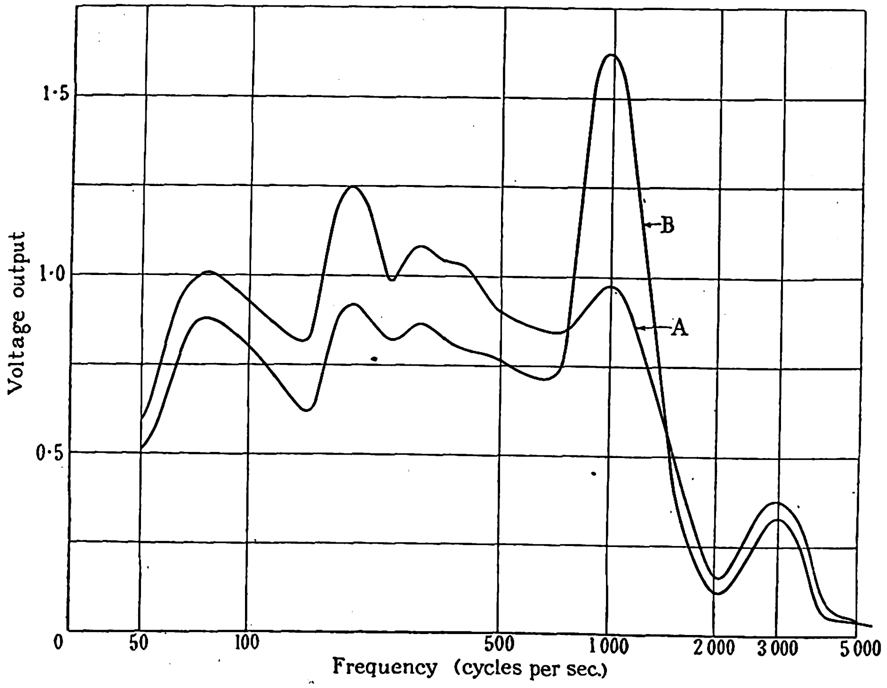

FIG. 11.—Voltage output of sound-box pick-up.

A.—When loaded acoustically. B.—With tone-arm closed, preventing the full acoustic output.

In comparing the curves of Fig. 10 with those of Fig. 11 it is noticeable that the output falls off above 2 000 cycles much more in the latter case than in the former. This was doubtless due to the greater rigidity of the lever system in the former. An appreciable lack of brilliance in the reproduction from the second sound-box, both in the case of the electrical and the mechanical methods, was very apparent.

These curves show clearly, when compared with Fig. 12, the advantage to be gained by the use of the simple rigid vibrating system of the electrical pick-up as compared with the more complicated one necessary in the case of the sound-box.

(10) RÉSUMÉ OF THE THEORY OF OPERATION.

In Appendix 2 the equations of motion of the vibrating armature of a pick-up are examined and it is found that the position on the scale of frequency of the principal resonance is governed by the inertia of the armature and the sum of the stiffnesses of the armature suspension and of the needle. In a well designed instrument the stiffness of the suspension will be small compared with that of the needle (of the order of one-tenth), so that the latter is virtually the governing factor. In fact the only means available to the designer to raise the principal resonance to a high figure (as suggested in Section 8) is to reduce the armature inertia.

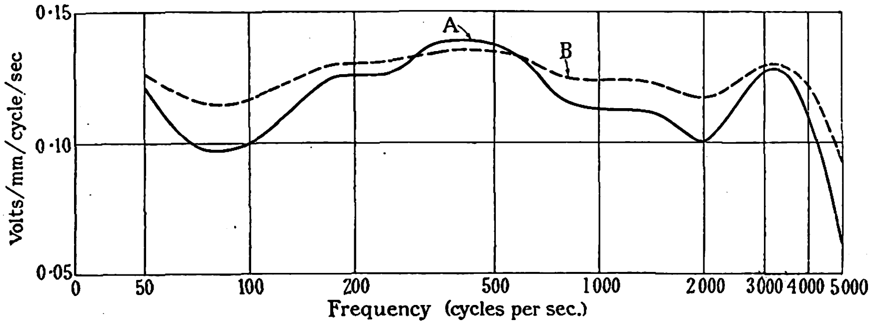

FIG. 12.—Voltage characteristic of experimental model used with a 6 : 1 step-up transformer.

A.—To a scale of volts (measured at secondary of transformer). B.—To a scale of log (volts).

It is also seen that a state of resonance arises at a very low frequency, the pick-up vibrating as a whole about the point of the needle and the pivot of the tone-arm or lever. This frequency is governed by the stiffness of the suspension and the inertia of the body of the pick-up about the axis of suspension of the armature. It is not a difficult matter, therefore, to reduce it to so low a figure that its effect is of no importance, by increasing the mass of the pick-up and its support. Except for the two resonant conditions just mentioned, there appears to be no reason why the amplitude/frequency characteristic of the armature of a pick-up should not be a horizontal straight line up to the point at which it is no longer justifiable to assume it to be a rigid structure.

An attempt is made in Appendix 3 to deduce the conditions under which the needle is liable to leave the groove.

It is seen from equation (11) that the inertia of the pick-up about the support pivots should be large, so that $1/(\omega^2 m)$ may be small compared with $g^2/\mathbf{T}$. Also that **T**, the suspension control constant, should be as small as possible so that $m_1 g$, the bearing pressure on the needle, may be reduced to a minimum.

It is a common experience to find that in a commercial pick-up which has been "damped" by inserting small rubber blocks in the air-gap, the value of **T** has been raised to such a value that the needle will not follow the groove of a test record at 100 or even 150 cycles per sec. without holding it down (i.e. raising $m_1 g$ considerably).

(11) METHOD OF DESIGN.

The reasons for adopting the balanced armature system have already been given in Section (1). It remains to deduce from the foregoing data and those in Appendices 2 and 3 the best dimensions and constants for the vibrating system.

The most important single property of this system is its moment of inertia, and every effort must be made to reduce it to a minimum. The system must consist of the needle itself, needle-clamp and armature. In the case of types (1) and (2) (see page 566) it is possible to dispense with a separate portion for the armature and to use either the needle or the clamp for the purpose. An attempt was made to use the clamp in this double role in the first model which the author constructed to fulfil the conditions of type (3), but it was then found difficult to incorporate a damping device within the limited space involved, and the attempt was abandoned.

It is an advantage to suspend the system at its mid-point, since for a given mass this leads to the lowest moment of inertia and also facilitates the application of additional damping.

Analysis of the performance of the commercial instrument of Fig. 1 leads to the conclusion that its inertia constant is much too high (1·5 gramme-cm^2). The experimental armature was therefore designed so that **I** should be not more than 0·5 gramme-cm^2. This was achieved by making the armature portion hollow (see Fig. 9). It is well known that a given mass distributed in the form of a hollow cylinder or rectangular block will possess much greater rigidity than the same mass in the form of a rod. Two further advantages accrue from this construction. Skin effect would in any case restrict the flux to the surface of the armature at the higher frequencies. Hollowing it out will therefore tend to produce a more uniform characteristic; while the greater diameter of armature involved lengthens the magnetic paths straight from pole-face to pole-face for a given length of air-gap between armature and pole-face.

The hollow in the armature has also been used for coupling the system with rubber or oil (i.e. "capacity" or "resistance" coupling) to a second vibrating system mounted above the first, to provide increased damping.

The armatures in the experimental models subsequently built were mounted on mica discs as shown in Fig. 9. Mica was used since it is non-magnetic and has a high stiffness/mass ratio. Moreover, having decided on a suitable thickness (0·010 in. was employed finally) the discs are easily made to specification and are very uniform in their properties.

In order to prevent motion of the armature in a plane parallel to the pole-faces due to irregularities in the record groove, two elliptical washers were clamped into the positions shown in Fig. 9. The minor axes of these were made equal to the armature diameter, and the major axes were made about twice as long. Measurement showed that this rendered the stiffness of the support in the plane parallel to the pole-faces nearly twice that in the plane of normal armature vibration.

The mica disc was clamped at its outer edge between two heavy rings, with carefully turned flat faces, and these in their turn were bolted to the pole-pieces (Fig. 9).

The thickness of the disc was adjusted by experiment until it was just sufficient to prevent the armature sticking to the poles by magnetic attraction. The value of **T** was then found to be $13 \cdot 8 \times 10^6$ dyne-cm per radian, which is little more than half the value for the commercial instrument previously tested. The above value was determined by deflecting the armature by a known torque in the usual manner. It appears probable that at high frequencies the effective value of **T** increases due to the mode of vibration of the disc and the resilience of the air in the cavities around the armature, since the values obtained from the tests illustrated in Fig. 4 are considerably higher than this. Thus the resonant frequency shown in curve A would be 890 cycles per sec. from $\mathbf{T} = 13 \cdot 8 \times 10^6$ dyne-cm per sec. and $\mathbf{I} = 0 \cdot 45$ gramme-cm^2, whereas it is actually 1 250 cycles per sec., indicating either an increase in the effective value of **T** at these frequencies, or an error in calculating **I**.

The values of **I** calculated from these curves, in terms of a known increment of moment of inertia (attaching a known weight at a measured distance from the axis), were 0·42 and 0·51 gramme-cm^2 (0·45 gramme-cm^2 calculated from dimensions). It was difficult to measure accurately the effective radius of gyration of the added mass, owing to the small dimensions of the armature and the irregularity of its contour. The value of **T** calculated from the curves, using $\mathbf{I} = 0 \cdot 45$ gramme-cm^2, is 30×10^6.

It has been seen (equation 11) that **T** should have as small a value as possible to reduce the tendency for the needle to leave the groove and the consequent wear and tear on the record, at frequencies of the order of 100 cycles per sec. At these low frequencies it is safe to assume that the effective value of **T** approximates much more closely to the value $13 \cdot 8 \times 10^6$ (obtained statically) than 30×10^6 (obtained dynamically at 1 000 cycles per sec. and over). This is confirmed by the comparative freedom of this model from tone-arm vibration at 100 cycles per sec.

That the value of **T** (measured statically) was sufficient to prevent amplitude distortion is indicated by the linear relationship found to exist between deflecting torque and angular displacement for the armature, up to values far in excess of the amplitudes obtained in operation, even at low frequencies.

The air-gap length was about 0·3 mm, whereas the maximum amplitude of displacement of the armature in the gap was about 0·05 mm.

Having thus determined **I** and **T**, the remaining important quantities are the mass of the pick-up itself and the bearing pressure on the needle. From consideration of equation (11) it is seen that the former should be as large as possible *—of the order of 300 or 400 grammes—while the latter should be no more than is sufficient to prevent the needle leaving the groove at the lowest frequencies and the largest amplitudes of vibration. These conditions may be fulfilled by connecting the pick-up very rigidly to a massive and rigid supporting lever. The weight of the lever should be so disposed about its pivots that the bearing pressure on the needle is about 100 grammes. This, assuming the given values of g and **T**, provides a sufficient margin of safety.

It will be seen from Fig. 9 that the construction of this model leaves a space above the mica disc and around the armature which may be rendered liquid-tight by varnishing, and may then be filled with oil of suitable viscosity to provide the necessary additional damping.

The voltage characteristic for this instrument is given in Fig. 12, both to a scale of volts/mm/cycle/sec. and also to the logarithm of this quantity.

(12) Regulation of Voltage Output.

It is usual to employ a simple resistance potential-divider for this purpose. Unless its ohmic resistance is very high, however, this will cause considerable falling off of output in the upper part of the frequency scale.

The coil of the experimental instrument just described had 6 000 turns and an inductance, measured at 500 cycles per sec., of 2·25 H. Neglecting its resistance, this corresponds to an impedance of about 700 ohms at 50 cycles and 70 000 ohms at 5 000 cycles. Consequently even a 70 000-ohm potential divider would lead to a 50 per cent loss of output voltage at 5 000 as compared with 50 cycles per sec. A tapped choke, having a liberal iron core in order to prevent excessive voltage-drop at low frequencies, and an inductance of at least 10 H, would be preferable for the purpose.

It is even better to use a transformer with a tapped secondary. The pick-up can then be wound with a few hundred turns of heavier-gauge wire, thus reducing the tendency to oscillation of the amplifier when long leads are used to connect the two.

---

* Thus making the term $1/(\omega^2 m)$ in equation (11) negligible compared with $g^2/\mathbf{T}$ at 100 cycles per sec.

ACKNOWLEDGMENT.

The work was carried out at the Telegraphy and Telephony Laboratories of the City and Guilds (Engineering) College, and the author is indebted to Prof. C. L. Fortescue, O.B.E., Member, and to Prof. E. Mallett, Member, for facilities placed at his disposal and for helpful suggestions made.

APPENDIX 1.

PRELIMINARY EXPERIMENTS. THE MEASUREMENT OF VOLTAGE OUTPUT.

A set of sine-wave "constant power" records covering a range of frequencies from 50 to 5 000 cycles per sec. was employed to drive the pick-up. The amplifier and valve voltmeter for measuring the output presented little difficulty. The voltmeter was of a type previously described by the author.* The rapidity of indication of this type enables readings to be obtained in very rapid succession and with a minimum of wear on the record—an important point when a large number of comparative tests are carried out.

TABLE 1.

Lever setting	0	1	2	3	4	5	6	7
Speed (r.p.m.)	46·5	58·8	67·4	74·0	79·4	84·3	88·3	92·3
Speed (r.p.m.) taken at a different time	47·4	58·5	67·4	73·9	79·6	84·2	88·2	92·0

TABLE 2.

Frequency (cycles per sec.)	50	75	100	150	200	250	300	400	500	750	1 000	1 500	2 000	3 000	4 000	5 000
	1·0	0·91	0·78	0·80	0·47	0·42	0·66	0·50	0·40	0·53	0·53	0·56	0·67	0·56	0·48	0·32

To obtain readings intermediate between the fixed frequencies (50, 75, 100 and 150 cycles per sec. and so on) provided by the records, the speed of the mechanical motor driving the record turn-table was varied by means of the mechanical governor. A range of speed of from 46 to 88 r.p.m. was thus rendered available. The speed at any given setting of the control lever was found to be remarkably constant. This is illustrated by the readings set out in Table 1.

The range of speed variation was of the greatest use in taking the characteristics, as it enabled points of inflexion in the curve to be accurately ascertained. For speeds other than that at which the record is intended to be run, correction of the voltage reading has, of course, to be made.

Although the product of amplitude and frequency was supposed to be constant over the whole of the records, it was soon suspected that this was only approximately the case. To ascertain the extent to which the product varied from one frequency to the next, the voltage output from a good pick-up on the 50-cycle groove when running at, say, 90 r.p.m. was compared with that from the 75-cycle groove running at 60 r.p.m. The frequency is the same in both cases and, provided the amplitude characteristic of the pick-up used is reasonably good, the ratio of the voltages is the ratio of the groove amplitudes. By a succession of such measurements each groove may be compared with the next in the series. The results of this test are shown in Table 2.

The figures given express the actual amplitude as a decimal of that which would render the product with frequency equal to the corresponding product for the 50-cycle groove.

The test was found to be difficult to carry out with accuracy as the groove for any one frequency varied in amplitude slightly from point to point, and accidental irregularities were troublesome. Moreover, the errors are obviously cumulative in ascending the frequency scale, and no simple method of check from, say, the 500-cycle to the 50-cycle groove suggests itself. The departures from the ideal in the matter of amplitude are so serious, however, that even an approximate correction is valuable.

The measurement of absolute amplitude of the grooves was carried out by driving the pick-up from a tuning fork which was excited by a valve oscillator. The vibration of the tip of the fork was observed and measured by a microscope whilst the needle of the generator was allowed to rest on a small piece of broken gramophone record firmly attached to the prong close to the tip. The amplitude of vibration of the fork was adjusted by controlling the current from the maintaining valve until the voltage generated by the pick-up was the same as that produced when it was driven by a record of the same frequency.

APPENDIX 2.

THEORY OF THE PICK-UP.

We may consider the generator to have a total mass of m grammes, and to be mounted on a tone-arm which exerts negligible control and frictional forces. The armature is assumed to have a moment of inertia of $\mathbf{I}$ gramme-cm^2, and its suspension to exert a control torque of $\mathbf{T}$ dyne-cm per radian, together with a frictional force A dyne-cm per radian per sec. In addition, the armature itself is assumed to be rigid, whilst the needle is not rigid, i.e. it is capable of bending when its point is deflected. The effect of the stiffness of the needle on the armature may be represented by an additional control torque $\mathbf{T}_n$ dyne-cm per radian, the angle considered being that subtended by the point of the needle when bent, and its mean position, at the axis of vibration.

---

* *Proceedings of the Physical Society of London*, 1927–8, vol. 40, p. 14.

Let y be the instantaneous displacement of the point p (Fig. 5) by the action of the record groove. This will result in a bodily displacement x of the generator, an angular displacement θ of the armature, and an angular displacement $(\theta + \phi)$ of p about the axis 0.

Let the horizontal component of the forces exerted by the groove at this instant be F dynes. This is equivalent to an equal force acting horizontally through 0 and a couple Fg acting on the armature.

The reaction couple acting on the armature

$$\begin{aligned} &= \mathbf{T}\theta + Ad\theta/dt + \mathbf{I}d^2\theta/dt^2 \quad . \quad . \quad . \quad (1) \\ &= Fg \end{aligned}$$

Also, along the axis AB we have

$$F = md^2x/dt^2 \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and, for the bending of the needle,

$$Fg = \mathbf{T}_n\phi \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

If the displacement of p varies harmonically and the resultant reaction forces are as given in the above equations, the force exerted by the groove will be harmonic and so also will the displacement x, θ and ϕ.

Therefore we may write

$$\begin{aligned} F'g &= \mathbf{T}\theta' + jA\omega\theta' - \omega^2\mathbf{I}\theta' \quad . \quad . \quad . \quad (4) \\ &= \alpha\theta' \end{aligned}$$

and $$F' = -\,\omega^2 mx' = -\,\beta x' \quad . \quad . \quad . \quad (5)$$

Where F' and θ' are vectors representing harmonically varying quantities.

The alteration in gap length due to the above displacement is $= e\theta$, and the movement of the needle-point is

$$x + g(\theta + \phi)$$

$e\theta/[x + g(\theta + \phi)]$ may be called the "output factor" of the pick-up, and would have a value e/g, independent of frequency, in the ideal instrument.

Taking R.M.S. values we have

$$\begin{aligned} \frac{e\theta'}{x' + g(\theta' + \phi')} &= \frac{e(g/\alpha)F'}{F'/\beta + g(F'g/\alpha + F'g/\mathbf{T}_n)} \\ &= \frac{eg/\alpha}{1/\beta + g^2(1/\alpha + 1/\mathbf{T}_n)} \\ &= \frac{eg}{\left\{(g^2/\mathbf{T}_n - 1/\omega^2 m)\right\}(\mathbf{T} - \omega^2\mathbf{I} + jA\omega) + g^2} \end{aligned}$$

Simplifying by putting $e = g$ and re-arranging, we have

$$\begin{aligned} \frac{e\theta'}{x' + g(\theta' + \phi')} &= \frac{\mathbf{T}_n\omega^2 mg^2}{[(\omega^2 mg^2 - \mathbf{T}_n)(\mathbf{T} - \omega^2\mathbf{I}) + \mathbf{T}_n\omega^2 mg^2] + jA\omega(\omega^2 mg^2 - \mathbf{T}_n)} \quad . \quad . \quad . \quad . \quad (6) \\ &= \frac{\mathbf{T}_n\omega^2 mg^2}{y + j\delta} \end{aligned}$$

the amplitude of which is

$$\frac{\mathbf{T}_n\omega^2 mg^2}{\sqrt{[y^2 + \delta^2]}}$$

The values of the quantities involved, in the case of the generator of Fig. 1, are as follows:—

$m = 135$ grammes, $\mathbf{I} = 1{\cdot}52$ gramme-cm^2, $g = 2$ cm,
$\mathbf{T} = 23 \times 10^6$ dyne-cm per radian

At 3 000 cycles per sec, $\omega^2\mathbf{I} = 5{\cdot}4 \times 10^8$ and $\omega^2 mg^2 = 19{\cdot}2 \times 10^{10}$.

It is assumed, and is confirmed later, that at this and neighbouring frequencies $\mathbf{T}_n$ is negligible in comparison with $\omega^2 mg^2$, and y (equation 6) then reduces to

$$\omega^2 mg^2(\mathbf{T} - \omega^2\mathbf{I}) + \mathbf{T}_n\omega^2 mg^2$$

This indicates a state of resonance when

$$\mathbf{T}_n + \mathbf{T} - \omega^2\mathbf{I} = 0 \quad . \quad . \quad . \quad . \quad (7)$$

made possible by the bending of the needle. This is seen to occur for a "loud" needle at 2 100 cycles per sec. in both Figs. 1 and 3. Substitution of the known values for $\mathbf{T}$, $\mathbf{I}$ and ω in equation (7) gives $\mathbf{T}_n$ the value 240×10^6 dyne-cm per radian.

At 30 cycles per sec. $\omega^2\mathbf{I} = 5{\cdot}4 \times 10^4$ and $\omega^2 mg^2 = 19{\cdot}2 \times 10^6$.

At this and lower frequencies we may neglect $\omega^2\mathbf{I}$ in comparison with $\mathbf{T}$, when y becomes

$$(\omega^2 mg^2 - \mathbf{T}_n)\mathbf{T} + \mathbf{T}_n\omega^2 mg^2 \quad \text{or} \quad (\mathbf{T} + \mathbf{T}_n)\omega^2 mg^2 - \mathbf{T}_n\mathbf{T}$$

When $$\omega^2 mg^2 = \frac{\mathbf{T}_n\mathbf{T}}{\mathbf{T} + \mathbf{T}_n} \simeq \mathbf{T}_n \quad . \quad . \quad . \quad . \quad (8)$$

$y = 0$, indicating a state of resonance in the operation of the pick-up, the instrument vibrating as a whole about the point of the needle as axis. Such a state of vibration is known to exist at low frequencies, being made apparent by feeling the instrument with the tips of the fingers.

Substituting numerical values in the above expression, the resonant frequency is found to be 32 cycles per sec., which agrees with the value indicated in Figs. 1 and 3. This peak may readily be removed to a still lower frequency, if necessary, by increasing the mass of the pick-up or by attaching it rigidly to a massive supporting lever. The mass of the lever should, of course, be distributed in such a manner as to prevent excessive bearing pressure on the needle point.

At frequencies above about 3 000 cycles per sec. it is inadmissible to assume rigidity of the armature. The voltage output will fall off, moreover, owing to eddy-current effects in the magnetic circuit. The high-frequency peak may therefore serve the useful purpose of maintaining the voltage output at frequencies at which this would otherwise decrease. To achieve this it should occur at at least 3 000 cycles per sec.

APPENDIX 3.

Tendency of the Pick-up Needle to Leave the Record Groove.

The profile of the groove in a record is approximately as shown in Fig. 6, and the forces exerted by the needle on the groove are illustrated there. If F becomes greater than mg the direction of the resultant force will subtend an angle of more than 45° with the vertical and the needle point will leave the groove. The tendency for this to happen is greatest at the lowest frequencies, when the amplitude of vibration is greatest. At such frequencies $\mathbf{I}d^2\theta/dt^2$ is small compared with $\mathbf{T}\theta$, so that the reaction force exerted by the needle point becomes

$$F = md^2x/dt^2 = \frac{\mathbf{T}\theta + Ad\theta/dt + \mathbf{T}_n\phi}{g}$$

or

$$F' = -\,\omega^2 mx' = \frac{\mathbf{T}\theta' + jwA\theta' + \mathbf{T}_n\phi'}{g}$$

At low frequencies the amplitudes of x and θ are high compared with ϕ, so that

$$F' \simeq \frac{\mathbf{T}\theta' + j\omega A\theta'}{g}$$

As previously shown, $y = x + g\theta$, hence

$$y' = -\,F'/(\omega^2 m) + g^2F'/(\mathbf{T} + j\omega A)$$

$$= F'\left(\frac{g^2\mathbf{T}}{\mathbf{T}^2 + \omega^2A^2} - \frac{1}{\omega^2 m} - \frac{g^2 jA\omega}{\mathbf{T}^2 + \omega^2A^2}\right) = F'(a - jb) \quad (9)$$

It has been seen that if $F_{max.}$ exceeds m_1g* the needle will leave the groove, i.e.

$$y_{max.} \ngtr m_1g\sqrt{[a^2 + b^2]} \quad . \quad . \quad . \quad (10)$$

The tendency to leave the groove first becomes apparent, when using constant-power test-records, when the frequency is reduced to 100 cycles per sec. or lower. At this frequency we may neglect ω^2A^2 in comparison with $\mathbf{T}^2$ in equation (9), which reduces equation (10) to

$$y_{max.} \ngtr m_1g\left(\frac{g^2}{\mathbf{T}} - \frac{1}{\omega^2 m}\right) \quad . \quad . \quad . \quad (11)$$

Inserting numerical values, $y_{max.} = 0{\cdot}0205$ cm. The amplitude of the constant-power record of this frequency was 0·0037 cm, which is less than a fifth of the permissible value. At 50 cycles per sec. $y_{max.} = 0{\cdot}0131$ cm, while the groove amplitude was 0·0075 cm, or more than one-half of the permissible value. As might be expected from this, this particular pick-up followed the 50-cycle groove without jumping, although with considerable tone-arm vibration. Unfortunately, the values of g, $\mathbf{T}$ and m were not determined for the instruments which left the low-frequency grooves when under voltage test.

---

* It should be noted that the mass which provides the vertical force m_1g will not be the same as that which provides the horizontal force ω^2mx' in the case of a pick-up which is rigidly attached to a lever and counterbalance weight. m_1 will then be considerably less than m, owing to the effect of the counterbalance weight.

FREQUENCY STABILIZATION OF VALVE OSCILLATORS.

By Professor E. MALLETT, D.Sc., Member.

(*Paper first received* 8*th December*, 1929, *and in final form* 4*th January*, 1930; *read before the* WIRELESS SECTION 5*th February*, 1930.)

SUMMARY.

The addition of a series inductance of suitable value to the anode circuit of a valve oscillator results in the frequency of the oscillations generated being independent of fluctuations in the valve constants.

There is no need to stress the importance of definitely fixing the frequency of transmitting stations, and the general practice to-day is towards using master oscillators of quite small power output to provide, through a series of amplifiers if necessary, the necessary grid swing of the power valves. Valve-maintained tuning-forks with frequency multipliers, and valve-maintained quartz crystals, are often used as the master oscillators on account of the great degree of frequency stability secured. The ordinary valve oscillator, however, has advantages, such as ease of frequency adjustment and simplicity of apparatus, not possessed by the mechanical oscillators, and, were it not for the frequency drift commonly encountered, it would undoubedly be far more used.

(1) THEORETICAL.

Considering the common type of oscillator in which an oscillatory circuit LRC is connected to the anode and a grid coil is coupled with L by a mutual inductance M, the frequency departures from the value $f = 1/\{2\pi\sqrt{(LC)}\}$ may conveniently be divided into two groups, primary and secondary. In the first group may be placed changes in the LC value itself, such as alteration of the effective value of L by a load coupled with L, and by grid currents flowing in the grid coil. The first of these is minimized by using the oscillator as a master, that is, by coupling to a second valve in which no grid current flows, and the second by using a bright-emitter valve showing definite saturation and having sufficiently high anode and grid biasing voltages, under which circumstances oscillations may be maintained without grid current flowing. These devices do not entirely avoid departures of this kind as there remain the grid-filament capacities through which currents flow, and the anode-filament capacity which shunts the condenser; but these are not likely to change.

The second group comprises the frequency departure imposed by the constants of the valve itself, and includes alterations due to change of anode- and filament-battery voltages, and of filament emission. The main effect of these changes on the frequency is through their alteration of the internal resistance R_a of the valve.

For an oscillator such as the one under consideration, neglecting the effects of valve capacities, the text-books find

$$\omega = \sqrt{\left[\frac{1}{CL}\left(1 + \frac{R}{R_a}\right)\right]} \quad . \quad . \quad . \quad (1)$$

for determining the frequency of the oscillations. Thus any change in R_a definitely affects the frequency. Suppose now that a series impedance Z' (inductance L', resistance R') is placed in the anode circuit as indicated in Fig. 1. Writing the parallel impedance of the LRC circuit Z_p and the series impedance Z, calling the anode current I_a and the current through L, I_1 (I_a and I_1 being vector currents), and supposing for a moment that a voltage E of frequency $\omega/(2\pi)$ is induced in the grid coil from an external source, then

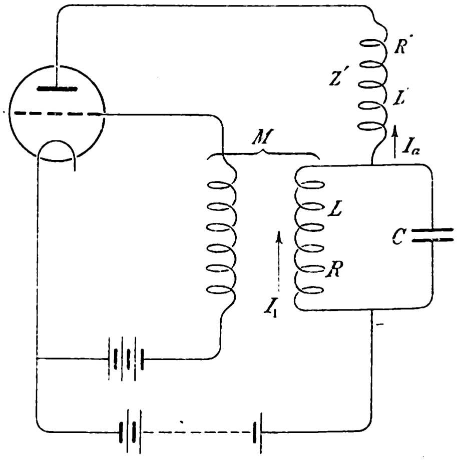

FIG. 1.

$$I_a = \mu E/(R_a + Z' + Z_p) \quad . \quad . \quad . \quad (2)$$

and

$$I_1 = -\frac{j}{\omega CZ} I_a \quad . \quad . \quad . \quad . \quad (3)$$

and the grid voltage induced by I_1 is $V_g = j\omega MI_1 = MI_a/(CZ)$. Hence E in (2) must be replaced by $E + V_g$, giving

$$I_a = \frac{\mu}{R_a + Z' + Z_p}\left(E + \frac{M}{CZ} I_a\right)$$

i.e.

$$I_a\left(R_a + Z' + Z_p - \frac{\mu M}{CZ}\right) = \mu E$$

In order that oscillations may persist when E is made zero, the left-hand side of this expression must also be zero, whence

$$R_a + Z' + Z_p - \frac{\mu M}{CZ} = 0 \quad . \quad . \quad . \quad (4)$$

Writing for Z, Z_p, and Z', their values, viz.

$$Z = R + j\left(\omega L - \frac{1}{\omega C}\right)$$

$$Z_p = (R + j\omega L)\left(-\frac{j}{\omega C}\right)\Big/\left\{R + j\left(\omega L - \frac{1}{\omega C}\right)\right\}$$

and $Z' = R' + j\omega L$

equation (4) gives

$$CR(R_a + R') - \omega CL'\left(\omega L - \frac{1}{\omega C}\right) + L - \mu M$$
$$+ j(R_a + R')\left(\omega L - \frac{1}{\omega C}\right)C + j\omega L'RC - j\frac{R}{\omega} = 0$$

Equating the imaginary terms to zero yields

$$\omega^2 = \frac{1}{LC} \cdot \frac{R_a + R + R'}{R_a + R' + (L'/L)R} \quad . \quad . \quad (5)$$

for the frequency.

Note that if $R' = L' = 0$, (5) becomes (1). Note also that if $L' = L$, (5) becomes

$$\omega^2 = 1/(LC) \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

and the frequency is quite independent of the valve constants.

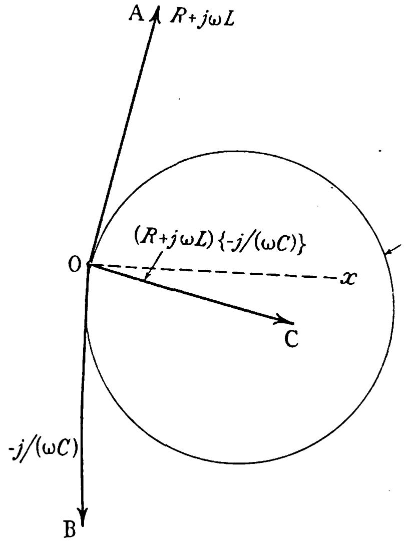

FIG. 2.

Equating the real terms to zero gives for the condition of maintenance

$$CR(R_a + R') - \omega CL'\{\omega L - 1/(\omega C)\} + L = \mu M$$

If $L' = R' = 0$ this becomes the well-known expression

$$CRR_a + L = \mu M$$

whereas if $L' = L$, so that $\omega = 1/(LC)$, it becomes

$$CR(R_a + R') + L = \mu M \quad . \quad . \quad . \quad (7)$$

These conclusions can be arrived at graphically in an illuminating manner. The condition for oscillations is, from (4),

$$R_a + Z' + Z_p - \frac{\mu M}{CZ} = 0 \quad . \quad . \quad . \quad (8)$$

The locus of $1/Z$ is a circle with a horizontal diameter of length R, and the complex quantity $(R + j\omega L)\{-j/(\omega C)\}$ is found in Fig. 2, where OA = $(R + j\omega L)$, OB = $-j/(\omega C)$, and OC is the product of these two and varies very little with the frequency-changes involved.

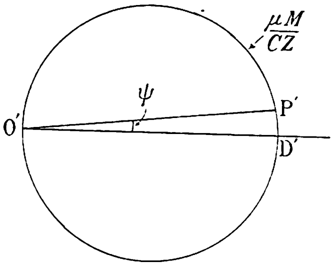

FIG. 3.

Thus the locus of Z_p is very nearly a circle drawn with its diameter in the direction OC; the diameter is the complex quantity $(R + j\omega L)\{-(\omega C)\}/R$.

Fig. 3 shows the locus of $\mu M/(CZ)$ — a circle with a horizontal diameter O′D′ of length $\mu M/(CR)$.

The vector diagram corresponding to (8) is drawn in Fig. 4. OA is made equal to R_a, AA′ to R', and $A'B$ to $j\omega L'$. From B the Z_p circle is drawn as in Fig. 2. To complete the diagram the subtraction of $\mu M/(CZ)$ must bring the point back to O, i.e. a point P must be found on the Z_p circle, such that OP = $\mu M/(CZ)$.

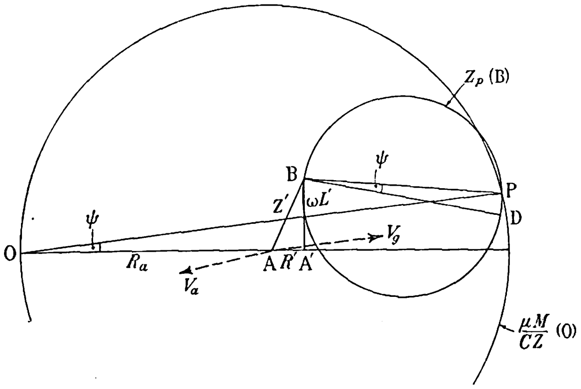

FIG. 4.

It is necessary therefore that O′P′ in Fig. 3 drawn parallel to OP in Fig. 4 shall make the same angle ψ with the diameter O′D′ that BP makes with BD in Fig. 4. The angle ψ determines the frequency, and the extent to which the circle of Fig. 3 must be enlarged to make O′P′ = OP determines M. In the diagram the frequency is below resonance. If A′B (i.e. $\omega L'$) is so adjusted that D falls on OA produced, then the point P must fall on D, P′ falls on D′ and the frequency is that of resonance of the circuit, i.e. $\omega^2 = 1/(LC)$.

Since $\mathrm{BD} = (R + j\omega L)\left(-\frac{j}{\omega C}\right)/R = \frac{L}{CR} - j \cdot \frac{1}{\omega C}$ it is clear that D will fall on the axis when $\mathrm{A'B} = 1/(\omega C)$; i.e. $\omega L' = 1/(\omega C)$ or $L' = 1/(\omega^2 C) = L$, and that then

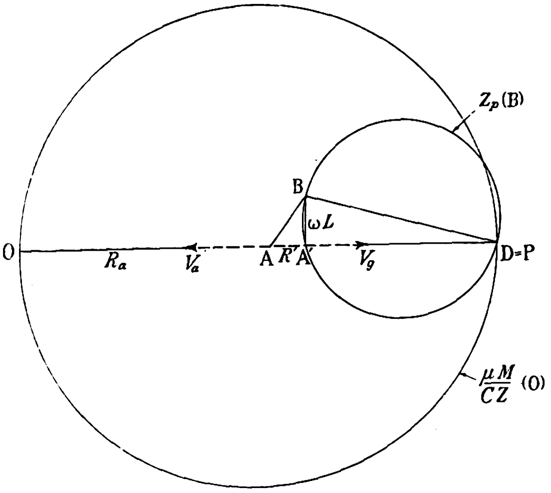

FIG. 5.

$\mathrm{O'D'} = \mathrm{OD}$, or $\mu M/(CR) = R_a + R' + L/(CR)$ in agreement with (7). The diagram is now as drawn in Fig. 5.

$$\text{Since} \quad V_a = -I_a(Z' + Z_p)$$
$$= -I_a(\mathrm{AB} + \mathrm{BD}) = -I_a \times \mathrm{AD}$$

V_a is drawn horizontally to the left from A.

$$\text{And since} \quad V_g = \frac{M}{CZ} I_a$$
$$= \frac{M}{CR} I_a.$$

V_g is drawn horizontally to the right from A. V_a and

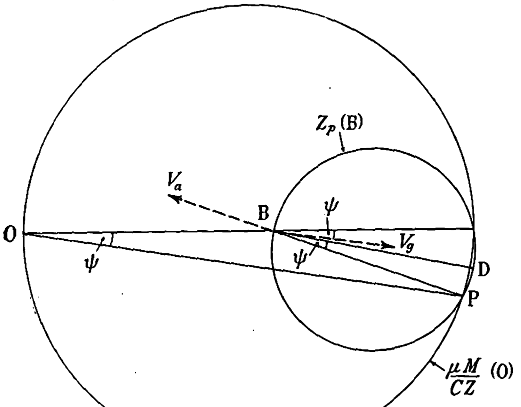

FIG. 6.

V_g are thus in exact phase opposition. With Z' omitted, that is in the usual circuit, the vector diagram is as drawn in Fig. 6, and the resonant frequency is higher than resonance. V_a is drawn in extension of PB and V_g is parallel to OP; there is not exact phase opposition. Similarly, in Fig. 4, V_a is drawn in the direction PA produced, and V_g is drawn parallel to OP. Here again there is not exact phase opposition.

The effect of adding the inductance L' of suitable value to the circuit is thus to bring the grid and anode voltages into exact phase opposition, which results—according to the simple theory given—in the frequency of the maintained oscillations being that of the free undamped oscillations of the oscillatory circuit.

(2) EXPERIMENTAL.

Some preliminary experiments, made with the assistance first of Mr. C. R. Urwin, and later of Mr. W. J. E. Tobin, have indicated that the possibility of frequency stabilization in the manner described does exist. The valve chosen was a Mullard ORA which, with an anode battery voltage of 300 volts and a grid-bias voltage of 34 volts, maintained oscillations in a circuit of inductance 350 μH and capacity 556 $\mu\mu$F without grid current flowing and without alteration of mean anode current. The characteristic curve with these adjustments is given in Fig. 7. The frequency was thus about 360 000 cycles per sec. (wavelength 835 m).

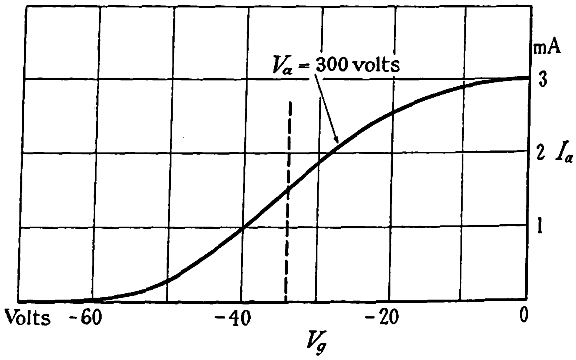

FIG. 7.

A second oscillator was set up some distance away to "receive" the oscillations of the first by heterodyne, and a third (low-frequency) oscillator enabled the heterodyne note to be adjusted by beats to a fixed value by alteration of the frequency of the second oscillator. The small alterations of frequency required were made (and estimated) by alteration of the capacity of a standard 200-$\mu\mu$F condenser with vernier adjustment in series with a fixed 10-$\mu\mu$F condenser, the combination being in parallel with the main oscillatory condenser. If C_1 is the capacity of the standard condenser and C_2 that of the fixed condenser (= 10 $\mu\mu$F) then the additional capacity across the oscillatory condenser is $C_1C_2/(C_1 + C_2)$, and if the change of this is δC, then $\delta f = \frac{f_0}{2C_0} \delta C$, where f_0 in the experiments was 360 000 cycles per sec., and C_0 was 556 $\mu\mu$F.

It appeared that the insertion of resistance in the oscillatory circuit lowered the frequency, instead of raising it as is indicated by equation (1). This was ascribed to alteration, by stray capacity effects, of the effective LC value, i.e. a primary alteration not due to the valve. This effect was great enough to mask any improvement due to the insertion of an inductance. It was, however, found that the insertion of the inductance L' did lower the frequency.

Changing the anode battery voltage yielded more promising results. It was found to be necessary to avoid cutting off the battery when changing over, and a quadruplex increment key was used (as indicated in Fig. 8), in which contact with the front stop is made before contact with the back stop is broken, the resistances "r" preventing excessive currents flowing while contact is made with both stops.

The results of one preliminary experiment are given in the table. The added inductance L' is given in the first column. In the second and third columns are given the readings of the condenser C_1, A for an anode voltage of 270 volts and B for an anode voltage of 300 volts. In the fourth and fifth columns the corresponding values of $C_1C_2/(C_1 + C_2)$ are entered. These were read off from a chart prepared from the calibration curve of C_1. δC in the sixth column is the difference of these, and δf in the last column is the frequency change, reckoned positive if an increase of anode battery voltage causes an increase of frequency.

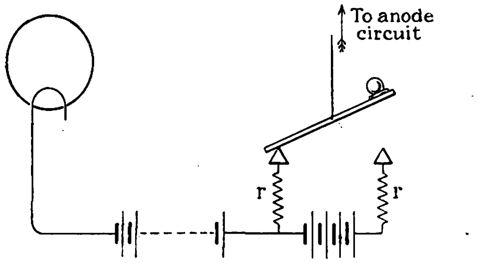

FIG. 8.

The frequency change produced by the 30-volt change in anode battery is plotted against the added inductance L' in Fig. 9, and from the curve obtained it would appear that with an added inductance of 63 μH no frequency-change would have been produced.

Altering the filament current by short-circuiting a small resistance in series yielded no positive result; the frequency alteration due to the change made was very small, and was not made any smaller by the insertion of inductances.

The fact that a smaller value of inserted inductance was found experimentally than is required by the theory is of interest. It may be due to the effect of the capacity between the anode and the grid, and the anode coil and the grid coil,* or to the effect of resistance in the capacity arm of the oscillatory circuit.† Other capacities may also be expected to modify the vector diagram; Appendix 1 is merely illustrative.

Other experiments at different frequencies have shown that the correct value for the inductance does depend upon the frequency and that the stray capacities may be such that the value of L' required is negative, i.e. a capacity must be added. Intermediately it may just happen that the circuit is already stabilized at the particular frequency in use.

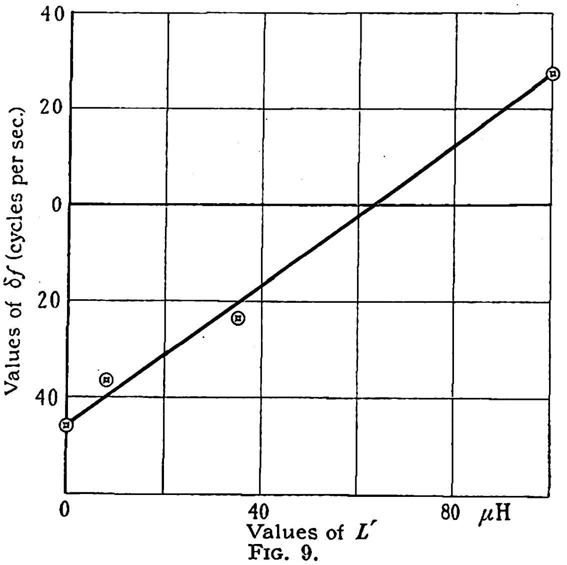

FIG. 9.

Experiments are being continued with a view to ascertaining whether the triode circuit modified in this way can take the place of the tuning fork or quartz crystal. The mechanical vibrator is always placed in a thermostatic chamber to avoid frequency-changes due to temperature-changes; it would equally be necessary to place the whole of the oscillatory circuit of the electrical oscillator in a constant-temperature chamber.

While only one of many valve oscillator circuits (including those with mechanical vibrators) has been examined, it may be said in conclusion that the same principle would appear to apply to all—frequency stabilization is carried out by a circuit adjustment which eliminates the influence of the valve constants on the frequency —and that this adjustment will be found to ensure

Added inductance L'	Reading of C_1		$C_1C_2/(C_1 + C_2)$		δC	δf
	A	B	A	B		
μH			μμF	μμF	μμF	Cycles/sec.

that the grid and anode potentials are in exact phase opposition.

The experimental work has been done in the Telegraph and Telephone Laboratories of the City and Guilds (Engineering) College, and the author wishes to thank Professor C. L. Fortescue, O.B.E., Member, for the interest that he has taken in the work.

APPENDIX 1.

Effect of Anode-Grid Capacity.

In Fig. 10 the condenser C_g represents the combined effect of the anode-grid capacity and the capacity between the anode and grid coils.

Let I' be the current through the grid coil and the capacity C_g, and R_g be the resistance and L_g the inductance of the grid coil. The current I' is small compared with I_a, and is due mainly to the voltage V_a established across the points A and B, and only to a smaller degree to the voltage induced from the anode coil.

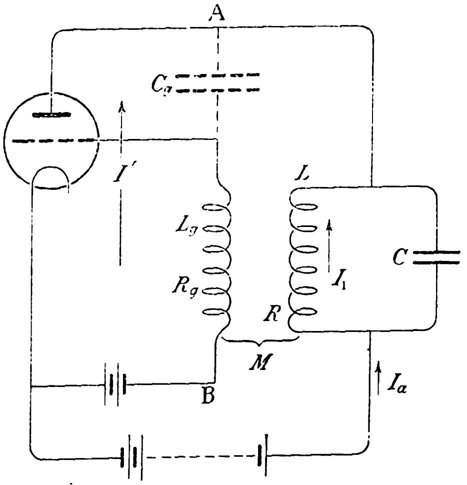

FIG. 10.

Thus, approximately,

$$I' = \frac{V_a}{R_g + j\omega L_g - j/(\omega C_g)} \doteqdot j\omega C_g V_a$$

$$V_a = -Z_p I_a$$

$$\therefore V_g = j\omega M I_1 + (R_g + j\omega L_g)I'$$

$$= \left\{\frac{M}{CZ} - j\omega C_g Z_p (R_g + j\omega L_g)\right\} I_a$$

and the condition for oscillations becomes

$$R_a + Z_p + j\mu\omega C_g Z_p (R_g + j\omega L_g) - \frac{\mu M}{CZ} = 0$$

or

$$R_a + Z_p(1 - \mu\omega^2 L_g C_g + j\mu\omega C_g R_g) - \frac{\mu M}{CZ} = 0$$

The general effect on Fig. 6 is a reduction of the diameter BD and a decrease of the angle of depression. Thus a smaller inserted inductance L' is required to bring D on to the axis.

It might therefore be possible to effect the adjustment for stability by adding to the anode-grid capacity instead of by the insertion of the inductance L'.

APPENDIX 2.

Effect of Resistance in Capacity Arm of the Oscillatory Circuit.

Let the resistance of the capacity arm be R_c and of the inductance arm be R_l, and let $R = R_c + R_l$.

Equation (3) becomes

$$I_1 = \frac{R_c - j/(\omega C)}{Z} I_a$$

and equation (4)

$$R_a + Z' + Z_p - \frac{\mu M}{CZ} - \frac{j\omega\mu M R_c}{Z} = 0$$

with

$$Z_p = (R_l + j\omega L)\{R_c - j/(\omega C)\}/Z$$

This yields for the frequency of the oscillations

$$\omega^2 = \frac{R_a + R' + R_l}{LC\{R_a + R' + (L'/L)R + R_c - \mu M R_c/L\}}$$

and in order that this may be $1/(LC)$,

$$L' = L\left(\frac{R_l}{R} - \frac{R_c}{R} + \frac{\mu M R_c}{RL}\right)$$

For maintenance with greatest output power

$$CRR_a = L \text{ (nearly)} \quad \text{and} \quad \mu M = 2L.$$

The expression then becomes $L' = L$, as before. If, however, the inductance is too great (i.e. if an anode tap is required for largest output, which generally happens at high frequencies), the value of L' required is less than L, whereas if the inductance is too small, L' must be greater than L.

AN INSTRUMENT FOR PROJECTING AND RECORDING THE RESPONSE CURVES OF ELECTRICAL CIRCUITS.

By Professor C. L. FORTESCUE, O.B.E., M.A., Member, and F. RALPH.

(*Paper first received* 16*th November*, 1929, *and in final form* 12*th February*, 1930; *read before the* WIRELESS SECTION 5*th February*, 1930.)

SUMMARY.

The paper describes a combination of a projection oscillograph, a special amplifier, and a variable condenser coupled to the rocking mirror of the oscillograph, by means of which response curves can be thrown on to a screen for observation or may be recorded photographically.

The amplifier may also be used with the oscillograph in the ordinary way for low-frequency observations, the amplifier then functioning as a special form of valve voltmeter giving an output suitable for operating the oscillograph.

(1) INTRODUCTION.

There are many occasions when it is desirable to observe with a minimum of trouble the response curves of electrical circuit arrangements, such, for example, as those of an ordinary wireless receiver, over some predetermined range of frequency. This can, of course, always be done by taking the necessary observations and plotting the curves, but where there are a large number of variables this becomes too long a process for the proper investigation of the properties of the circuits. The instrument described in this paper is an attempt to overcome this difficulty by a combination of a specially designed amplifier and a projection-type Duddell oscillograph. The horizontal deflection of the spot is made dependent upon the frequency change, and the vertical deflection is dependent upon the amplitude of the output of the circuits under test. The curve is repeated some 10 or 15 times per second, just sufficiently rapidly for the normal persistence of vision to give the impression of a continuous curve. This curve is projected on to a small screen in view of the operator adjusting the circuits. The effects of changing any particular variable are thus immediately seen. Photographic apparatus of the usual type can also be used for recording all response curves of sufficient interest to justify the time and expense involved.

In addition to this, the terminals are so arranged that the low-frequency parts of the instrument can be used for converting small voltages into currents large enough to operate the oscillograph. This is useful in such cases as the measurement of leakage fluxes where even an oscillograph current would cause appreciable changes in the flux being measured.

(2) THE SOURCE OF THE HIGH-FREQUENCY CURRENTS.

A variable-frequency screened oscillator is used in which the frequency is dependent upon the inductance and capacity in the oscillatory circuit. Both inductance and capacity are varied to give the necessary ranges of frequency change. The circuit arrangements are such that the wave-form is reasonably good over the whole range of frequency change, but at the same time the voltage amplitude in the oscillatory circuit remains constant. This adjustment is easily obtainable with any simple magnetically-coupled circuit, if the grid bias is so arranged that the change of anode current at the onset of oscillations is comparatively small. The coupling should be a little greater than the minimum value for which the oscillations will start.

The capacity in the oscillating circuit is in two parts. One part consists of a variable condenser adjusted by hand in order to give the correct mean value of the frequency—the appropriate inductance having been decided upon beforehand. The second part consists of a motor-driven variable condenser made up of two sets of fixed vanes and two sets of moving vanes, the latter being mounted on a long extension of the shaft of the driving motor. The two parts of the double condenser are in series and, as the vanes rotate, the capacity varies from maximum to minimum and back again during one revolution. This arrangement has the advantage that there are no sliding contacts in the high-frequency circuit. It has the disadvantage, however, that the moving vanes are not at earth potential, and consequently an insulating coupling must be used to connect the condenser spindle to the motor shaft.

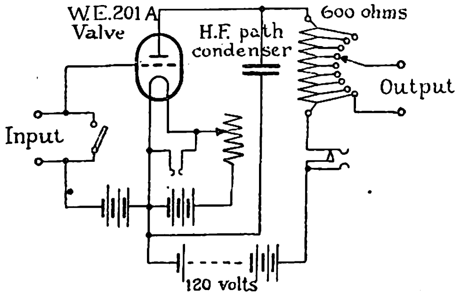

FIG. 1.

This motor-driven condenser is arranged to give a capacity of from about 50 to 200 $\mu\mu$F. By choosing various values of the inductance and hand-adjusted capacity, it is usually possible to arrange for this change of capacity to give the desired range of frequency. The only difficulty experienced occurred when a very large range of frequency was required.

In some cases it is more convenient to keep the frequency of the oscillator constant and to vary the tuning of the receiving circuit. This can be done, where the receiver consists of only a single resonant circuit, by connecting the motor-driven condenser in parallel with the capacity of this resonant circuit.

An extension of the condenser spindle carries a cam operating the usual rocking mirror of the oscillograph. By this means the spot of light is deflected horizontally in proportion to the change of capacity above and below the mean value. If this change is small compared with the total capacity, the horizontal scale is then practically a frequency scale. When desired, the frequency scale can be checked at several points by means of a wavemeter.

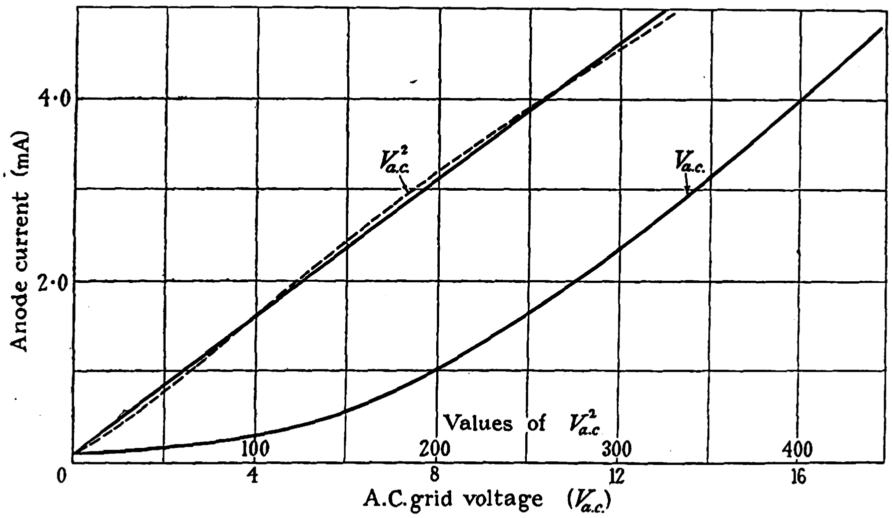

FIG. 2.

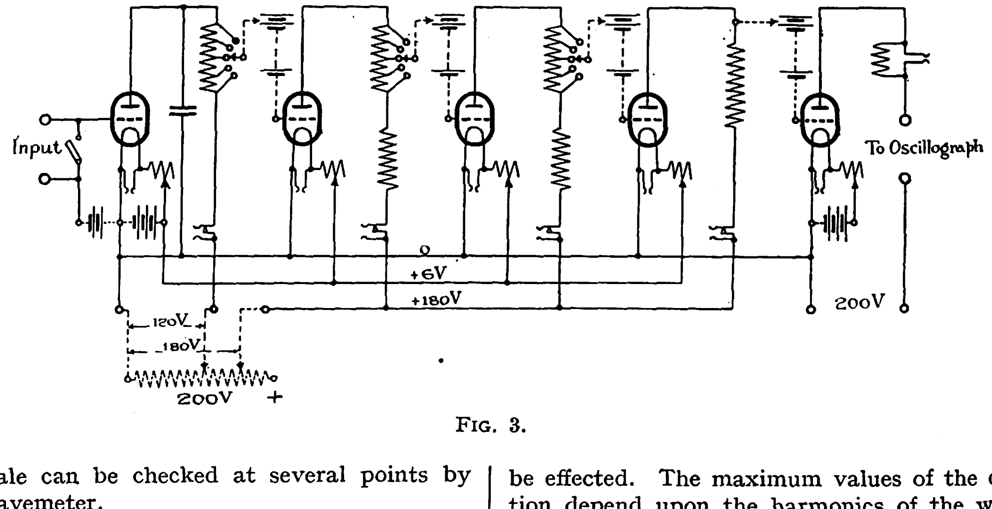

FIG. 3.

The motor shaft also carries a shutter which cuts off the light for one half-revolution. This is necessary as the rotary condenser plates may not be exactly symmetrical.

(3) THE RECTIFYING UNIT.

This consists of a single Western Electric 201A valve connected as shown in Fig. 1. The output voltage from the circuit is applied directly to the grid, superimposed upon a steady grid-bias voltage of about 6 volts. The anode circuit consists of a resistance with a capacity across it so proportioned that no more than 1 per cent of the high-frequency component passes through the resistance, and no more than 1 per cent of the rectified current passes through the capacity.

If a condenser were not used in this way the high-frequency components would go through all stages of the amplifier and upset the proportionality of the response to the rectified component. This necessity imposes certain limits on the frequencies, since the oscillation frequency must be sufficiently above the frequency of the cyclic variation for this separation to be effected. The maximum values of the cyclic variation depend upon the harmonics of the wave-form of the response curve, and include all those that can be recorded by the oscillograph. Any harmonics higher than this need not be provided for as they will be lost in any case owing to the moving strips and mirror being unable to follow them. The maximum cyclic frequency may therefore be put at about 1 000. The minimum oscillation frequency is then in the neighbourhood of 100 000, depending upon the degree of accuracy which is required.

The Western Electric 201A valve was chosen as experience has shown that the rectification follows the square law over a considerable range. Fig. 2 gives the result of an actual test with one of these valves.

(4) The Amplifier.

The output voltage of the rectifying unit may be as much as 1 volt. The R.M.S. current required by the projection-type oscillograph is about 0·15 ampere. Thus with a variation of input voltage of, say, ± 1·4 volts, the variation of the output current is to be about ± 0·2 ampere, and these two should be proportional to one another to within an accuracy of a few per cent.

When the amplifier is used without the rectifying unit for flux measurement, the voltages are often as low as 0·1 volt (R.M.S.). The amplifier is therefore designed to deal with only this small input if necessary, and to be used with larger inputs with a reduced amplification per stage.

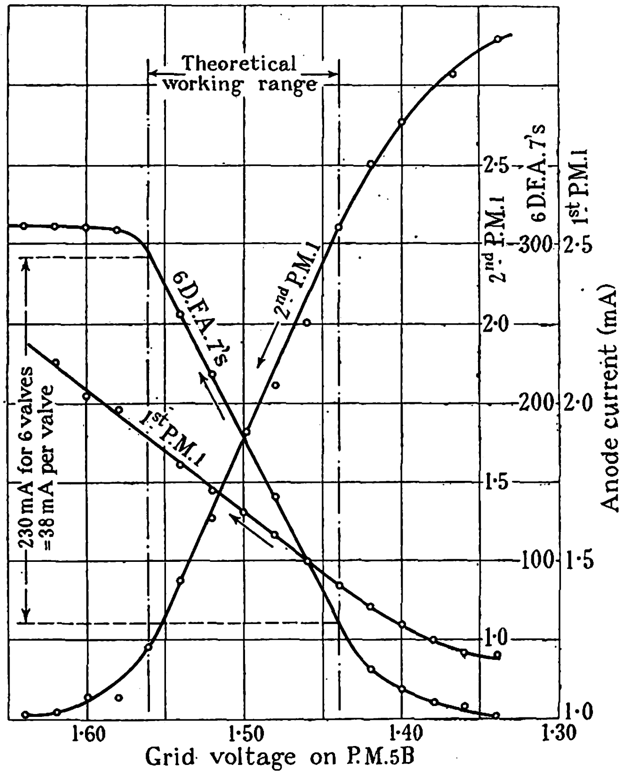

Fig. 4.

A further special requirement in this case is that the amplifier should perform equally well at zero cyclic frequency, i.e. with step-by-step changes of input voltage. This is necessary for calibration purposes and immediately determines one point in the design of the instrument, viz. that it must be resistance-coupled with separate grid batteries for each stage.

The output stage was determined by the variation of the current required for the oscillograph. Eight Mullard D.F.A.7 valves working with an anode voltage of 200 and a mean anode current of about 175 mA were found satisfactory.

Three intermediate stages were employed as follows:—

1st stage: Mullard P.M.5B valve ($V_a = 180$ volts).

2nd and 3rd stages: One Mullard P.M.1 L.F. valve ($V_a = 180$ volts).

The resistances in the anode circuits were 84 000, 26 000 and 50 000 ohms respectively. Some variation of resistance was provided in the first two intermediate stages. Fig. 3 gives the connections for the complete amplifier. Other combinations of valves and resistances have also been used, with similar results.

With careful adjustment it was found possible to compensate for the curvature of the characteristics of the output valves by that of the valves in the intermediate stages. This is possible because each stage reverses the phase and a current limitation on one valve leads to a voltage limitation on the next in the direction in which the current would normally be too large.

The final result for the whole amplifier, but with only six valves in the output stage, is shown in Fig. 4, where the current in the output circuit is shown plotted against the voltage applied to the grid of the first amplifier valve.

Very similar curves are obtained with eight valves in the output stage.

Where the maximum amplification is not required it is generally convenient to cut out the second amplifying valve by taking the grid connection of the third valve to the anode of the first valve instead of the second. The straight-line amplification is still preserved within the limits of accuracy required.

(5) The Oscillograph.

This was a standard Duddell instrument constructed by the Cambridge Instrument Co. The strips were larger than those fitted to the ordinary instruments, in order to provide for the larger mirrors necessary for projection purposes. The large strips were capable of carrying a considerable current, but actually the mean current is usually diverted by a battery and resistance in parallel with the strip. For this purpose the parallel resistance is made about 10 times the strip resistance so that about 90 per cent of the current change passes through the strips themselves.

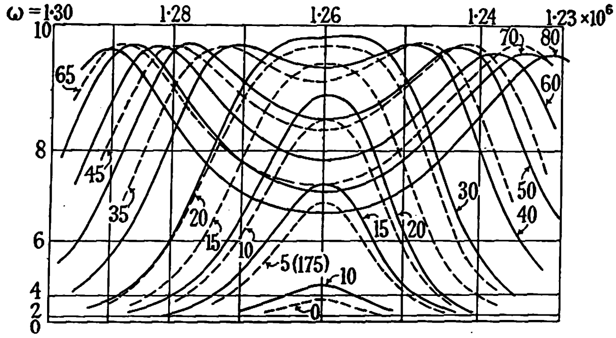

Fig. 5.—Test No. 3. Mutual only. Secondary current.

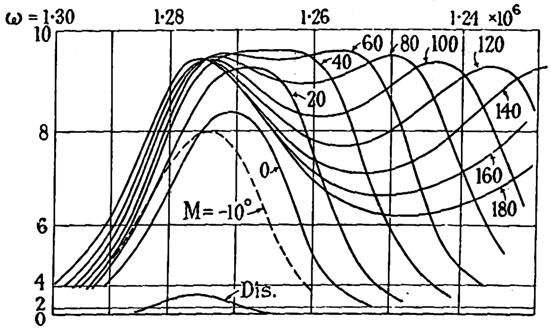

Fig. 6.—Test No. 9. Capacity coupling; $M = 0$. Secondary current.

(6) CIRCUIT ADJUSTMENTS.

The mean anode currents for all the stages were found by preliminary experiments and kept constant throughout. The amplifier was fitted with a voltmeter and a milliammeter, which could be connected in turn to each stage to verify the conditions. Once adjusted, the only changes called for were those due to batteries running down. This is perhaps the most serious difficulty in using the instrument, and it can only be overcome by using good batteries throughout and keeping them in good condition.

(7) EXAMPLES OF THE APPLICATION OF THE AMPLIFIER.

(*a*) *Response curves.*—The curves of Figs. 5 and 6 are reproduced directly from records obtained from coupled circuits, magnetic and capacity coupling respectively.

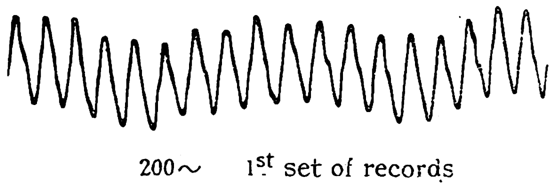

Fig. 7.

(*b*) *Other applications.*—Fig. 7 is reproduced from a record of the output of an electrical gramophone pick-up when working from a "sine wave" record. The output is not sinusoidal and the question arose as to whether this was attributable to the amplifier, the pick-up or the record. On driving the pick-up by means of a maintained fork the curves of Fig. 8 were obtained; they are obviously much more nearly sinusoidal, thus showing that the irregularities of Fig. 7 are due to the record itself.

[*] Further information, bringing the subject up to date, will probably be available during the year 1930.

[†] The Papers Committee invite written communications, with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

INTRODUCTION.

In 1922 a Committee on telephone interference was formed by the Association. Before considering experimental work it was decided to make an exhaustive survey of what had already been done in this field; and for that purpose Professor C. Parker Smith, D.Sc., with Mr. S. A. Knight, B.Sc., as his assistant, was appointed to make a critical résumé of all the available information on the subject. In March 1928 Professor Parker Smith presented a report which covered information published prior to the middle of 1925.

The present résumé consists of a brief summary of the material included in the report mentioned above, and the Association desires to express its appreciation to Mr. S. A. Pollock and Mr. W. G. Radley of the Post Office for its preparation.

Later work is under consideration by the Association, and a supplementary report will be issued shortly.

SYNOPSIS.

A general review of the subject and a statement of the physical principles underlying remedial measures are included in Section 1 (pages 589 to 591).

The methods of CALCULATING THE VOLTAGE induced in a telephone or telegraph circuit due to the disturbing influences of heavy current or high-tension open-wire power lines are indicated in Section 2 (pages 591 to 593).

The design of POWER transmission and TRACTION circuits is considered in Sections 3 and 4 (pages 593 to 597), from the point of view of causing least interference, and the design of TELEGRAPH and TELEPHONE circuits is dealt with in Sections 5 and 6 (pages 598 to 599), from the point of view of suffering least interference. An endeavour has been made to collect into each of these sections a brief mention of the whole of the information regarding the particular type of circuit under discussion.

Inductive effects from both current and voltage under normal operating conditions of the power circuit may be very greatly reduced by transposing individual conductors of both power and communication circuits at definite intervals. In Section 7 (pages 599 to 601) the various TRANSPOSITION schemes which have been tried are outlined and the most suitable pointed out, together with the best arrangement of the conductors in the case of both single and twin-circuit power lines. In order that any transposition scheme may be fully effective there must be close co-operation between the power and communication authorities.

Disturbances to the normal telephone working are generally due to the presence of high-frequency HARMONICS in the power circuit. Section 8 (pages 601 to 603) deals with the generation of harmonics by machinery or apparatus connected to the power lines. Certain modifications in the design of rotating machinery enable these harmonics to be reduced or eliminated; and the technical devices whereby this may be done are mentioned. The importance of the disturbing effects of triple-frequency harmonics manifests itself especially in power systems where the neutral point is earthed.

The mathematical work, together with a detailed discussion of many of the points which arise, is contained in a series of appendices attached herewith. References to them are given in the report. In addition the original digests prepared by Professor Parker Smith, together with more detailed data from the articles digested, have been filed away at the offices of the Association and are available to interested parties on application. Appendix 1 to this résumé gives a list of the articles from which the original digests were prepared.

A summary of the points which have been regarded by the various investigating authorities as important, and on which there is some measure of agreement, are presented in the form of a series of conclusions (Section 9). Based on the conclusions a code of guiding rules might be drawn up for the purpose of directing authorities in designing their systems. The outstanding problems on which further research work was required are also mentioned in this section.

From a general study of the available information, it would seem to be possible with the experience gained to suppress satisfactorily all inductive interference from all sources whatsoever, with the exception of shocks on short circuit, in which case the evidence is not conclusive. The elimination of interference, however, may not only entail capital cost, but also a high degree of maintenance on the part of both power and communication authorities.

DEFINITIONS.

1. *Communication circuit.*

Any type of signalling circuit arranged in cable or open wire. Communication circuits are sub-divided under—

- (*a*) Telephone circuits comprising—
  - Public long-distance trunk lines.
  - Public inter-exchange local lines.
  - Public subscribers' lines.
  - Railway despatching lines.
  - Private power companies' lines.
- (*b*) Telegraph circuits.
- (*c*) Signal circuits.

2. *Line.*

Circuit or aggregation of circuits carried on a single series of poles.

3. *Power circuit.*

Constant-potential circuits supplying energy, excluding traction circuits and communication circuits.

4. *Traction circuit.*

Constant-potential circuit used for traction and utilizing the earth as a part of the circuit.

5. *Interference.*

Disturbance and danger occurring on communication circuits due to inductive effects of power and traction circuits.

6. *Disturbance.*

Dislocation of traffic and impairment of transmission on communication circuits.

7. *Danger.*

Risk of damage to plant and of shock to personnel and the public.

8. *Parallel.*

Where a power or traction circuit and a communication circuit follow routes likely to cause interference.

9. *Normal parallel.*

Where interference may occur on a parallel due to normal operating conditions.

10. *Abnormal parallel.*

Where interference may occur on a parallel due to abnormal conditions.

11. *Separation.*

Distance between lines forming a parallel measured as a perpendicular from the power or traction circuit.

12. *Constant separation parallel.*

Part of a parallel in which discontinuities occur, but the separation remains constant.

13. *Converging parallel.*

Part of a parallel in which the separation decreases uniformly.

14. *Configuration.*

Geometrical arrangement of a circuit or circuits including size of wires and their relative positions with respect to one another and to earth.

15. *Uniform parallel.*

Part of a parallel in which there are no discontinuities.

16. *Balanced voltages and currents.*

Components of voltages and currents in the conductors whose algebraic sum equals zero at any instant.

17. *Residual voltages and currents.*

Components of voltages and currents in the conductors whose algebraic sum does not equal zero at any instant.

18. *Longitudinal voltage.*

Voltage induced along the conductors of a communication circuit or between the conductors and earth.

19. *Transverse voltage.*

Voltage induced between the two conductors of a communication circuit.

20. *Magnetic induction.*

Interference due to electro-magnetic effects of the currents in the power or traction circuits.

21. *Electric induction.*

Interference due to electrostatic effects of the voltages in the power or traction circuits.

22. *Transposition.*

Interchange of conductor positions of a circuit between successive lengths.

23. *Discontinuity.*

Any abrupt change on either circuit of the physical dimensions, electrical characteristics, apparatus or load which materially affects magnitude or phase of induced voltages or currents per unit length.

24. *Barrel.*

Section of a power circuit in which each conductor occupies each of the conductor positions for such distances to give best balance.

25. *Co-ordination.*

Transposition of both power and communication circuits efficiently located with regard to each other and to discontinuities in order to reduce induction.

26. *Protector.*

Over-voltage protective device consisting of some form of spark-gap which may be connected between each wire of a telephone circuit and earth.

27. *Characteristic residual voltage.*

Residual voltage of a short uniform non-transposed power circuit when insulated from earth and energized with balanced three-phase voltages between conductors.

28. *Unbalanced exposure.*

That length of parallel of the same cross-sectional dimensions as the given parallel and between a telephone and power circuit neither of which is transposed, which will produce inductive effects of the same magnitude as those produced in the given parallel with the given transpositions in the power and telephone circuits.

29. *Coefficient of induction.*

Ratio of the induced voltages in the communication circuit to the inducing factors (components of voltage or current) of the parallel power circuit.

30. *Reduction factor.*

The value by which the calculated values of the induced voltage or current requires to be multiplied to take into account the shielding effect due to earthed bodies near the power lines or communication lines.

(1) CIHEF FEATURES OF THE PROBLEM.*

Inductive effects are produced in communication circuits whenever they lie in the electrostatic or electromagnetic fields of power circuits.

In general, both magnetic and electric induction are present, although their effects on a communication circuit may be such that one effect may be negligible relative to the other.

ELECTRIC INDUCTION.

Due to the alternating electric field surrounding a power line having a difference of potential between itself and earth, any neighbouring line will have induced on it an electric charge. This charge varies directly with the potential of the disturbing line and depends on the capacities of the neighbouring line to the disturbing line and to earth. The charging current which flows is proportional to the frequency of the inducing voltage and to the length of the line.

---

* The references given are numbered in accordance with list of articles digested given in Appendix 1.

MAGNETIC INDUCTION.

Due to the alternating magnetic field surrounding a power conductor and produced by the current flowing in it, an e.m.f. is induced by mutual induction on any neighbouring line. This induced e.m.f. is dependent on the current, frequency, length of parallelism and the mutual inductance.

EFFECT OF INDUCTION ON A TELEPHONE OR OTHER COMMUNICATION CIRCUIT.

Due to the varying magnetic and electric fields in which it is situated a conductor located near to a power or traction line will have a *longitudinal voltage* induced along it, or between it and earth. If one conductor of a telephone circuit is nearer than the other to the power line the longitudinal voltage induced in the two will be different. The difference between these longitudinal voltages is the *transverse voltage*. This is produced between the two sides of a circuit and causes a disturbing current to flow through the receivers at the ends of the circuit. Even in the event of both wires of the telephone circuit being uniformly exposed to the disturbing line, disturbing currents may be caused to flow unless both wires are perfectly balanced as regards series impedance, capacity and leakage to earth.

The effects of interference may be considered under the headings of disturbance and danger.

DISTURBANCE.

To telegraph circuits.—Since telegraph systems work under conditions such that the frequencies of the main components of the current transmitted are less than 300 cycles per second, only the fundamental and lower harmonics of the extraneous current disturb reception by distorting or mutilating the signals or causing relays to chatter. Telegraph instruments are not sensitive to higher harmonics. Signal circuits, other than telephone circuits, resemble, in general, telegraph circuits and are most affected by the fundamental.

A number of tests have been carried out by various investigators in order to determine the permitted amount of disturbing current which will not cause trouble to telegraphic communication.

To telephone circuits.—According to Helmholtz, the physiological limits of audition are about 25 to 30 cycles per second for the lower limit, and about 30 000 cycles per second for the upper limit. Transmission of speech over telephone circuits is carried out by currents, the frequencies of which lie between limits of about 100 to 4 000 cycles per second, the mean frequency being approximately 800 cycles per second. This figure is used in telephone transmission calculations. Although this point is not definitely stated to be the case in any published paper, noise due to fundamental frequencies (60 cycles or less) of power and traction circuits is not heard in a telephone receiver; and induction due to these frequencies causes very little interference.

The effect of higher harmonics is to produce noise in the telephone receiver, which reduces the transmission value of the circuit and may interfere with speech or render it impossible. The amount of noise that can be tolerated on a telephone circuit without undue interference with speech has not been specially investigated by the Post Office.*

Increasing importance is being given to this aspect of the subject of interference by the use of land lines for the purpose of simultaneous broadcasting.

DANGER.

High interfering voltages due to the fundamental components of the voltage or current in the power line render apparatus generally liable to damage and risk of fire, and personnel to electric shock.

Metallic telephone circuits are protected by carbon-block protector gaps between each wire and earth, these gaps being arranged to break down if the voltage to earth exceeds approximately 300 volts. When, due to the longitudinal voltage exceeding this critical figure, a protector breaks down, a sudden rush of current discharges from the other wire of the circuit through the receiver and gives an acoustic shock to the listener. In addition signalling devices, such as the subscriber's bell or the calling device at the telephone exchange, may be operated. Loading coils in trunk lines may be permanently damaged by the out-of-balance current. Similar effects are produced when abnormal conditions occur on the power circuit, such as a short-circuit or a switching operation.

Table 1 is shown, giving these effects in skeleton form.

BALANCED AND RESIDUAL COMPONENTS OF CURRENT AND VOLTAGE.

In analysing inductive effects it is convenient to classify the currents and voltages on power circuits into two classes:—

(i) Balanced currents and voltages.
(ii) Residual current and voltage.

Balanced currents and voltages.—Components of current or voltage in the several conductors of a power circuit such that at every instant their algebraic sum is zero. As an example, the currents in a three-phase line with no earth connection and with its three conductors symmetrically arranged with respect to the earth's surface are balanced currents. In power circuits generally part of the currents and voltages are usually balanced.

Residual current and voltage.—The algebraic sum of the currents or voltages in the conductors of a power circuit, when this is not equal to zero at every instant. Thus an overhead traction circuit with a return through the rails and earth is completely unbalanced with respect to earth; its total voltage and current being residual.

The necessity for this division arises since their inductive effects have little in common and the remedies are often fundamentally different. The inductive effects of residual components (residuals) are much greater comparatively than those of balanced components. Current or voltage residuals in the conductors of a power circuit are in phase with each other and act as if the power circuit were single-phase with all the line conductors in parallel, earth being utilized as a return. The inductive effects of the conductors are, therefore, cumulative, and the neutralizing effect of the earth return is small. On the other hand, the balanced components in the power conductors are mutually out of phase and the inductive effects are neutralized considerably.

NOTE.—D.C. ripples are considered as harmonics.

Both the balanced and residual components contain harmonics, but these form a greater proportion of the residual components than of the balanced components.

During abnormal and transient conditions on power or traction circuits, the residual components are greatly increased. These conditions can be produced by switching operations and faults.

(2) METHODS OF CALCULATION.

Before limitations can be fixed regarding the permissible length and separation of a parallel it is necessary to be able to estimate the inductive effects which may be present.

The methods of calculation for both electric and magnetic induction which have been investigated are given in full in Appendix 2.

ELECTRIC INDUCTION.

Formulæ giving the electric induction for a number of practical cases involving one, two and three power lines, paralleled by a communication circuit, will be found in Table 1, Appendix 2. This table also gives the value of the electric induction when the power circuit is unbalanced by an earth fault on one of the phases. The formulæ in this table have been corrected from certain formulæ given originally by Brauns (111). During their examination of the data the investigators found that there was a difference of the order of 250 per cent between the value of the induced current flowing through the apparatus obtained by Brauns and as calculated from the formulæ given with the French rules (102). As the limits of separation given by the Comité Consultatif International are based on the latter formulæ, this discrepancy was very carefully investigated. No error was found in the formulæ given by the C.C.I.

In the above methods the results are expressed in terms of potential coefficients, which in turn may be evaluated when the numerical dimensions of the spacing and height of the two circuits are known. Similar methods were used by the Californian Railroad Commission in their Technical Report No. 64 (30). This contains a theoretical study of the variation of the electric induction in communication circuits paralleled by three-phase power circuits, with the relative position and configuration of the two classes of circuit. Open-circuit induced voltages are determined both for single conductors and metallic circuits, and serve as criteria for comparing various configurations of power and communication circuits, and for judging the relative severity of the inductive effects of parallels. The necessary calculations in this study were made with the help of several types of calculation form, which enabled the determination of the induced voltages to be carried out with the aid of a calculating machine. Technical training was, for the most part, not required.

The investigators have also examined a number of approximate formulæ given by Lienemann (109), which enable the interference effects to be expressed directly in terms of the separation and other dimensions.

For a single interfering line, such as the overhead contact line of an a.c. railway, the induced voltage to earth in a parallel communication circuit is

$$\frac{1}{4} \times \frac{Vbc}{a^2 + b^2 + c^2}$$

where V is the working voltage of the h.t. line.

In this formula:—

a is the separation between the two lines,
b is the height of the h.t. line, and
c is the height of the telephone or telegraph wire above the earth.

A number of these simplified forms are given in the Appendix. They can be employed when 10 per cent inaccuracy is permissible.

MAGNETIC INDUCTION.

Formulæ are given in the Appendix by means of which the magnetic induction may be calculated. These formulæ are given in a form involving physical dimensions and apply both to the induction from residual and balanced currents. They were used by the C.R.R.C. in their calculations in Technical Report No. 64. The calculations necessary to determine the interference effects by means of these formulæ are, in principle, simpler and less laborious than those outlined for electric induction, but the results are less rigid, since it becomes necessary to modify in an empirical manner the terms expressing the height of the conductors above the ground, in order to take account of the effect of earth currents.

Owing to the fact that the earth possesses considerable conductivity, it will in itself provide a path for eddy currents which will be induced in it by the magnetic field from the power circuit. The effect of these eddy currents will be to reduce the magnetic flux entering the earth and consequently the induction. The formulæ given in Appendix 2 simulate the effect of the earth by replacing the earth by images of the conductors at a suitable distance below the earth's surface. If the earth were a perfect conductor the magnetic neutral zone would exist at the earth's surface; so that the correct position of the image conductors would be at a distance below the earth's surface equal to the height of the conductors above it, as in the case of electric induction.*

According to Californian Railroad Commission (30):—

" Experience has shown that this is not permissible. . . . Since the earth is not a perfect conductor the locus of earth currents is a considerable distance below the earth's surface. This distance varies with the frequency of the current and the character of the country."

" The results of tests made by the Joint Committee at three different localities show that the image conductors for computations of magnetic induction should be taken with respect to an 'equivalent earth plane' from 300 to 500 ft. below the actual surface. The figures given are for 60 cycles. For higher frequencies the equivalent earth plane is nearer the surface."

The special case of induction to phantom telephone circuits is referred to in the Appendix, as is also the induction arising from twin-circuit power lines.

Magnetic induction between lines with an earth return.—In the case where one or both of the circuits has an earth return the solution is more difficult and is not rigid, since the path of the earth currents is not exactly known and varies with the geological characteristics of the locality.

A number of specific cases is dealt with in the Appendix. These include:—

(i) Communication line with earth return.
(ii) Power line with earth return.
(iii) Both power and communication circuits with earth return.

The first case does not appear to enter into practice from the evidence collected, although telegraph circuits paralleling metallic single-phase power lines would fulfil the conditions.

The second case corresponds to parallels formed by metallic telephone circuits and a single-phase railway, but in general little consideration has been given to it by writers.

Breisig has obtained an approximate formula giving the mutual inductance, M, between two lines of equal length, l, with a common earth return; but it becomes necessary to modify this formula in an empirical manner in order to take account of the fact that the earth is not an ideal uniformly conducting medium. The formula then becomes:—

$$M = 2l\left(\log_e \frac{2l}{a} - q\right)10^{-4} \text{ henry per kilometre,}$$

where q is a number which varies from about 0·5 to 5, depending on the length of the line, according to experiments carried out by Brauns (111), and a is the separation of the two lines.

L. Truxa (107) gives a formula for lines of unequal length, but the derivation of this formula has not been rigidly investigated at the moment.

In the case of a single-phase railway the calculations are complicated by the fact that currents are induced in the earth by the magnetic field, and these form a circuit along the rails returning through the earth. From a theoretical consideration of this particular case, Pleijel (108) draws the conclusion that the induction is independent of the leakage coefficient of the rail lines and also of the conductivity of the earth.

Although many tests have been carried out in order to investigate the value of the mutual inductance between earth-return lines, the data on which the various authors base their conclusions is still not clear. The distribution of earth currents cannot be stated with certainty.

---

* The application of the formula used by the Californian Railroad Commission to the calculation of the induction from the residual currents in the case of an earth fault on the power system leads to results which differ very materially from those obtained by the formulæ developed by Breisig, Pollaczek or Rüdenberg. The conditions under which the C.C.I. allow proximity between telephone lines and power lines with an earthed neutral point are based on the latter formulæ.

(3) POWER CIRCUITS.

OPEN-WIRE TRANSMISSION LINES.*

DIMENSIONAL ASPECTS.

HORIZONTAL SEPARATION OF THE TWO CIRCUITS.

In general, as the horizontal separation between power and communication circuits is increased, the electric induction decreases. The rate of decrease varies from near direct proportionality to about the third power of the separation, and depends on the type of circuit. Due to the relatively great depth of the return current in the earth the magnetic induction due to load currents decreases much more slowly than the electric induction.

The Californian Railroad Commission has made a very thorough study of the dimensional aspects in connection with three-phase lines, and in their Technical Report No. 65 give a large number of curves plotted from calculations based on formulæ obtained as indicated in the preceding section. These curves apply to both electric and magnetic induction. In each case studied the induction was calculated for a range of separation of from five to one hundred times the unit of power-conductor spacing. From the discussion of the results the following statements are drawn concerning *both magnetic and electric induction.*

The decrease of the coefficients of induction with increase of horizontal separation is expressed approximately by the formula

$$V = K\left(\frac{a}{\delta}\right)^{-n}$$

where a is the separation between the two circuits and δ the spacing of the power circuit conductors.

Table 1, Appendix 3, presents average values of the exponent, n, for the several configurations and classes of coefficients. It is clear that the value of n is greater for induction into metallic communication circuits than into earthed circuits, the difference being about 0·9 with the one exception for induction from residual current, where the difference is only 0·4.

HEIGHT OF POWER LINE ABOVE GROUND.

"Increase in the height of the conductors of *both* power and disturbed circuits, is, in general, accompanied by an increase in the coefficients of induction, the rate of variation of the coefficients becoming greater as the horizontal separation of circuits is increased. This effect is somewhat greater on the induction from the residual than on induction from the balanced components of both voltages and currents." The effects of variation in height are much less pronounced on the coefficients of induction due to the currents than on the coefficients of induction due to voltages.

"Increase in the height of power conductors, height of disturbed conductors remaining constant, may cause either an increase or a decrease in the coefficients of induction depending upon particular conditions."

The effect of variation of height of the conductors on the capacity unbalance of the power line is small for vertical and horizontal configurations. For triangular configurations the unbalance decreases approximately as the height of the conductors above the earth is increased.

VERTICAL SEPARATION OF THE TWO CIRCUITS.

"With disturbed conductors below the power conductors, the coefficients of induction decrease with increase in vertical separation, measured from the plane of the lowest power conductors."

"This relation is approximately linear except at the smaller horizontal separations. The practical variations of vertical separation have much less effect on induction from currents than on induction from the voltages since for the former the equivalent ground plane is much below the surface. Circuits on and even somewhat below the earth's surface are subject to the inductive effects of the currents of parallel power circuits though unaffected by the voltages."

DIAMETER OF POWER CONDUCTORS.

Induction from power-circuit voltages increases slowly with the conductor diameter, due to the increased value of the electric charges on the line.

For all configurations increase in the size of the conductors is accompanied by an increase in the characteristic residual voltage of the line. This term is defined in the section dealing with the geometrical arrangement of the conductors.

SPACING OF POWER CONDUCTORS.

"In general, for all types of power circuit an increase in the spacing of the conductors causes an approximate proportionate increase in the magnitudes of the coefficients of induction from the balanced voltages and currents." This conclusion is in agreement with the formulæ given by Lienemann.

"The effect of the spacing of the power conductors on the coefficients of induction from residual currents is very small." "The coefficients of induction from residual voltage increase slowly with the spacing of the conductors due to increased charge per unit of voltage."

In the case of the equilateral triangular configuration the characteristic residual voltage increases approximately with increasing conductor spacing.

EXCEPTIONAL EFFECTS WITH VERTICAL CONFIGURATION.

"The different power-line configurations are, with the exception of the vertical, quite similar as regards manner of variation of the coefficients of induction with the variation of the cross-sectional dimensions of the parallel." "There are some marked peculiarities of the electric and magnetic fields about vertical power circuits, due to balanced voltages and currents. For example, as the horizontal separation increases the coefficients of induction from balanced currents decrease very rapidly at first, pass a sharp minimum, increase rapidly, reach a maximum and thereafter decrease at a rate approximating to that of curves for other configurations. Curves of a somewhat similar nature occur for other variables. For balanced currents the effects are much more pronounced than for balanced voltages." Brauns first pointed out these minima and maxima for balanced voltages in 1907.

---

* Except transposition schemes which are dealt with in Section 7.

GEOMETRICAL ARRANGEMENT OF THE POWER CONDUCTORS.

In addition to determining the intensity of the inductive effects produced in parallel communication circuits by the balanced voltages and currents in the power circuit, the arrangement and spacing of the power-circuit conductors gives rise to inequalities among the capacities of several conductors to each other and to earth. In the case of a system insulated from earth, unbalances among the admittances of the several conductors will, in general, cause their voltages to earth to be unbalanced, even though the voltages between conductors are balanced. A residual voltage is thus created by the line unbalance.

Characteristic residual voltage.—The line unbalance of a particular type of power-circuit configuration is indicated by the " characteristic residual voltage " by which is termed " the residual voltage of a short uniform non-transposed power circuit when isolated from earth and energized with balanced three-phase voltages between conductors."

The geometrical arrangement which, for a given size and separation of conductors, gives a minimum characteristic residual voltage, does not of necessity give the minimum interference effects due to balanced currents and voltages, when paralleled by a communication circuit. Within the limits of a parallel the configuration which will give the minimum interference effects should be chosen. Outside the limits of the parallel the conductor arrangement may be made such as to give the minimum residual voltage.

The two cases will be considered separately.

CONFIGURATION TO GIVE MINIMUM CHARACTERISTIC RESIDUAL VOLTAGE.

Formulæ have been developed enabling the residual voltage of lines which are short compared with a wave-length to be determined from the physical dimensions of the line. From the formulæ a study was made during the Californian investigation of the variation of the characteristic residual voltage of circuits with the relative position, spacing, size and height of conductors and position of the earth wire. The calculated results were shown graphically by curves attached to Technical Report No. 51. From these curves the range of values to be expected with various configurations are shown in Table 2.

It will be observed that of the several configurations studied the triangular arrangement gives the lowest characteristic residual voltage. For this configuration the characteristic residual voltage is practically the same whether the base of the triangle is horizontal, vertical or otherwise. With the same ratios of height and size to spacing of outside conductors, the vertical configuration has a larger characteristic residual voltage than the symmetrical horizontal. This difference is small, however, being of the order of 1 per cent of the balanced three-phase voltage between conductors. " When the spacing of adjacent conductors in the horizontal configuration is made unequal the residual voltage is increased over the vertical, and this arrangement gives rise to the maximum characteristic residual voltage found."

For the peaked triangular configuration (i.e. ratio of altitude to base is $> \sqrt{3}/2$) with base horizontal and vertex upward, and for the flattened triangular configuration (i.e. ratio of altitude to base is $< \sqrt{3}/2$) with base horizontal and vertex downward, the characteristic residual voltage is zero with a particular value of the altitudes of the triangle in each case, depending on the height of the conductors. Curves are given in Technical Report No. 51 " showing the relationships of height, base and altitude of isosceles triangles, the bases being horizontal, for which the characteristic voltage is zero."

TABLE 2.

Range of Characteristic Residual Voltage : Single-Circuit Lines.

Configuration	Characteristic residual voltage: per cent of balanced 3-phase voltage between conductors
Equilateral triangle	0·5–4
Vertical	6–11
Horizontal—	
Symmetrical	5–9
Unsymmetrical	7–13
Isosceles triangle—	
Base horizontal	0–8
Base vertical	0·5–9
" L "*	2
Inverted " L "*	5·5

* In these two cases single values only are available.

No mention has been made in the preceding discussion of the effect of unbalances in the insulation resistance of the conductors. Experimental tests made by the Californian Railroad Commission on a 37-mile line under wet weather conditions show that " unbalanced leakage is of relatively small importance as compared to unbalanced capacitances in determining the residual voltage of a well-maintained isolated system " (30).

Table 2 in Appendix 3 gives the characteristic residual voltage for typical single and twin-circuit lines.

CONFIGURATION TO GIVE MINIMUM INTERFERENCE EFFECTS FROM BALANCED VOLTAGES AND CURRENTS.

To obtain a comparison of different configurations of single-circuit power lines with respect to induction in a parallel communication circuit, representative dimensions were chosen during the Californian investigation for 100, 60, 30 and 11 kV lines and the induced voltages in a parallel communication circuit were determined from the curves.

"The figures in Table 3 show the range of horizontal separations within which the specified configuration gives the minimum coefficients of induction." "It is not possible to draw a generally applicable conclusion regarding the most advantageous type of power circuit for minimizing the inductive disturbances, as it varies with the spacing of the power conductors, the type of induction and the horizontal separation."

The table shows that "considering the range of separations from 50 to 75 ft., which will include most cases of parallel lines separated by the width of a highway," the vertical type of power circuit will nearly always cause the smallest inductive effects for lines over 30 kV. For power circuits of less than 30 kV the vertical and equilateral triangular configurations have nearly equal effects, and for these circuits the triangular configuration may be preferred under certain conditions. The induction from the latter type of circuit is practically the same whether the base is horizontal or vertical, and, if vertical, whether the vertex is toward or away from the communication circuit.

TABLE 3.

Limits of Horizontal Separation (Feet) for Configuration giving Minimum Induction.

		Earthed circuit				Metallic circuit			
Configuration		△ ◁ ▷	•—•—•	•——•–•	⋮	△ ◁ ▷	•—•—∘	•——•–•	⋮
Balanced voltages	100 kV	95–170	170–1 000	—	30–95	140–280	280–1 000	—	30–140
	60 kV	70–170	170–600	—	30–70	110–250	250–600	—	30–110
	30 kV	65–125	—	125–350	30–65	95–195	—	195–350	30–95
	11 kV	40–120	—	120–200	30–40	70–180	—	180–200	30–70
Balanced currents	100 kV	580–1 000	—	—	30–580	30–50	—	—	50–1 000
	60 kV	460–600	—	—	30–460	30–45	—	—	45–600
	30 kV	—	—	—	30–350	30–55	—	—	55–350
	11 kV	—	—	—	30–200	30–45	—	—	45–200

Horizontal types of circuit give the greatest inductive effects for lines separated by the width of an ordinary roadway, but for large separations give the smallest coefficients of induction from balanced voltages. For horizontal circuits a displacement of the intermediate conductor from mid-position up to 30 per cent of the spacing of the outside conductors was considered. Induction from balanced currents is approximately a minimum when the intermediate conductor is in the mid-position, but the total change due to extreme displacements amounts to only a few per cent. The coefficients of induction from balanced voltages vary between limits of 60 to 190 per cent of those for the mid-position, the lowest values occurring when the intermediate conductor is displaced towards the communication circuit. Where an unsymmetrical configuration is used it is therefore advantageous to have the intermediate conductor on the side towards the communication circuit.

Triangular configurations other than equilateral.—The Californian Railroad Commission's Report gives curves showing the variation of induction from both balanced voltages and currents as the altitude of the power-circuit triangle is increased. The curves apply to both horizontal and vertical base triangles and show minimum induction for certain limiting cases corresponding to a vertical or horizontal configuration. The magnitude of the variation depends largely on the height of the power conductors and the relative position of the circuits.

TWIN-CIRCUIT POWER LINES.

INTERCONNECTION FOR MINIMUM UNBALANCE.

When two synchronous circuits are carried on the same line of poles, it is possible to interconnect them, or otherwise fix the phase relationships between the various conductors, so that their capacity unbalances tend to neutralize. Appendix 3, already referred to, shows the characteristic residual voltage due to this capacitance unbalance for six different methods of interconnecting twin-circuit lines. It is shown that for twin circuits of any type the maximum unbalances occur when conductors at the same potential are symmetrically located with respect to an intermediate vertical plane.

"For circuits of the vertical type, or with top and lowest conductors in the vertical plane and middle conductors displaced outwards a small distance, the minimum resultant unbalances are obtained when the top conductors of the two circuits are at common potential and the middle and lowest conductors of one circuit are at the potentials of the lowest and middle conductors respectively of the other." For triangular and horizontal circuits the minimum resultant unbalances are obtained when similarly placed conductors of each circuit are at common potential.

Figures given in the Appendix show that "of the cases studied, with one exception, twin circuits have a very material advantage over the corresponding single circuit, provided care is taken to interconnect them so as to secure minimum characteristic residual voltage. On the other hand, the result may be very much worse if such care is not taken."

When earth wires are used, or in cases where unsymmetrical circuits or more than two circuits are involved, a special study is necessary to determine the best arrangement.

Transposition of the conductors materially reduces the capacitance unbalance of both single-circuit and twin-circuit lines.

INTERCONNECTION TO GIVE MINIMUM INDUCTION.

With twin circuits of the vertical type, or having the middle conductors slightly displaced outward from the plane of the top and lowest conductors, the two circuits may be so operated that the induction from them is less than that from a single circuit of the same type. In general, the most favourable condition is to have the diagonally opposite conductors at common potential. For circuits of other types it is not possible to give a general recommendation. In some cases it is possible to interconnect the two circuits so that the induction is less than it would be for either one alone, but no method of interconnection of two horizontal-type power circuits gives induction from the balanced voltages less than that due to a single circuit of the same type.

Induction from Residual Voltages and Currents.

No considerable advantage is gained by the use of any particular configuration for a single-circuit line, or from any particular method of interconnection of twin-circuit lines with respect to the induction from the residual components of current and voltage.

EARTH-CONNECTED SYSTEMS.

Single earth connection.—The effect of earthing the neutral at one end of the power line is to reduce the residual voltage, since a residual current can now flow. The value of this residual current is given "by the product of one-third the residual voltage which would exist were the line isolated from earth, and the admittance to earth of the conductors of the circuit in parallel."

Insertion of resistance in the earth connection to reduce undesirable large fault currents has little effect in reducing the residual capacity currents, as pointed out by Marchant (25).

Multiple earthing.—The third-harmonic currents and voltages which tend to be present whenever transformers are connected to the line are residual currents and voltages. In cases where a simple system, such as a transmission line transmitting power between two points only, is concerned, earthing the system at the second point leads to an undesirable increase in triple-harmonic currents through the earth connections and earth. Practical experience has shown that this increase in residual current may result in serious interference.

With a view to limiting this increase in triple-harmonic currents the regulations of the Board of Trade* allow each distinct high-pressure three-phase circuit to be insulated from earth or earthed at one point only. If the earth connection is made through a resistance, this must be low enough to ensure that the system is disconnected when a fault occurs.

On extensive systems interconnecting several generating stations, earthing the system at one point only causes the operation of protective gear to be uncertain. It is possible that the fault may not be disconnected rapidly. The continuance of the large residual currents resulting therefrom provides the conditions which may result in serious interference. In order to reduce the induction effects, which are liable to cause damage to plant, acoustic shock and danger to life, it appears that restricted multiple earthing is necessary although the effect on induction during normal conditions has not been fully investigated.

Stigant and Lacey † state, however, that as a result of experience gained in the U.S.A. the restriction on multiple earthing is unnecessary; and many large systems are said to operate with several neutral points earthed and with little telephone interference.

As a result of certain tests described in Appendix 4, "multiple earthing on the North-East Coast systems has been agreed to, subject to certain qualifications which include an embargo on generators feeding directly into a circuit" (32).

Petersen earth coils.—Earthing the neutral of power circuits through reactance coils has been adopted in many cases in Europe, and reference is made to this matter in Appendix 4. Although the Petersen earth coil appears promising as limiting the magnetic induction arising from faults to earth, experiences appear to be conflicting; and the possibility of over voltages arising with the earth coil systems is apparently not fully understood.

OTHER CAUSES OF RESIDUALS.

Single-phase tappings.—Single-phase tappings, metallically connected to a three-phase circuit, unbalance the line admittances. "Even short branches of this character may cause an unbalance equal to that of the three-phase circuit without transpositions" (30). Elimination of the metallic connection by the insertion of a transformer with a 1/1 ratio removes the unbalanced admittances from the three-phase line.

Unbalanced loads.—Unbalanced load between phases and earth on star-connected circuits with earthed neutral can cause both types of residual. Removal of the earth path by allowing only one point to be earthed on the line is the most effective and reliable remedy to eliminate the residual currents. A slight voltage unbalance will, apparently, remain, but there is no evidence that this is of importance.

Unequal ratios of transformers.—Unequal ratios, or unequal impedances of the transformer phases, may be the cause of residual components. In the same way as mentioned under paragraph (*b*) above, allowing only one earthed neutral point on the circuit eliminates current residuals.

---

* Now the Electricity Commissioners' Regulations.
† "The J. and P. Transformer Book," p. 236.

ABNORMAL AND TRANSIENT CONDITIONS.

Under abnormal conditions, such as those due to earth faults and switching operations, large residual components exist for a very short time usually. Interference is, therefore, very much greater during this time than that existing under normal conditions.

Switching operations.—Large residual voltages and currents exist momentarily during switching operations, when the phases of a three-phase system are not connected or disconnected simultaneously. Oil-break switches, having their poles mechanically interconnected for simultaneous action, were considered by the Californian Railroad Commission to be preferable to air switches and non-interconnected single-pole oil switches. A description of some air-break switch tests (98) shows that an air-break switch may take from 120 to 1 500 cycles to interrupt a circuit, depending mainly on weather conditions.

Charging electrolytic lightning arresters.—" Transient disturbances of severe nature to telephone circuits are sometimes caused by the charging of electrolytic lightning arresters," according to the Preliminary Report of the Californian Investigation. The use of charging contacts with spring clips and auxiliary charging resistances in order to prevent arcing and to reduce the current rush enables such interference to be greatly reduced.

SHIELDING EFFECT OF EARTHED BODIES.

A summary of the experimental results obtained by the Californian Railroad Commission on the shielding effects of earthed conductors is contained in Appendix 5, together with results obtained in England, Germany and New Zealand.

The Committees responsible for drawing up the French and German rules seem to have arrived at the conclusions that the effect of shielding due to neighbouring earthed bodies is insufficient for such to be an effective remedy in itself for electric induction. The reduction is, however, sufficient to warrant its inclusion in the calculations. Values are given in the German and French rules as follows:—

Reduction factor $p = 0{\cdot}75$ for a continuous earth wire (lightning guard wire) on the power line.

Reduction factor $q = 0{\cdot}7$ for a continuous row of trees in the neighbourhood of the power line.

Reduction factor $r = 0{\cdot}7$ for a continuous row of trees in the neighbourhood of the communication line.

Factors q and r are to be made $= 1$ if the tree-tops are more than 3 metres from the line concerned.

The question of shielding is considered in some detail in the Appendix, since there appears to be an impression that by the use of one or two earth wires interference due to electric induction can be obviated. The data shows that, in general, only a small reduction is obtained, and that even with a large number of earthed wires the elimination is by no means complete.

UNDERGROUND CABLES.

No information has been collected as to the interference caused by power circuits contained in lead-covered underground cables.

(4) TRACTION CIRCUITS.

ALTERNATING-CURRENT SYSTEMS.

An empirical formula, determined from tests made at 15 to 50 cycles per second, has been given for the mutual inductance in the case of a single interfering line, such as an a.c. railway, and a communication circuit with earth return:—

$$M = \frac{4}{\sqrt{a}} \times 10^{-3} \text{ henry per kilometre,}$$

where a is the separation in metres. Jäger (88) gives an experimental curve showing a similar result.

It may be stated here that in the U.S.A. the chief trouble from 25-cycle traction is not noise but operation of bells, production of e.m.f., etc. The telephone cable is found to be an ineffective remedy against magnetic induction for 25-cycle railways—the booster seems to be the only successful device. This is unpopular with the railway authorities.

DIRECT-CURRENT SYSTEMS.

Tramways.—Bartholomew (32) mentions that if the tramway system is extensive, with substations feeding the system in common, the disturbance is usually more severe owing to balancing currents constantly flowing between substations. Independent feeding of each section of the trolley wire will usually reduce trouble. In such cases it should be pointed out that this may result in an uneconomical feeder lay-out or poor voltage regulation.

Tests were carried out during a joint investigation by the General Electric Company and the American Telephone and Telegraph Company, both of America (125), to determine causes of disturbance produced by trolley cars, but to what extent trolley arcing is a serious disturbance, we have no definite evidence. The success of the application of resonant shunts in reducing supply harmonics, and with them the disturbing noise, indicates that this cause is not important. Modifications in the design of the trolley-wire lay-out and hangers have not been suggested as a remedy.

Railways.—On d.c. railways the most serious disturbances occur during conditions of short-circuit. In order to limit the duration of the transient conditions, high-speed circuit breakers have been developed (133).

Comparative figures showing the values of the induced voltages with and without high-speed circuit breakers are not available, so that the degree of protection afforded is not known. Wüthrich has given a summary of the views of Behn-Eschenburg and Kristen in which it was stated that " the maximum induced pressures are not reduced by the quick-acting switches; the advantages secured reside in the fact that the duration of action of the phenomena is reduced and the disturbances thus rendered less harmful."

(5) TELEGRAPH CIRCUITS.

Telegraph circuits are usually single-wire circuits with an earth return. The highest pressure employed in this country is 120 volts, higher voltages being used in some other countries. There are various types of circuit giving a range of speed of working of from 20 to 200 words per minute, and sometimes higher. The minimum current required to operate the relays varies from 0·5 to 5 milliamperes, but for certain types of apparatus, and for the higher speed circuits generally, it may be larger.

Interference to telegraph circuits chiefly occurs through induction from the fundamental frequency of the power or traction circuit. Since telegraph circuits are usually operated by nominal direct current and the disturbing current is alternating, many remedies have been evolved by which telegraph apparatus may be protected from the effects of induction. In Appendix 6 numerous devices are described which have been tried, or suggested, mainly to overcome induction due to single-phase railways.

The majority of these devices call either for some special modification of the apparatus, or for the insertion of additional apparatus into the telegraph circuit. With certain of the systems described successful working has been obtained with induced voltages considerably above 100, and, in at least one case, up to 300 volts. Most of these tests have been carried out in France.

The use of metallic circuits for telegraphs should not require any of the above modifications to apparatus, but it does not appear to have been applied in practice as a usual remedy. Apparatus should be connected symmetrically to both wires of a metallic circuit in order to prevent interference due to capacity currents resulting from an unbalance of the line.

(6) TELEPHONE CIRCUITS.

Open-Wire Circuits.*

BALANCE OF TELEPHONE CIRCUITS.

A telephone circuit would be balanced if, in each elementary section of its length, its two sides had equal self and mutual impedances and equal admittances to earth and to other conductors. Under these conditions, with equal longitudinal voltages induced in each side, there would be no transverse voltage. This definition does not require longitudinal uniformity, but only that corresponding constants of the two sides should be equal at the same point, and similarly through the circuit.

There are two general types of unbalance:—

(i) Self unbalances involving only wires and earth,
(ii) Mutual unbalances involving other conductors.

Removal of unbalances.—Since both sides of a circuit are constructed of the same wire and are the same height above earth, self unbalances are not inherent. They are largely accidental due to defective joints, defective loading coils, broken insulators, tree leaks, dissymmetry in apparatus inserting series impedances in circuit or connection of admittances between the sides of the circuit and earth.

By transpositions, mutual unbalances in one section neutralize those in the next section.

"The degree of balance that can be obtained commercially in open-wire circuits can be fairly expressed as one with which the telephone circuit is undisturbed by other telephone or telegraph circuits on the same route" (32). The absence of cross-talk between communication circuits is not, however, an effective criterion of the balance of a circuit with respect to other external disturbances (110).

Effect of unbalances.—Differences in admittance to earth, or in series impedance of the two sides of a circuit, will cause disturbing currents to flow through the terminal apparatus, even though both wires may be similarly situated with respect to the source of interference.

Small defects in the circuits and slight unbalances in apparatus, particularly if such is earth-connected, become of importance, since the induced voltages may be high compared with the operating voltage.

CONDUCTOR ARRANGEMENTS TO GIVE MINIMUM INDUCTION.

Three methods of arranging the four conductors forming a phantom group were considered by the Californian Railroad Commission (30).

(i) Horizontal phantom:

All four conductors on one arm, adjacent wires forming the two side circuits.

(ii) Vertical phantom:

Two conductors on one arm grouped with the two on the arm immediately below. The two side circuits consist of conductors on the same arm.

(iii) Square phantom:

As the vertical phantom, but the two side circuits made up from diagonally opposite conductors.

It was found that the coefficients of induction for the transverse voltages induced in the phantom circuits of the square phantom group were "less than 4 per cent and in one case as low as 0·02 per cent of the corresponding coefficients for the horizontal phantom." In most cases, however, the coefficients of induction for the two side circuits of the square phantom group are greater than those for the side circuits with either of the other two methods of conductor arrangement. The relative magnitudes of the coefficients for horizontal and vertical phantoms depend largely upon the configuration of the power circuit and the type of induction.

The transverse voltages induced in the side circuits of vertical and horizontal phantoms are closely proportional to the spacing of the conductors.

Curves were also prepared showing the induction coefficient as functions of the angular position of the conductors for two values of the separation. The curves for induction from residual voltages and currents are approximately sinusoidal. "The angular position for which the coefficient is zero varies with the relative position of the circuits."

The method of arranging the telephone conductors in forming the phantom group has no appreciable effect on the longitudinal voltages induced by voltages or currents.

---

* Except transposition schemes which are dealt with in Section 7.

TELEPHONE CABLE CIRCUITS.

Communication circuits contained in underground cable are not subject to electric induction.

The transverse induced voltage due to magnetic induction will be considerably diminished, since this decreases with reduction in conductor spacing and in a cable metallic circuit conductors are twisted together, while, when two such physical circuits are connected to form a phantom circuit, the physical circuits are twisted together to form a quad which maintains its identity throughout the cable.

The consequence of earthing the lead sheath is to bring into play a compensating effect which reduces to some extent the longitudinal induced voltage. A number of writers have considered this effect in particular connection with induction due to single-phase railways. Jäger (88) gives a figure of 29 per cent for the amount of compensation in an existing normal cable with good sheath connection. In tests carried out by Siemens and Halske (80) a reduction of 80 per cent was obtained using a specially armoured cable. The compensating effects are greater for the higher frequency components.

Telephone circuits placed in cable demand a high degree of balance to avoid cross-talk between adjacent circuits, so that interference would be less than on open-wire circuits even if the coefficients of induction were the same in each case. It is clear that weather and other conditions which cause the circuit unbalance of open-wire lines to vary are absent in the case of cabled circuits.

In Great Britain, and in most other countries in Europe, the majority of important telephone circuits have been placed underground.

No experiences are available regarding interference to cabled circuits due to power lines. Considerable experience is available in cases where single-phase railways are concerned, and this tends to show that on sections with heavy traffic and during short-circuit conditions interference will occur on cabled circuits.

The above discussion applies to cables carried overhead as well as to underground cables, provided the sheath is well earthed.

REDUCTION OF EFFECTS PRODUCED IN TELEPHONE RECEIVER.

BY TRANSVERSE INDUCTION.

Transposition of the telephone conductors eliminates or materially reduces the transverse voltage due to induction from both the balanced and residual components of voltage and current in the power circuit.

BY LONGITUDINAL INDUCTION.

Telephone transformers.—It is evident that any circuit liable to be connected to the circuit exposed to induction requires to be equally free from unbalance. Separation of such circuits may be obtained by making the connections between the circuits through transformers or repeating coils. Well-balanced circuits can therefore be connected to circuits of a lower standard or to exchange apparatus without degrading the whole combination. The induced voltage due to longitudinal induction is separated from exchange apparatus, thus avoiding possible danger to apparatus. A certain loss in speech efficiency is introduced with these transformers and changes in the signalling arrangements are necessary in some cases (32).

The use of transformers between the local subscribers' circuit and trunk, or long junction circuits, is standard practice in this country, and also for toll circuits of the Bell system in the U.S.A.

Overvoltage protectors.—As explained in Section 2, dangerous noise is caused in the receiver when the induced voltage exceeds the protector breakdown voltage, a condition which may occur during transient power-circuit conditions. This danger arises since the safety device on one wire operates before that on the other. In order to meet this difficulty attempts have been made to produce a protective device which would give simultaneous operation, e.g. vacuum-tube protectors with three electrodes; but, although a number of these have been described in various publications a thoroughly satisfactory type, or one providing for the simultaneous earthing of both sides of the circuit, has not yet been constructed.

Acoustic shocks have affected the personnel of the German Telegraph Administration considerably.

Special circuits.—Telephone transformers insulated to withstand a very high voltage between windings are employed on telephone circuits used by power companies for control purposes (22). Separation in these cases is small and induction is intense.

Since these circuits are of a special nature and of great importance economic considerations occupy a minor place.

Drainage coils.—The use of a drainage coil, consisting of a high-impedance coil connected across the conductors of the telephone circuit and earthed at its mid-point, is mentioned by various authorities. The general conclusion is that, although these coils may be used with good effect on strongly induced lines, such as private lines carried on power poles, they cannot be regarded as a general remedy for public service lines (118).

These and other special systems are mentioned in Appendix 7.

Earth-return signalling circuits.—The earth is used as a return for signalling currents on some junction circuits. On such circuits interference is possible, due to differences in earth potential—as well as that due to induction—from traction circuits.

In Appendix 8, reference is made to a portable noise-measuring set developed in the U.S.A., by means of which the noise on any circuit can be directly measured in terms of an arbitrary noise unit.

(7) TRANSPOSITION SCHEMES.

Transpositions in power and telephone circuits constitute a very important factor in mitigating the interference experienced from parallelism of the two classes of circuit. They also serve to improve the balance of the individual circuits.

TELEPHONE CIRCUITS.

In order to reduce cross-talk between metallic telephone circuits and induction from single-wire telegraph circuits it is usual to transpose metallic circuits on open-wire lines. Two systems of transpositions have been used. The symmetrical twist system is the older and in it groups of four adjacent wires are chosen as units, so that the wires of a group occupy positions on the pole-arm corresponding to the corners of a square. The diagonal wires form the two circuits. At successive poles each wire changes its position to the next corner of the square, so that the four wires go through a complete revolution every four poles.

The transposition system of cross-overs has been employed in the past by the American Telegraph and Telephone Company. On this system all the wires are run straight, and each circuit is made up from two adjacent wires on the same arm. The two wires forming a circuit are crossed at intervals on the line, whilst cross-talk between circuits is obviated by a systematic arrangement of crosses in those circuits which are likely to interfere with one another. Crosses are so placed that over an 8-mile section each circuit is balanced against the others. The transposition points vary for each circuit. This system has been adopted as the standard transposition system by the British Post Office.

POWER CIRCUITS.

Barrel.—Transposition of the power conductors is an effective remedy for unbalanced capacitances, according to the final report of the Californian Railroad Commission (30). " Such transpositions must be located with proper regard to changes in configuration, and at short enough distances from each other so that there is no material difference in the electrical conditions at two such points at any given instant."

Owing to the fact that neither along the power circuit nor along the communication circuit is the speed of propagation of the electric waves infinite, the efficiency of a transposition scheme involving long barrels decreases for the higher frequency components of the power wave. The effects of both attenuation and phase-change are discussed more fully in Appendix 9.

Where there is more than one barrel, three simple arrangements may be used having barrels of equal length. Using like transpositions throughout, equally spaced, the barrelling is " *continuous.*" With every third transposition omitted the barrels are of the " *halting* " type. The same with the transpositions of alternate barrels reversed are designated as " *halting-reversing.*"

The following paragraph taken from Technical Report No. 51 of the Californian Railroad Commission sums up the length and type of transposition barrels which appear desirable to reduce the residual voltages due to line unbalance:—

" In determining the length of barrels required to limit the residual voltage of power circuits isolated from earth to a given magnitude, the characteristic residual voltage of the circuit is an important factor, shorter barrels being required with larger characteristic residual voltages. The exact relationship of these two factors for a constant residual voltage has not been determined. Under average conditions of wave-form it should be expected that 9-mile barrels will effectually balance triangular lines (or twin-circuit lines so interconnected that their characteristic residual voltages are of the same order of magnitude as that of a single-circuit triangular line) and that 6-mile barrels will balance lines of other configurations, so as to limit the residual voltages of fundamental and higher frequencies to relatively small magnitudes as compared with those of a non-transposed line." " Halting "-type barrels will probably be more effective, since the effects of phase-change are thereby reduced.

CO-ORDINATION OF TRANSPOSITION SCHEMES.

The effect of transpositions in each circuit on the induction from the balanced and residual components of current and voltage is shown by the following table:—

TABLE 4.

Voltage or current component	Induction	Effect on induction due to	
		Power transposition	Communication transposition
Balanced	Longitudinal	Reduction	None
Balanced	Transverse	None	Reduction
Residual	Longitudinal	None	None
Residual	Transverse	None	Reduction

It will be seen that the transposition of neither circuit alone is a sufficient remedy, and that no transpositions have any effect on the longitudinal induction from residuals. The importance of reducing these in the first place is therefore apparent. Longitudinal induction due to balanced components is reduced to some extent by the power transpositions, whatever their locations. If the power and telephone transpositions are not co-ordinated, transverse induction may be greater with both power and telephone transpositions present than if either kind were absent.

The object of co-ordinated systems of power and telephone transpositions is to provide such relative location of transpositions in the two classes of circuit, that maximum effectiveness in reducing the unbalanced exposure for both balanced and residual voltages and currents is secured. The *unbalanced exposure* is defined as the length of parallel between two non-transposed circuits of the given configuration and separation which will produce inductive effects of the same magnitude as those produced in the actual parallel.

In practice, points of discontinuity occur due to an abrupt change of the separation, or of the physical or electrical characteristics of either circuit. These divide the complete parallel into a number of different uniform parallels, each of which needs to be considered separately. " Ordinarily it is desirable to obtain a balance (zero unbalanced exposure) within each such uniform section " (30).

The method for obtaining the amounts of unbalanced exposure in an actual parallel is given in Appendix 10, where a practical example is referred to.

Even though the transpositions are so co-ordinated that the unbalanced exposures as calculated are zero, neutralization is not perfect. This is due to the following causes:—

(a) Non-uniformity of uniform parallels, since only major points in actual lines can be taken into account and numerous minor ones must be disregarded.
(b) Attenuation and phase-change in the power and communication circuits are neglected. The unbalanced exposures thus introduced may be considerable.
(c) Since it is impracticable to balance perfectly the series impedance and the admittances to earth of the sides of a telephone circuit, longitudinal induction causes current in the telephone circuits.

Power circuit transposition as part of a co-ordinated scheme.—Special transpositions are possible in which pairs of conductors are interchanged only, enabling the effect of cross-overs between power and telephone lines to be approximately neutralized when the separation is large compared with the length of the telephone cross-arms and is the same on both sides of the cross-over. By superimposing a cyclic transposition upon such a special transposition the effect of an ordinary transposition is obtained. It is thus possible to eliminate the point of discontinuity or to use it as an ordinary transposition point, where the above limitations allow.

Telephone circuit transposition as part of a co-ordinated scheme.—Studies were made during the Californian investigation of the unbalances present with various arrangements of telephone transposition sections and power barrels. As a partial result of these studies it was concluded that the standard telephone transposition scheme "is unsuitable for co-ordination with power barrels." Large unbalances on some circuits and long distances between balance points on others are characteristic of this system, when considered in conjunction with a parallel power circuit transposed in other than half-mile barrels.

To meet the need of a system which would give increased flexibility in co-ordination with power transposition barrels of several lengths, the American Telephone and Telegraph Company has developed three methods which, singly or in combination, make it practicable to reduce the unbalanced exposures to small amounts, while at the same time the standard of balance with respect to cross-talk and telegraph induction is maintained:—

(1) "E" and "L" sections, nominally 8 and 4 miles in length, balanced to nominal $\frac{1}{2}$, 3 and multiples of 3-mile barrels.
2) Consecutive "X" sections, that is, successive sections $\frac{1}{2}$ mile or less in length.
(3) "Whole line" transpositions, whereby extra transpositions are inserted in all the circuits of the telephone line.

These are described more fully in Appendix 11.

Results obtained.—33-kV transmission lines, transposed in accordance with the recommendations of the C.R.R.C., have given rise to no complaints of interference at Adelaide in spite of many long parallels with telephone lines at a separation equal to the road width.

Considerable reduction in interference has also been obtained by a co-ordinated scheme of transpositions at Iowa, U.S.A. (96).

(8) HARMONICS.

Under normal operating conditions interference to telephone circuits is almost entirely due to higher harmonics of the power-circuit voltages and currents. These cover a considerable portion of the range of frequencies used for the transmission of human speech, and over which the telephone is most sensitive.

Interference Effects of the Various Harmonics; Telephone-Interference-Factor-Meter.

Experimental tests have been carried out by the American Telephone and Telegraph Company at various times in order to determine the relative effect of harmonics of different frequencies in producing interference in telephone systems. These indicate a maximum interfering effect at about 1 100 cycles per second. Particulars of these tests are given in Appendix 12, where also a network is described, such that the current in one branch resulting from a complex voltage wave at the terminals of the network gives an indication of the disturbance which would be caused in a telephone receiver through the distortion of the voltage wave in question. When the distortion is due to the presence of a number of harmonics a reading is given which is proportional to the square root of the sum of the squares of the individual harmonics. Data obtained on the summation law of a number of noises of various frequencies indicate that this law varies under different extreme conditions.

Analysis of Wave Shape.

When it is necessary to locate the origin of harmonics causing interference, exact measurements of their magnitudes will not be required so much as the determination of their frequencies. Methods for a complete analysis of the wave shape are given in Appendix 12.

Sources of Harmonics.

Features in the design of machines or apparatus which contribute to the production of disturbing harmonics are dealt with at greater length in Appendix 13. Together with the various technical devices which have been proposed for diminishing the harmonics, they are summarized in the following paragraphs.

A.C. generators.—Generator harmonics may be divided into two groups:—

(1) Spacing ripples or harmonics.
(2) Tooth ripples or harmonics.

While the causes of these harmonics are clearly different when the phenomena are discussed in the simple fundamental case, there seems to be a possibility of confusion in actual cases. This may be partly because the orders of the harmonics of each type present are likely to be the same.

Spacing harmonics are not present when there is a sine wave of flux.

In salient-pole alternators, harmonics may be largely avoided by shaping the pole-shoes so that the air-gap is increased from the centre of the pole-pitch to the pole-shoe tips. Then in conjunction with a suitable interpolar gap a near approach to a sinusoidal flux-space wave may be obtained.

The harmonics present in the flux wave of a non-salient pole turbo-generator due to the concentration of the exciting winding into the rotor slots are of the order $(2R \pm 1)$, where R is the number of rotor slots per pole. They reappear greatly reduced in the phase e.m.f., except when both rotor and stator have approximately equal slot pitch. In this case there is no diminution.

Suitable chording of the winding to some fraction of the pole pitch (possible in two-layer windings), with a whole number of slots per pole, enables certain harmonics to be reduced as indicated in the Appendix. With high-speed alternators, having few poles and coils of very wide span, a certain amount of chording has much in its favour.

The toothed armature may be reduced in effect to a smooth-core armature with the distribution factors as for uniform distribution, if either the armature slots or the edges of the pole-shoes are skewed along their axial length through an amount equal to a tooth-pitch.

A simpler and almost equally effective method is to move all the poles of one sign circumferentially in the same direction through half a tooth-pitch.

The use of a fractional number of slots per pole pair, as by the use of a d.c. two-layer wave winding, reduces the reduction factors for the harmonics to practically those for a uniformly distributed winding. In the case of single-layer windings this condition may be reached by—

(a) Fractional number of wound slots, using divided coils.
(b) Whole number of wound slots, plus a fractional number of empty slots per pole-pair.

Increasing values of the slots per pole per phase closely approach the curve for uniform distribution over one-third of the pole-pitch, due to the coil sides of a phase occupying different positions in successive fields.

Shaping of the pole-shoes of salient-pole alternators also tends to reduce the tooth ripple and a careful adjustment of combined air-gap length and tooth reluctance may result in a negligible ripple.

If the unwound part of the rotor is left unslotted or if magnetic wedges are used to close these slots, harmonics—particularly the third—may be increased, as pointed out by Smith and Boulding.

Where damper windings are present in the pole-shoes of salient-pole alternators, the pitch of the damper bars should not be the same as the armature slot-pitch, in order to avoid conditions similar to that when the rotor and stator slot-pitches of turbo-alternators are nearly the same.

Harmonics which are multiples of the third give rise to residual currents and voltages and are therefore specially to be avoided.

D.C. generators and motors.—Tooth ripples are present due to the slots in the same way as in alternators, their frequency being equal to the number of slots passing the brushes per second.

Ripples may also be caused by the commutator segments, their frequency being equal to the number of segments passing the brushes per second.

Remedies mentioned above are, in some cases, applicable. Shaping of pole-shoes and remedies reducing the winding in effect to a uniformly-distributed winding reduce the slot ripples.

Rotary convertors.—Jakeman has pointed out that by a certain arrangement of the six rings the slots per pole may be made fractional, reducing largely the slot ripple. The arrangement of tapping points also reduces the sixth frequency ripple. A 9-ring rotary convertor with a fractional number of slots per pole has also been proposed.

Other remedies which endeavour to overcome tooth ripples by making the winding as far as possible equivalent to a uniformly-distributed winding are—

(a) To displace the pole-shoes circumferentially.
(b) To skew the pole-shoes.
(c) To skew the slots.

Each of these remedies has been mentioned in connection with a.c. generators.

Transformers.—With a sine wave of flux and consequently of induced e.m.f. if conditions allow, the no-load current may contain a prominent third harmonic, which produces a peakiness in the wave of the magnetizing current component. This is mainly through a variation in the permeability of the sheet steel and only in a very small degree through the hysteresis component of the current due to cyclic hysteresis.

With a sine wave of no-load current, the flux and consequently the induced e.m.f. may, if conditions allow, contain prominent third harmonics which produce a flat-topped flux and peaked induced e.m.f. waves.

The fifth and higher harmonics may also be present with reduced amplitude, but as regards harmonics other than triple harmonics there is always an external path enabling corresponding currents to flow. The voltage harmonics remaining depend on the impedance of such paths.

The provision of a low impedance path to enable the third-harmonic currents to flow, leads to a small resultant third-harmonic flux and in consequence to a small third-harmonic voltage. The path supplied must naturally be confined to the close neighbourhood of the transformer, to avoid the possibility of these third-harmonic currents causing interference. Transformers with one or both windings connected in delta fulfil this condition. Where a star/star connection is necessary, a delta-connected tertiary winding is suitable. Where transformers connected star/star are already installed, the provision of an auxiliary transformer with a delta-connected secondary winding provides a path for third-harmonic currents when the neutrals are connected.

These conclusions apply to single-phase transformers of both shell and core types, and to three-phase shell-type transformers. With three-phase core-type transformers any third-harmonic fluxes must find their return path outside the core. Such a path is of very high reluctance and consequently the third harmonics in the flux and induced pressure waves are very small.

The relationship between triple-harmonic residuals and the magnetic-flux density in transformers is the subject of a report in connection with the Californian Railroad Commission, based on theoretical and practical work. The conclusion reached, which is confirmed by other investigators, is that avoidance of excessive flux densities as far as possible is the fundamental remedy.

Single-phase commutator motors.—It has been found that disturbances due to this type of traction motor are chiefly due to the high-frequency currents in the commutating armature coils (19). These currents induce in the field winding a high-frequency voltage, which sends a corresponding current through the motor circuit.

From a mathematical investigation a remedy, whereby oscillations due to commutation can be eliminated, has been developed and tested in conjunction with the A.S.E.A. The remedy consists in placing a condenser as a shunt across the field winding of the motor, by means of which the high-frequency voltage induced in the field winding is effectively short-circuited. By connecting two motors in series, the remaining higher harmonics are still more reduced, so that they only amount to 0·03 per cent of the total current. The same phenomenon occurs in direct-current motors, but in this case, these currents are damped by the short-circuiting effect of the non-laminated yoke.

Mercury rectifiers.—Due to the nature of mercury rectifiers ripples are inherent. The d.c. voltage wave-form may be considered as consisting of a constant component, superimposed upon which is a ripple of complex wave-form, the fundamental requency of which is *N* times the supply frequency, where *N* is the number of anodes.

Figures given from various sources show that for a six-phase rectifier the sixth harmonic may amount to nearly 10 per cent of the constant voltage.

General Remedies.

Resonant circuits.—A shunt placed across the source of the ripple and adjusted to the frequency of the harmonic requiring to be eliminated has been found of great value. In order to reduce the magnitude of the harmonic the impedance of the source must be high compared with that of the resonant shunt for the particular frequency. It may be necessary to add a series inductance and connect the resonant shunt as a long shunt across the source and external inductance.

Where the ripple present is due to one pronounced harmonic, this method is an advantage; but where the ripple consists of a number of harmonics this method is likely to be of little use.

Considerable success has attended the application of resonant shunts to the elimination of the ripples from mercury rectifiers (33) and also to the elimination of the tooth ripple from d.c. machines.

Floating battery.—A battery floating across the terminals of a rotary convertor has been effective in reducing the interference to adjoining telephone circuits (32).

(9) CONCLUSIONS.

From a review of the information published up to the year 1925, the several causes of interference appear to have been extensively studied and effective preventatives and protective devices to be well known. Outstanding problems then remaining to be settled were:—

(i) The method of calculation to be adopted for estimating the voltage induced in a communication circuit due to the residual current in a traction circuit with earth return, or power circuit with earthed neutral under short-circuit conditions. This depends to a certain extent on the geological formation of the locality; but there remains a wide divergence between the results given by the application of the different formulæ. Field tests in a number of different localities are required before the induced voltage in the communication circuit can be estimated with any degree of certainty.

(ii) The amount of induced energy necessary to produce acoustic shock.

(iii) The amount of noise that can be tolerated in a telephone receiver without undue interference to speech.*

(iv) The effect of the provision of more than one neutral earth connection on an extensive system interconnecting several generating stations on the interference caused by the normal working of the system. Also, the effect of using reactances in the earth connection requires study. Sufficient experience has probably been gained on this point to enable a decision to be reached if the evidence were collated.

Both the V.D.E. (129) and the Comité Consultatif International (102) have issued guiding rules giving limits which express the màximum permissible amount of disturbance and danger, together with formulæ enabling calculations to be made for particular parallels in order to determine whether these limits are exceeded. The rules drawn up by the V.D.E. were adopted in Germany in 1925. Table 5, prepared by the investigators, is included here, in order to show in a condensed form the chief features of the proposed instructions drawn up by the C.C.I.

The outstanding feature in both the German and French Rules is that the limits are based for the main part on induction during fault conditions, e.g. due to an earthed phase.

As a result of investigations in the field the Californian Railroad Commission (C.R.R.C.) issued in 1918 its General Order No. 52 (31) for open-wire power lines with line voltage above 5 000 volts. These rules lay down, in general terms, the lines on which power systems should be designed and operated.

As a rule, only a close study of the conditions will enable the best results to be obtained in any given case, but the following generalized conclusions, drawn from the various authorities already quoted, may be of service both to power and communication authorities in connection with future lay-outs and projects.

---

* Tests carried out in the Research Section of the Post Office indicate that for international or important circuits the induced voltage on the line terminals should not exceed (as regards the intensity of noise in the telephone receivers) an alternating voltage of 3 millivolts at 800 cycles per second. From the point of view of the effectiveness of the connection, there is no reason to differentiate between open wire and cable lines in setting this limit (cf. C.C.I., Proposed Instructions, Table 5).

Design of Machinery and Apparatus.

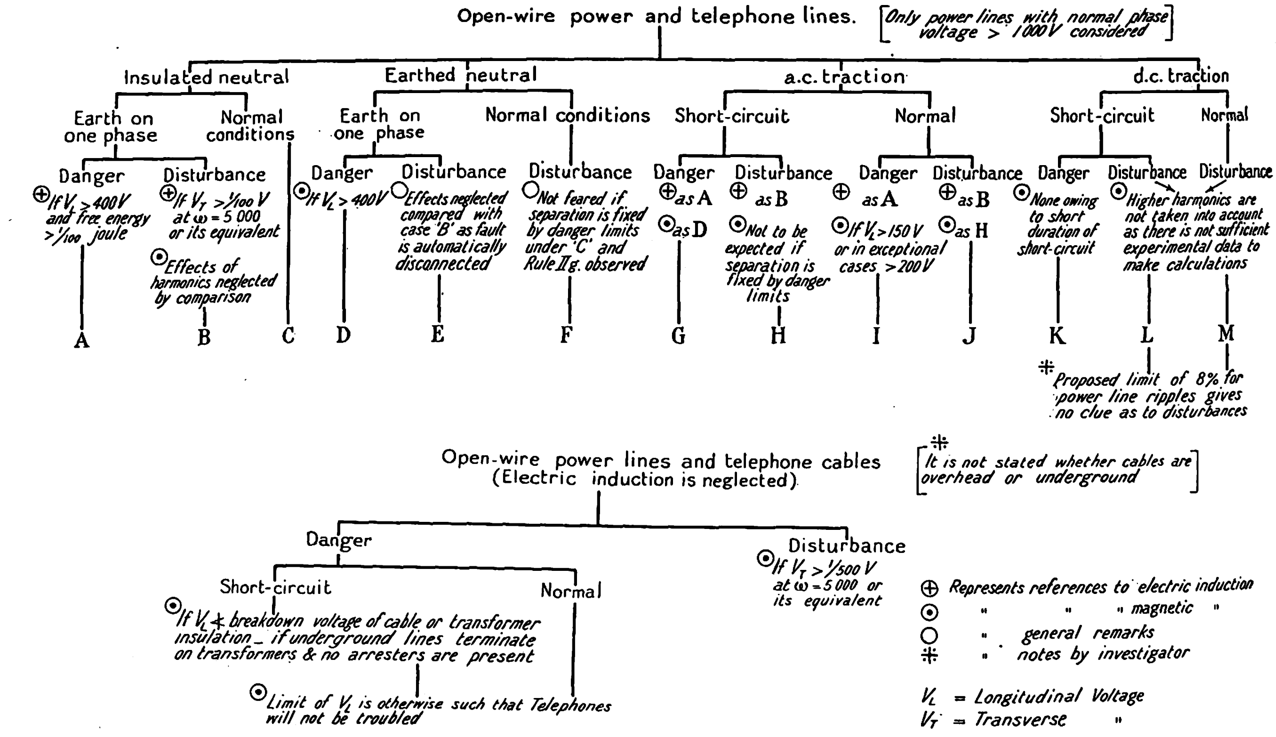
RECOMMENDATIONS.

(1) The wave-form of electromotive force of rotating machines should be approximately sine-shaped under all conditions of load. The C.R.R.C. specify that the maximum deviation of the wave-form from the equivalent sine wave, when superimposed so as to give the least difference, shall not exceed 10 per cent of the maximum ordinate of the equivalent sine wave. The equivalent sine wave is taken as one having the same root-mean-square value and the same wavelength (frequency). The B.E.S.A. rules make provision for a similar requirement.*

Table 5.

Table prepared by Investigator to show Chief Features of the " Proposed Instructions."

Most unfavourable conditions are considered when fixing limits.



Open-wire power and telephone lines.

⁜Proposed limit of 8% for power line ripples gives no clue as to disturbances
Open-wire power lines and telephone cables (Electric induction is neglected)
⁜[It is not stated whether cables are overhead or underground]
Danger
Short-circuit
⊙If V_L ≮ breakdown voltage of cable or transformer insulation – if underground lines terminate on transformers & no arresters are present
Normal
⊙Limit of V_L is otherwise such that Telephones will not be troubled
Disturbance
⊙If V_T > 1/500 V at ω = 5 000 or its equivalent
⊕ Represents references to electric induction
⊙ " " " magnetic "
○ " general remarks
⁜ " notes by investigator
V_L = Longitudinal Voltage
V_T = Transverse "

(2) In the design of stationary direct-current machines and traction motors, use may be made of various technical devices in order to limit the amplitude of the ripples produced by the slots, etc.†

(3) The disturbance caused by rotary convertors can frequently be greatly reduced by a slight displacement of the poles. A special arrangement of the tapping points gives greatly improved results.

(4) No methods are known whereby the design of mercury-arc rectifiers, themselves, has enabled the sixth frequency ripple to be eliminated. Special precautions may be necessary when mercury-arc rectifiers are connected to the system.

(5) Large triple-frequency voltages and currents may be produced by transformers in which the iron is highly saturated. " With a view to limiting the saturation of the iron, the exciting current at normal voltage should not exceed 10 per cent of the normal full-load current " (C.R.R.C.). When transformers are connected together for three-phase working, the type of connection may be so chosen as to provide a local path for the necessary third harmonic of current. The line voltage and current are then sine-shaped. Three-phase core-type transformers are inherently less liable to produce third-harmonic voltages than three-phase shell-type.

(6) With a polyphase system, switches having their poles mechanically interconnected for simultaneous action must be employed. " Wherever practicable all switching operations should be made on the station side of transformer banks as the transient disturbances on the line are thereby less severe " (C.R.R.C.).

Open-wire power lines.—(7) Excessive conductor spacing should be avoided.

(8) Taking into account the inductive effects, the

---

* The rules drawn up by the C.C.I. limit the maximum deviation under the same conditions to 5 per cent of the maximum ordinate of the equivalent sine wave.

In B.E.S.A. Specifications, Nos. 169, 225, 226, published in December 1925, more stringent limitations are imposed in the case of certain classes of machine; the 10 per cent limit referred to above is reduced to 5 per cent, and a still smaller limit is set to high-frequency ripples in the following terms:—

> When a ripple of frequency of 400 per second or above is present in the wave form of electromotive force between any line terminal and neutral, the deviation of this ripple from a mean curve drawn through the ripple shall not exceed 2½ per cent of the maximum ordinate of the mean curve.

† In their final form the C.C.I. rules state that in the case of continuous-current machines, other than convertors and mercury-arc rectifiers, the maximum deviation of the voltage in respect to the average voltage shall not exceed 3 per cent.

reduction of line unbalance and practical considerations of construction, " the equilateral triangular configuration (either horizontal base or vertical base) is in general recommended for single-circuit power lines; and the vertical configuration (including type of construction with middle conductors displaced slightly outwards from the vertical plane of the other two) for twin-circuit power lines " (C.R.R.C.).

(9) Transposition of the whole line should be carried out with " halting "-type barrels of limited length. Single-circuit lines with a triangular arrangement of conductors, or twin-circuit lines so interconnected that their characteristic residual voltage is small, can generally be effectively balanced by 9-mile barrels; 6-mile barrels will balance lines of other configuration (C.R.R.C.).*

(10) Twin-circuit lines are definitely advantageous, as it is possible so to fix the phase relations of the conductors of the two circuits that a partial neutralization of the inductive effects takes place.

(11) In a three-phase system it is essential that the load should be evenly distributed between the phases. Single-phase branches, metallically connected to the conductors, should not be allowed.

(12) Resistance inserted in the earth connection of the star point of the power system will effectively reduce interference trouble in case of breakdown.

Open-wire telephone lines.—(13) Co-ordinated transpositions in power and telephone circuits constitute a most important factor in reducing the interference experienced from parallelism of the two classes of circuit. The " Standard " system of telephone transpositions of the British Post Office is not suitable for use in conjunction with power transposition schemes; but transposition methods for telephone circuits have been developed in America, which make it practicable to reduce the unbalanced exposure to small amounts.

Underground circuits.—(14) Telephone or telegraph circuits carried in underground cables are not subject to interference due to electrostatic induction. Disturbance due to magnetic induction may be very nearly eliminated by accurate balancing of the circuits. Although protection against disturbance does not require a fixed minimum distance of separation, experience has shown that interference will occur due to traction lines, and therefore due to power lines with an earth fault, and communication cables should not be laid in close proximity to such lines.

APPENDIX 1.

LIST OF ARTICLES, ETC., ON WHICH THE SUMMARY IS BASED.

1. " Interference with Communication Circuits," giving the results of investigations on the Mitterwald Railway, Austria. L. Truxa. *Zeitschrift des Oesterr. Ing. u. Arckitekter Verein. Bull.*, vol. 73, p. 149. *Electrician*, October 21, 1921, p. 515.
2. Application of Negative Transformers on the Single-Phase Line from Perpignan to Villefranche of the Midi Railway (France). Ch. Dachary. *Revue Générale de l'Élec.*, vol. 1, p. 331, March 3, 1917, p. 535, April 7, 1917.
3. Question of Power and System in Connection with the Electrification of the Swedish Railways. J. Korne. *Teknisk Tidskrift*, vol. 53 (*Elektrotechnik*), pp. 37–45. *Engineering Abstracts*, vol. 16, No. 251, 1923.
4. Successful Operation of a Telephone System Paralleling H.T. Power Lines. C. E. Bennett. *Gen. El. Review*, December 1914, vol. 17, pp. 1175–1181.
5. Telephones for Power Transmission Lines. J. B. Taylor. *Gen. El. Review*, July 1914, vol. 17, pp. 753, 754.
6. Apparatus for the Protection of Weak Current Cables against the Induction Effect of Traction Currents of Electric Railways. J. Kühle. *Der electrische Betrieb.*, November 26, 1923, vol. 21.
7. " The Influence of Electric Railway Working on the Communication Lines Running along the Railway," giving an account and the results of experiments carried out on the Berne-Scherzligen section of the Swiss Federal Railways. *Swiss Federal Railways Report.*
8. Experiment with the Three-Wire System and Negative Transformers on the Thun-Ostermundigen Section (Swiss Federal Railways). *Swiss Federal Railways Report.*
9. Review of Work of Sub-Committee on Wave-Shape Standard of the Standards Committee (A.I.E.E.). H. S. Osborne. *Trans. A.I.E.E.*, vol. 38, p. 261, 1919.
10. Potential Wave of A.C. Generators. W. J. Foster. *Trans. A.I.E.E.*, 1913.
11. A Proposed Wave-Shape Standard. C. M. Davies. *Trans. A.I.E.E.*, 1913.
12. Wave-Form Distortions and their Effects on Electrical Apparatus. P. M. Lincoln. *Trans. A.I.E.E.*, 1913.
13. Form Factor and its Significance. F. Bedell. *Trans. A.I.E.E.*, 1915.
14. Distortion Factors. F. Bedell. *Trans. A.I.E.E.*, 1915.
15. An Analytical and Graphical Solution for Non-Sinusoidal A.C. F. M. Mizushi. *Trans. A.I.E.E.*, 1915.
16. A.I.E.E. Discussion on Papers, Nos. 13, 14 and 15. *Trans. A.I.E.E.*, 1915.
17. Telephone Disturbance due to Electrified Railways, describing Experiments carried out on the Riksgräns Railway (Scandinavia). A. Holmgren. *Teknisk Tidskrift*, vol. 53 (*Elektrotechnik*), pp. 45–51. *Engineering Abstracts*, vol. 16, No. 206, 1923.
18. Correspondence, supplied by A. R. Everest, criticizing the paper by H. S. Osborne.
19. " Harmonics in Single-Phase Series Motors," describing Experiments carried out by the A.S.E.A. R. Liljeblad. *Teknisk Tidskrift, Elektrotechnik*, October 6, 1923.

APPENDIX 2.

CALCULATION OF INDUCTIVE EFFECTS.

ELECTRIC INDUCTION.

The formulæ worked out by various writers were obtained according to one or other of two general methods of calculation.

METHOD 1.

Kirchhoff's first law is applied to an equivalent circuit representing the circuits involved in the parallel, so that expressions are obtained which give the values of the voltage and current in the disturbed line in terms of the mutual capacities between the conductors and the self-admittances between conductors and earth. The mutual and self-capacities are then expressed in terms of the physical dimensions of the configuration.

This method was applied first by Schrottke (35), who worked out a number of simple cases. An indication of the results obtained is shown in the following case, where a single power conductor and a single communication conductor are concerned.

The equivalent circuit on which the calculation is based is shown in Fig. 1, reproduced with altered notation, from that given by Devaux-Charbonnel (36).

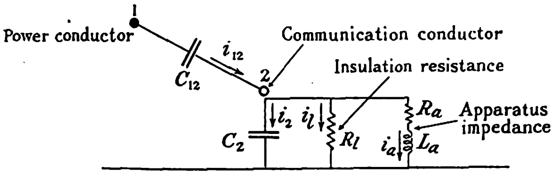

FIG. 1.

Then, applying Kirchhoff's second law—

$$i_{12} = i_2 + i_l + i_a \quad . \quad . \quad . \quad . \quad (1)$$

If v_1 = power-conductor voltage
and v_2 = induced voltage on communication conductor,

then

$$i_{12} = (v_1 - v_2)j\omega C_{12}$$
$$i_2 = v_2 j\omega C_2$$
$$i_l = \frac{v_2}{R_l}$$
$$i_a = \frac{v_2}{R_a + j\omega L_a}$$

Substituting these values in (1), we obtain

$$v_2 = v_1 \frac{\omega C_{12}}{\omega(C_{12} + C_2) - \frac{\omega L_a}{R_a^2 + \omega^2 L_a^2} - j\left(\frac{1}{R_l} + \frac{R_a}{R_a^2 + \omega^2 L_a^2}\right)}$$

If the apparatus is disconnected from the line (i.e. R_a and L_a infinite) the expression for v_2 reduces to

$$v_2 = v_1 \frac{\omega C_{12}}{\omega(C_{12} + C_2) - j\frac{1}{R_l}}$$

or replacing the instantaneous values by R.M.S. values and rewriting

$$V_2 = V_1 \frac{\omega C_{12}}{\sqrt{\omega^2(C_{12} + C_2)^2 + \frac{1}{R_l^2}}} \quad . \quad . \quad . \quad (2)$$

which is the expression obtained by Schrottke (35).

Proceeding as shown by Schrottke, the two limiting conditions can be considered.

(i) *Communication wire insulated from earth* (*i.e.* $R_l = \infty$ *in the limit*).

Then the open-circuit voltage induced is

$$V_{02} = V_1 \frac{C_{12}}{C_{12} + C_2} \quad . \quad . \quad . \quad . \quad (3)$$

(ii) *Communication line earthed* (*i.e.* $R_l = 0$ *in the limit.*

The current flowing though R_l is

$$I_l = \frac{V_2}{R_l}$$

which on substitution for V_2 from (2) becomes

$$= V_1 \frac{\omega C_{12}}{[1 + \omega^2(C_{12} + C_2)^2 R_l^2]^{\frac{1}{2}}} \quad . \quad . \quad . \quad . \quad (4)$$

If $R_l = 0$, the short-circuit current to earth through the communication line is·

$$I_{02} = V_1 \omega C_{12} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

From equations (2), (3), (4) and (5) a relationship is obtained between the open-circuit voltage and short-circuit current and the voltage and current induced when R_l has some finite value. The equation obtained is

$$\left(\frac{V_2}{V_{02}}\right)^2 + \left(\frac{I_2}{I_{02}}\right)^2 = 1 \quad . \quad . \quad . \quad . \quad (6)$$

This is the equation to the circle shown in Fig. 2, which is termed the communication line characteristic by Schrottke.

The angle a shown therein is given by the relation

$$\tan a = \omega(C_{12} + C_2)R_l$$

Hence if the open-circuit voltage and the short-circuit current of the disturbed line are calculated or known, the voltage and current can be obtained when the line is earthed through a resistance R_l.

Expression of results in terms of the physical dimensions.

Although Schrottke (35) left his results in the form shown above—equations (3) and (5)—it is possible to express the capacities between conductors and between conductors and earth in terms of Maxwell's potential coefficients, which are constants depending on the physical dimensions of the configuration. This substitution is discussed more fully under Method 2. Devaux-Charbonnel (36) made this substitution for the simple case we have considered above.

In this case, on substitution in equation (3), we have

$$V_{02} = V_1 \frac{C_{12}}{C_{12} + C_2} = V_1 \frac{p_{12}}{p_{11}} \quad . \quad . \quad . \quad (7)$$

The symbol p throughout this report represents with its appropriate subscript a Maxwell potential coefficient. These are defined under Method 2.

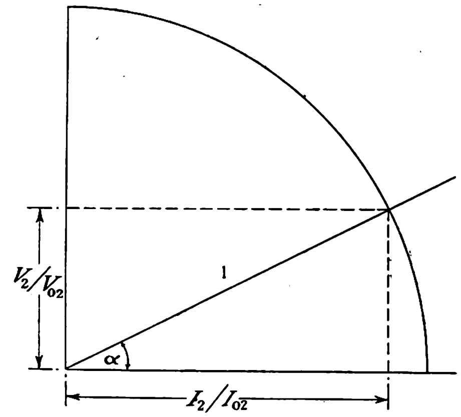

FIG. 2.

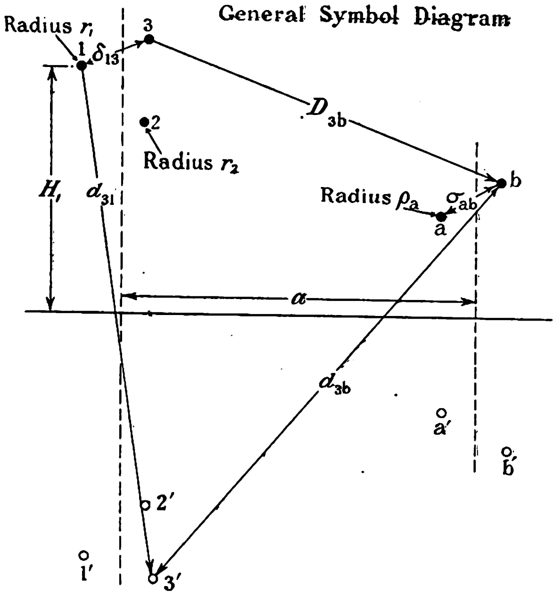

FIG. 3.

Substituting for the potential coefficients

$$V_{02} = V_1 \frac{\log_e \dfrac{d_{12}}{D_{12}}}{\log_e \dfrac{2H_1}{r_1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

The meanings of the symbols in this equation are given on the symbol diagram in Fig. 3.

Similar calculations were made by Schrottke for the case when a metallic communication circuit forms a parallel with a single-power conductor, but the results are in a cumbrous form. By applying the formulæ obtained to an actual example, Schrottke showed that the results obtained, when two disturbed wires are present but are not connected, are in close agreement with those obtained when only one disturbed wire is present.

When the two disturbed wires are connected together through a low resistance, the calculation can be simplified in the following manner, as pointed out by Schrottke (35). The two disturbed wires are replaced by an equivalent conductor placed mid-way between them and having a radius equal to (radius of wire × spacing of wires)$^{\frac{1}{2}}$. It is possible to show by examples the great accuracy of this approximation.

The equations become exceedingly cumbersome if more conductors are present, as, for example, in a parallel between a three-phase power line and a metallic communication line. In such cases the formulæ given by Schrottke are not in a form suitable for use. It is possible that by substituting potential coefficients for the capacities in these formulæ, the formulæ obtained would be the same as those given by the second method.

METHOD 2.

This method was first applied by Breisig (*Theoretische Telegraphie*, 1st edition, 1910, p. 270 *et seq.*), who pointed out that the method developed by Schrottke becomes troublesome when applied to systems with numerous lines owing to the lengthy calculations of the capacities.

The first step is to determine the electric charges on the conductors. These are obtained in terms of the potentials to earth of the conductors and coefficients which are constants depending on the physical dimensions of the configuration and separation.

Utilizing the method involving image conductors, the following equations give the relations between the potentials and electric charges of a system when n parallel lines are present.

$$\left.\begin{aligned} \dot{V}_1 &= p_{11}\dot{q}_1\dot{q}_2 + p_{21} + \ . \ . \ . \ p_{n1}\dot{q}_n \\ \dot{V}_2 &= p_{12}\dot{q}_1 + p_{22}\dot{q}_2 + \ . \ . \ . \ p_{n2}\dot{q}_n \\ \dot{V}_n &= p_{1n}\dot{q}_1 + p_{2n}\dot{q}_2 + \ . \ . \ . \ p_{nn}\dot{q}_n \end{aligned}\right\} \quad . \quad . \quad . \quad (9)$$

V_1, V_2, . . . V_n are the potentials relative to earth of the conductors denoted by the subscripts; Q_1, Q_2, . . . Q_n are the corresponding charges; p_{11}, p_{12}, p_{13}, etc., are termed "potential coefficients" and are constants depending on the physical dimensions of the system. The value of a potential coefficient is the potential of the conductor denoted by one of the subscripts when the charge on the conductor denoted by the other subscript is unity, the charges of all the other conductors being zero.

This series of equations can be rewritten in order to obtain expressions for the electric charges.

Then

$$\left.\begin{aligned} \dot{q}_1 &= k_{11}\dot{V}_1 + k_{12}\dot{V}_2 + \ . \ . \ . \ k_{1n}\dot{V}_n \\ \dot{q}_2 &= k_{21}\dot{V}_1 + k_{22}\dot{V}_2 + \ . \ . \ . \ k_{2n}\dot{V}_n \\ \dot{q}_n &= k_{n1}\dot{V}_1 + k_{n2}\dot{V}_2 + \ . \ . \ . \ k_{nn}\dot{V}_n \end{aligned}\right\} \quad . \quad . \quad (10)$$

k_{11}, k_{12}, etc., are termed " capacitance coefficients " in Technical Report No. 64 of the Californian Investigation, and correspond to Maxwell's coefficients of capacity and induction termed by Russell the coefficients of self and mutual induction for electrostatic charges.

These coefficients will be referred to throughout this Appendix as " capacitance coefficients " on account of simplicity.

From the series of equations (9) and (10) it is seen that the capacitance and potential coefficients are so related that any capacitance coefficient

$$k_{xy} = \frac{\Delta xy}{\Delta} \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

where Δxy signifies the minor or sub-determinant of p_{xy} in the determinant of the potential coefficients in equations (9), namely

$$\Delta = \begin{Bmatrix} p_{11}, p_{21}, \dots p_{n1} \\ p_{12}, p_{22}, \dots p_{n2} \\ p_{1n}, p_{2n}, \dots p_{nn} \end{Bmatrix}$$

A general expression is obtained, therefore, for the charge on a line of length l, namely

$$Q_n = l(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_n k_{nn}) \quad . \quad (12)$$

From this point two alternative methods of procedure are open. Following the first of these, the expression for the potential of any point " a " in the electric field surrounding the power conductors, when only these conductors and earth are present, is given by

$$l\dot{V}_a = P_{1a}\dot{Q}_1 + p_{2a}\dot{Q}_2 + \dots + p_{na}\dot{Q}_n \quad . \quad (13)$$

A parallel communication conductor passing through " a " will assume the potential V_a if isolated from earth and from other conductors. This will hold true for a number of such isolated conductors in the electric field distant apart ten diameters or more, since the modification to the electric field distribution is relatively inappreciable.

In order to calculate the induced potentials of the conductors of a parallel circuit when thus isolated from earth, from each other, from other conductors and from unexposed sections of the circuit, the charges on the power conductors are first calculated from the general equation (12), the capacitance coefficients being obtained from the values of the potential coefficients through equation (11). In order to evaluate the potential coefficient p_{xy} it is necessary to calculate the work done by an external agent against the repulsive force of a unit positive charge on the conductor denoted by one of the subscripts, in bringing a unit positive charge from infinity to the conductor denoted by the other subscript and whose potential is desired. The values of these potential coefficients are given with accuracy by the general formula

$$p_{xy} = 2 \log \frac{d_{xy}}{D_{xy}} \quad . \quad . \quad . \quad . \quad (14)$$

where d_{xy} is the distance of the axis of the conductor denoted by one subscript to the axis of the image conductor denoted by the other subscript, and D_{xy} is the distance between the axes of the conductors denoted by the subscripts. When the subscripts are alike, say D_{xx}, this distance becomes the radius of the conductor denoted by the subscripts. In order to avoid unnecessary complication, the expression for p_{xy} is given as a simple logarithmic ratio; because if, in equations (11) to (14) inclusive, logarithms are taken to the same base, either e or 10, and the dimensions are expressed in the same units throughout, the voltages induced in the parallel circuit are obtained in volts per volt impressed on the power circuit, without a further consideration of signs and units being necessary.

This method was used by the Californian Railroad Commission in their study of inductive interference.

An alternative way of proceeding from the general expression for the charge on a line, as given in equation (12), is that given by Breisig (*Theoretische Telegraphie*, 1st edition, 1910, p. 272 *et seq.*; 2nd edition, p. 296 *et seq.*) and applied by Brauns (111) to practical cases.

Considering the case in which line n lies in the fields of $n-1$ lines; then from equation (12),

$$\dot{Q}_n = l(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_n k_{nn})$$

It is clear from Kirchhoff's first law that the value of the current flowing along wire n from an external source must be equal to the time rate of increase of the charge Q_n on line n plus the currents flowing from line n to earth and to the other lines. When n is a communication conductor, the value of the above current is zero. The general equation expressing this is

$$\begin{aligned} 0 = j\omega l(&\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_n k_{nn}) \\ &+ G_{1n}(\dot{V}_n - \dot{V}_1) + G_{2n}(\dot{V}_n - \dot{V}_2) \\ &\quad + \dots G_{n-1}(\dot{V}_n - \dot{V}_{n-1}) + G_{nn}\dot{V}_n \dots \quad (15) \end{aligned}$$

where G_{xy} denotes the conductance between the conductors represented by the subscripts, and G_{xx} the conductance between the conductor denoted by the subscripts and earth.

If a special case be considered in which only one line, the nth, of the n lines present is a communication conductor, the remaining $n-1$ lines being power conductors, then equation (15) is reduced to the form

$$\begin{aligned} 0 = j\omega l(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_{n-1} k_{n-1, n}) \\ + \dot{V}_n(G_n + j\omega l k_{nn}) \end{aligned}$$

since there are no connections between the communication line and the power lines.

Hence the induced voltage

$$\dot{V}_n = -j\omega l \frac{(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_{n-1} k_{n-1,n})}{G_n + j\omega l k_{nn}} \quad . \quad (16)$$

and the open-circuit voltage when $G_n = 0$, is

$$\dot{V}_{0n} = -\frac{1}{k_{nn}}(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_{n-1} k_{n-1, n}) \quad (17)$$

The current flowing from line n to earth is given by

$$\dot{I}_n = \dot{V}_n G_n = -j\omega l \frac{(\dot{V}_1 k_{1n} + \dot{V}_2 k_{2n} + \dots \dot{V}_{n-1} k_{n-1, n})}{\dfrac{1 + j\omega l k_{nn}}{G_n}} \quad (18)$$

and the short-circuit current when $G_n = \infty$ is

$$\dot{I}_{0n} = -j\omega l(\dot{V}k_{1n} + \dot{V}_2k_{2n} + \dots \dot{V}_{n-1}k_{n-1,\,n})$$
$$= j\omega l\dot{V}_{0n}k_{nn} \quad . \quad (19)$$

From equations (16) to (19) inclusive the following is obtained

$$\frac{\dot{V}_n}{\dot{V}_{0n}} + \frac{\dot{I}_n}{\dot{I}_{0n}} = 1$$

This represents two vectors which are in quadrature when $1/G_n$ is a non-inductive resistance, giving, therefore,

$$\left(\frac{V_n}{V_{0n}}\right)^2 + \left(\frac{I_n}{I_{0n}}\right)^2 = 1$$

which is in agreement with equation (6) obtained by Schrottke.

From the general equations (17) and (19) for the case when only one communication conductor is present, the form of these equations, when particular conditions of the power conditions are considered, have been obtained by Breisig (*Theoretische Telegraphie*, 2nd edition, p. 296) and Brauns (loc. cit.).

As an example, the case is considered when a parallel consists of one power and one communication conductor, denoted by symbols 1 and 2 respectively. Then

$$\dot{V}_{02} = -\frac{1}{k_{22}}\dot{V}_1k_{12}$$

from equation (17).

Then substituting for k_{12} by means of equation (11), we have, therefore,

$$V_{02} = V_1\frac{p_{12}}{p_{11}} \quad . \quad . \quad . \quad . \quad . \quad (19a)$$

which in terms of the physical dimensions of the parallel becomes by using equation (14)

$$V_{02} = V_1\frac{\log\dfrac{d_{12}}{D_{12}}}{\log\dfrac{2H_1}{r_1}} \quad . \quad . \quad . \quad . \quad . \quad (19b)$$

which is identical with the result obtained from Schrottke's method and given by equation (8). Similarly, I_{02} can be obtained. Brauns (111) worked out a number of practical cases involving one, two and three power lines with and without an earth fault on one phase.

When two communication conductors are present, similar general equations can be obtained as worked out by Breisig (*Theoretische Telegraphie*, 2nd edition, p. 302) for the case when only one power line is present. Brauns in a published article, in which practical cases with a metallic communication circuit present are considered, avoids this additional series of equations by assuming in the first place that the open-circuit voltage induced on one communication conductor is the same whether a second communication conductor is present or not. The results finally arrived at in this article for the disturbing current flowing through the terminal apparatus differ considerably from those calculated according to the formulæ from which were derived the limits of separation laid down in the "French Rules." After a considerable amount of work by the present investigators this difference was traced to the use by Brauns of an equivalent conductor in a similar manner to Schrottke for the purpose of obtaining the total short-circuit current when both wires were earthed.

The combination of methods used to obtain the formulæ contained in the "French Rules" will now be described.

Kirchhoff's first law is applied to the more complicated case when three power conductors and a two-conductor (metallic) communication circuit are present and form a parallel. The equations thus obtained express the relationships between the apparatus resistance, conductor potentials and the capacities between conductors and earth and between conductors. In order to simplify the subsequent calculation the capacities in these equations are expressed at once in terms of the capacitance coefficients mentioned previously, which are connected by the following relations:—

$$k_{xy} = -C_{xy}$$

where x and y represent different conductors, and

$$k_{xx} = C_{x1} + C_{x2} + \dots C_{x,\,x-1} + C_{xx} + C_{x,\,x+1} + \dots C_{xn}$$

The equations then resulting are similar in type to those obtained by Breisig for the simpler case when only one power conductor is present instead of three. Proceeding then according to Method 2, potential coefficients are substituted for the capacitance coefficients, the equations being simplified by neglecting terms, the numerical values of which would be relatively so small in actual examples that they would not affect results. At the same time, one power conductor is assumed to be earthed due to a fault, a system with neutral insulated being considered. It is further assumed that the power line is sufficiently well transposed to enable certain simplifications to be made.

Formulæ giving the electric induction in the case of a number of practical cases involving one, two and three power lines, with and without an earth fault on one phase, are given in Table 1 to this Appendix. Attention has been drawn in a footnote to those cases in which the result obtained by Brauns differs from the formula given.

It will be realized that the formulæ in Table 1 are complicated and that some time would be required to work out actual cases. Further, the effect of separation and other dimensions is not directly apparent. Lienemann (100) simplified the formulæ obtained by Brauns by changing the equations from the awkward logarithmic form and was thus able to express the interference effects directly in terms of the separation and other dimensions. By writing the natural logarithms in Brauns' formulæ in a certain form, they can be replaced by rapidly converging series from the relations given by

$$\log_e(1 \pm x) = \pm x\left(1 \mp \frac{x}{2} + \frac{x^2}{3} \mp \frac{x^3}{4} + \dots\right) \quad (20)$$

and

$$\log_e\left(\frac{1+x}{1-x}\right) = 2x\left(1 + \frac{x^2}{3} + \frac{x^4}{5} + \dots\right) \quad . \quad (21)$$

$$K_{4-5} = [(p_{14} - p_{15})^2 + (p_{24} - p_{25})^2 + (p_{34} - p_{35})^2 - (p_{14} - p_{15})(p_{24} - p_{25}) - (p_{24} - p_{25})(p_{34} - p_{35}) - (p_{34} - p_{35})(p_{14} - p_{15})]^{\frac{1}{2}}$$

V = normal power-conductor voltage to earth

l = length of parallel in km.

* Denotes a formula giving a result differing from that of Brauns

† Denotes a more accurate formula which can be approximated to the formula given by Brauns.

‡ Denotes a formula which is in agreement with the formula given in the "French Rules."

which are both converging series for values of x between -1 and $+1$. Since the physical dimensions are seldom known accurately, it is assumed that it is only possible to aim at an accuracy of 10 per cent in the calculation. Although when making these substitutions the interference effect is due to the whole series, 10 per cent inaccuracy is permissible in determining the value of this series by taking the first term only. With the above limit of 10 per cent, the limiting values for x are $x \overset{=}{<} 0\cdot 2$ for equation (20) and $x \overset{=}{<} 0\cdot 53$ for equation (21).

As an example, the same case is considered as previously, i.e. when a parallel consists of one power and one communication conductor, denoted by symbols 1 and 2 respectively. The corresponding equation (19*b*), giving the open-circuit voltage as

$$V_{02} = V_1 \frac{\log \dfrac{d_{12}}{D_{12}}}{\log \dfrac{2H_1}{r_1}}.$$

can be worked out to show the type of formula which is produced by applying such approximations. Considering, therefore, the term

$$\log_e \frac{d_{12}}{D_{12}}$$

this can be written, by reference to the symbol diagram, equal to

$$\log_e \sqrt{\frac{a^2 + (b + c)^2}{a^2 + (b - c)^2}}$$

or

$$\tfrac{1}{2} \log_e \frac{1 + \dfrac{2bc}{a^2 + b^2 + c^2}}{1 - \dfrac{2bc}{a^2 + b^2 + c^2}}$$

This is then of the form

$$\log_e \frac{1 + x}{1 - x}$$

where

$$x = \frac{2bc}{a^2 + b^2 + c^2}$$

and is not greater than $0\cdot 5$, except for very close parallels where the separation equals the mean height of the conductors. Writing

$$\log_e \frac{d_{12}}{D_{12}} = \frac{2bc}{a^2 + b^2 + c^2}$$

will, therefore, give too small a value. The other term

$$\log_e \frac{2H_1}{r_1}$$

can be shown to be approximately a constant, for with $r_1 = 4$ mm and $b = 6$ to 10 m,

$$\log_e \frac{2H_1}{r_1} = 3\cdot 6 \times 2\cdot 3 \text{ to within } \pm 3 \text{ per cent}$$

Lienemann assumed a value for

$$\log_e \frac{2H_1}{r_1} = 3\cdot 48 \times 2\cdot 3 = 8$$

which he took on the low side in order to compensate partly for the error in the value of

$$\log_e \frac{d_{12}}{D_{12}}$$

Inserting these simplified values in the equation for V_{02}, we have

$$V_{02} = V_1 \frac{2bc}{a^2 + b^2 + c^2} \times \frac{1}{8} = \frac{V_1}{4} \times \frac{bc}{a^2 + b^2 + c^2} \quad (22)$$

From this equation the effect of separation and the heights of the conductors can be more readily obtained.

Lienemann applied this approximate method of calculation to a number of the formulæ given by Brauns. The simplified expressions corresponding to those cases in which the accuracy of the original formula has been established are given in Table 2. The formulæ for the current through the apparatus where a metallic communication circuit is concerned have been obtained by the investigators by applying the approximations developed by Lienemann to the formulæ given in the "French Rules."

In the preparation of this part of the report the work done by other writers, (24), (62), (90), (94), who have calculated the electric induction for certain cases, was also considered.

MAGNETIC INDUCTION.

The calculation of magnetic induction in cases involving circuits with an earth return is of special importance and is dealt with separately.

GENERAL CASE.

Devaux-Charbonnel showed that the well-known relation $E = j\omega MI$ between the e.m.f. E induced in the secondary of two circuits and the inducing current I of circular frequency ω in the primary, holds so long as the effect of the current in the secondary produced by the induced e.m.f. can be ignored. This is permissible when the impedance of the secondary circuit is high, which is the case in practice.

Brauns (100) has developed formulæ for the magnetic induction between power and communication circuits; but the effect of the earth on modifying the magnetic field of the power line is neglected in these formulæ, which treat of the case when the earth is at an infinite distance away. The method adopted by the Californian Railroad Commission and given in full in the Technical Report No. 64 takes account of the effect of the earth. This method will now be described.

The earth is considered as a common conductor of the three-phase power circuit and the metallic communication circuit, and as a path for eddy currents. The latter tend to reduce the magnetic flux passing through the earth. By replacing the earth by the images of the conductors at a suitable distance below the earth's surface, the effect of the earth can be simulated. But, as the earth is not a perfect conductor, the locus of earth currents is at a considerable depth, and the magnetic neutral zone does not exist at the earth's surface. Its depth varies with the frequency of the

The meaning of the symbols will be obtained from Fig. 4.

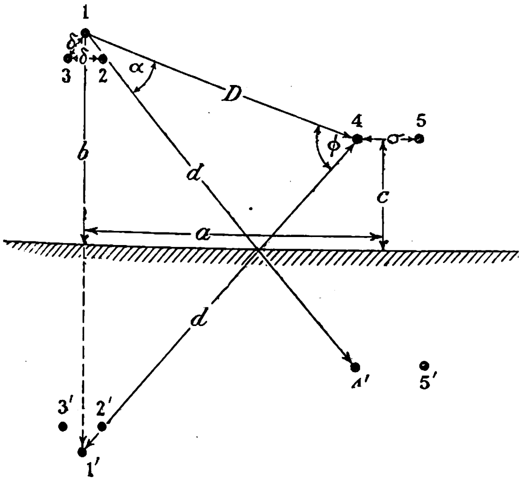

FIG. 4.

current and the character of the country. Tests made at three different localities by the Californian Railroad Commission show "that the image conductors for computations of magnetic induction should be taken with respect to an 'equivalent earth plane,' from 300 to 500 ft. below the surface. The figures given are for 60 cycles. For higher frequencies the equivalent earth plane is nearer the surface."

With the same notation as for electric induction, for the case when a three-phase power line and a metallic communication line form a parallel (where numbers 1, 2 and 3 denote the power conductors and numbers 4 and 5 the communication conductors), the induced voltage is

$$E_4 = -j\omega(\overline{M_{14}I_1} + \overline{M_{24}I_2} + \overline{M_{34}I_3})$$

where

$$M_{14} = 2 \log \frac{d_{14}}{D_{14}}$$

$$M_{24} = 2 \log \frac{d_{24}}{D_{24}}$$

$$M_{34} = 2 \log \frac{d_{34}}{D_{34}}$$

The values in the bracket require to be added vectorially, since I_1, I_2 and I_3 are vectors.

Three sets of components of the currents are considered in this report:—

(i) Balanced three-phase currents.
(ii) Single-phase current in a loop composed of two of the conductors.
(iii) Residual current flowing along the conductors and returning through the earth.

If the phase relationships are known, the resultant induced voltage can be obtained. For the above components we have the following formulæ, giving the magnitude of E_4:—

(i) *For balanced currents.*

$$E_4 = K\omega I \sqrt{\left[M_{14} - \tfrac{1}{2}(M_{24}+M_{34})\right]^2 + \left[\frac{\sqrt{3}}{2}(M_{24}-M_{34})\right]^2}$$

where I is the magnitude of balanced currents.

(ii) *For single-phase current.*

$$E_4 = K\omega I_S(M_{14} - M_{34})$$

assuming single-phase component I_S in conductors 1 and 3.

(iii) *For residual current.*

$$E_4 = \frac{K\omega I_R}{3}(M_{14} + M_{24} + M_{34})$$

where I_R is the magnitude of the residual current.

K is a constant converting E_4 to volts per 1 000 ft. of parallelism and equals $70 \cdot 183 \times 10^{-6}$, when the current is in amperes and the logarithmic ratios involved in the values of M_{14}, etc., are taken to the base 10.

Each of the above formulæ can be easily converted to forms involving physical dimensions—see Table 3 to this Appendix.

"If the separation of the two conductors a and b is small compared to their average separation from the power circuit, then the average of their induced voltages is approximately equal to that along a single conductor midway between them." This approximation was applied by the C.R.R.C. in obtaining the voltages induced in phantom telephone circuits.

"In the case of two or more disturbing circuits, as for example a twin-circuit power line, the resultant induced voltage is the vector sum of the induced voltages due to the individual circuits separately considered. The mutual effects between the several power circuits do not enter to complicate the computations as in the case of electric induction."

CIRCUITS WITH AN EARTH RETURN.

The solution in these cases is more difficult and is not rigid, since the path of the earth currents is not exactly known.

Various approximations are possible, based on a number of limiting cases.

Communication line with earth return.—If the communication line has an earth return, so that line 3 (see Fig. 5) is so far removed that $r_2 \simeq r_4$, then the formula

$$M = 2l \log_e \frac{r_2 r_3}{r_1 r_4} \times 10^{-4} \text{ henry per km}$$

for the mutual inductance M between metallic circuits reduces to

$$M = 2l \log_e \frac{r_3}{r_1} \times 10^{-4} \text{ henry per km}$$

This case does not appear to enter into practice from the evidence collected, although telegraph circuits paralleling metallic single-phase power lines would fulfil the conditions.

It seems doubtful whether, in the usual case, the earth return would be so distant that it would be permissible to write $r_2 = r_4$.

Power line with earth return.—If the power current returns through the earth entirely, this may be taken as a limiting case when considering the distribution of the return current of a single-phase railway. If the return current is assumed to be so far distant from the contact line and metallic communication line that it does not contribute to the mutual inductance, it is possible to write

$$M = 2l \log_e \frac{r_2}{r_1} \times 10^{-4} \text{ henry per km}$$

Although this case corresponds to parallels formed by metallic telephone circuits and a single-phase railway, little consideration has been given to it in general by writers.

Both power and communication circuits with earth return.—For two parallel lines of equal length with a common return over a medium unlimited in extent, Breisig obtained an approximate formula for the mutual inductance M between the circuits from a consideration of the magnetic-field energy. (See *Theoretische Telegraphie*, 2nd edition, p. 163 *et seq.*) This formula, which assumes that the separation a is small compared with the line length l, gives

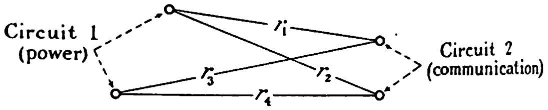

FIG. 5.

$$M = 2l\left(\log_e \frac{2l}{a} - 1\right)10^{-4} \text{ henry per km}$$

According to Breisig this formula represents the mutual inductance of two current systems consisting of two parallel lines of length l and separation a buried in a medium of unlimited dimensions and with their return currents flowing back through the medium.

In actual cases the return currents flow through the earth, which, therefore, forms a medium with a boundary surface and is not homogeneous. Also the conductivity of the earth needs to be looked upon as due only to a reasonably thick water-bearing stratum near the surface. Physically these conditions resemble those in the ideal case calculated in that the return currents spread out to a large extent compared with the currents flowing in the lines. It becomes necessary to modify the above equation in an empirical manner to take account of the effect of the earth currents.

The formula thus becomes

$$M = 2l\left(\log_e \frac{2l}{a} - q\right)10^{-4} \text{ henry per km}$$

where q is a number which varies from about 0·5 to 5, depending on the length of the line according to experiments carried out by Brauns (111).

L. Truxa states that the formula, as given above by Breisig for the mutual inductance between two lines with an earth return, becomes

$$M = 2a \log_e \frac{2\sqrt{bc}}{d} 10^{-4} \text{ henry per km}$$

when the second line, i.e. the communication line, is the longer of the two. The derivation of this formula has not been considered by the present investigators.

In a more recently published article Breisig stated from theoretical considerations the following approximate formula for M *:—

$$M = 2e^{-\omega_0}\left(\log_e \frac{\pi}{\omega_0} - 1\right) - j\frac{\pi}{2}$$

where $\omega_0 = a\sqrt{2\pi\sigma\omega}$
a = separation
σ = conductivity of the earth.

Single-phase railway.—In the case of the single-phase railway, Pleijel (108) has shown that currents are induced in the earth by magnetic induction and these form a circuit along the rails, returning through the earth. The rail current is then the sum of this current I_1 induced in the rail-earth circuit plus that portion I_R of the contact-line current which returns through the rails; while the earth current is the difference between that part I_E of the contact-line current returning through the earth and the current I_1 induced in the earth-rail circuit.

I_1

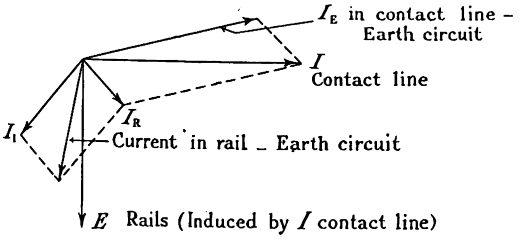
FIG. 6.



I_E in contact line - Earth circuit
I Contact line
I_R
I_1
Current in rail – Earth circuit
E Rails (Induced by I contact line)

FIG. 7.

Hence it can be considered that there are two circuits carrying current acting on the communication circuits—

(i) Contact-line-rail circuit acting as a metallic circuit along which current I_R and I_1 flows.
(ii) Contact-line-earth circuit, along which current $= I_E - I_1$ flows.

Fig. 6 shows the direction of currents flowing and Fig. 7 the phase relationships for this simple case.

It is also possible to consider the contact line and rails as two lines having an earth return, which gives the corresponding vector diagram, Fig. 8.

Considering the latter diagram, since it is easier to compare the effects of two earth-return circuits, it is clear that the inductive effects would be neutralized if the magnitude and phase of the current I_1 induced in the rail-earth circuit were suitable.

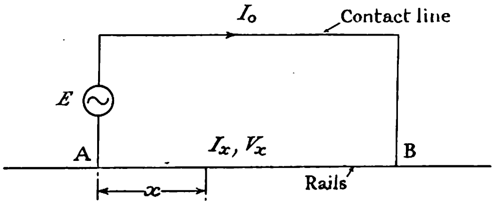
FIG. 8.

Pleijel has made a theoretical investigation into the distribution of voltage and current in *rail-lines.* He considered a lay-out as shown in Fig. 9; and taking into account the constants of the circuit, there follow the relations (assuming mutual inductance between the contact line and rails equal to M):—

$$-\frac{\delta V}{\delta x} = (r + j\omega l)I - j\omega M I_0$$

$$-\frac{\delta I}{\delta x} = aV$$



I_0

E
A
I_x, V_x
B
x
Rails

FIG. 9.

where I_0 = contact line current
I = current at any point on rails
r and l = resistance and inductance of rails per km.

Writing $I - kI_0 = I_1$

where $k = \dfrac{j\omega M}{r + j\omega l}$

and M = mutual inductance of contact-line and rails per km

we have $-\dfrac{\delta V}{\delta x} = (r + j\omega l)I_1$

From this it is shown that the effective voltage at any point on the rails is entirely determined by I_1, while the other part of the current in the rails, i.e. kI_0, has no effect on the value of the voltage, as the pressure-drop which this current causes is compensated by the induced e.m.f.

---

* The derivation of this formula will be considered in the Supplement to this Report. Reference has been made to this formula, in conjunction with those of Pollaczek and Rüdenberg, by the C.C.I. for the purpose of calculating the induction from earth currents due to a short-circuit on a power system with an earthed neutral point.

INDUCTION ON A WIRE PARALLEL TO THE CONTACT LINE.

Considering the case when the induced wire extends far beyond the contact line, it is assumed that the rail constants are uniform, so that the contact-line current divides where it enters the rails and the rail currents gradually decrease in value as the current I_0 leaks into the earth and returns by that path. The distribution of these "true" rail currents is shown in Fig. 10. It is clear that the sum of the "true" rail currents is zero.

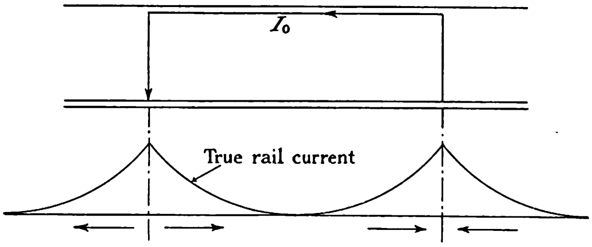

FIG. 10.

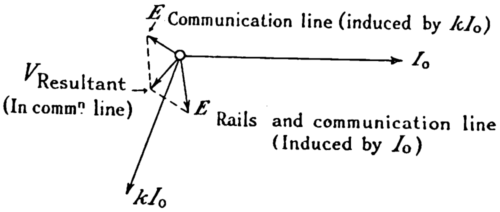
In other words, the sum of the currents which produce a pressure-drop in the rails equals zero. Therefore, only the induced part of the rail current, kI_0, causes induction in the inducing line, considering its whole length.

There are thus two currents, I_0 in the contact line and kI_0 in the rail line, each with an earth return, and these act inductively on the communication circuit. Pleijel draws the conclusions from this discussion that the induction is independent of the leakage coefficient of the rail line and also of the conductivity of the earth.



E Communication line (induced by kI_0)
I_0
V Resultant
(In commⁿ line)
E Rails and communication line
(Induced by I_0)
kI_0

FIG. 11.

From the above discussion the induced e.m.f. in the communication line can be written $E = j\omega I_0(M_0 - kM_1)$, taking account of phase relations. M_0 and M_1 are the mutual inductances of the communication circuit and contact-line-earth and rail-earth circuits respectively.

For communication lines with earth return, the formula

$$M = 2l\left(\log_e \frac{2l}{a} - q\right)$$

developed by Breisig for two lines of equal length is then inserted for M_0 and M_1, though in the case considered throughout, the communication line is much longer. Presumably, Pleijel intended that the value given to q should allow for this.

Hence

$$M_0 = 2l\left(\log_e \frac{2l}{h_0} - q\right)10^{-4} \text{ henry per km}$$

$$M_1 = 2l\left(\log_e \frac{2l}{h_1} - q\right)10^{-4} \text{ henry per km}$$

where h_0 = distance from contact line to induced line
h_1 = distance from rail to induced line.

At somewhat large separations, $M_0 \cong M_1$; so that the induction becomes proportional to $1 - k$. Fig. 11 shows how the resultant e.m.f. in the communication line depends on the phase relations.

CONSIDERATION OF THE RESULTS.

ELECTRIC INDUCTION.

It is clear from equation (2), and particularly from equation (3), that by increasing the value of C_2, the capacity of the disturbed line to earth, the induced voltage V_2 or, in particular, V_{02} will be reduced. Such an increase occurs in practice if the disturbed conductor extends beyond the parallel.

It has been suggested by Brauns (119) and by Caldwell and Marsden (24) that capacity could be added by connecting special condensers between the communication conductor and earth. Equation (3) shows that the open-circuit voltage induced in the disturbed line is independent of frequency and of the length of parallel, when the disturbed wire does not extend beyond the limits of the parallel.

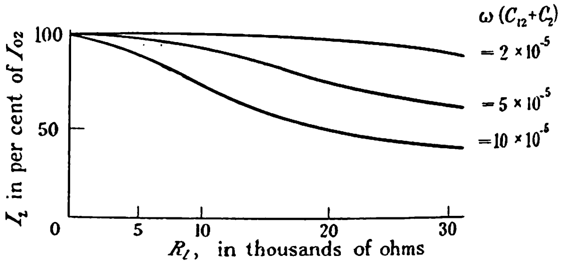


FIG. 12.

Consideration of equation (2) shows that the short-circuit current is proportional to frequency and the length of the parallel. From Fig. 2 it will be seen that the current I_l flowing through the earth resistance R_l only decreases slowly from the value of the short-circuit current I_{02} as the value of R_l increases from zero. The importance of this relation is brought out by Schrottke (35), who showed in an example that, in the case of a long parallel, if a person touches an insulated disturbed line the current passing is not appreciably less than the short-circuit current, although the voltage to earth is reduced to a small fraction of the open-circuit voltage. Fig. 12 has been drawn to show the variation in the induced current with the other variables.

The formulæ obtained by Lienemann (see Table 2) enable certain approximate conclusions to be drawn with regard to the effect of separation of the two circuits, height of conductors, etc., on the induced voltage and current due to one or two interfering lines.

For the more complicated case of induction from a three-phase power circuit, Technical Report No. 65 of the Californian Railroad Commission contains a large number of curves plotted from calculations which were based on formulæ obtained as previously indicated. Curves are given for both magnetic and electric induction. On the conclusions drawn from these curves much of the information given in Section 3 of this *résumé* is based.

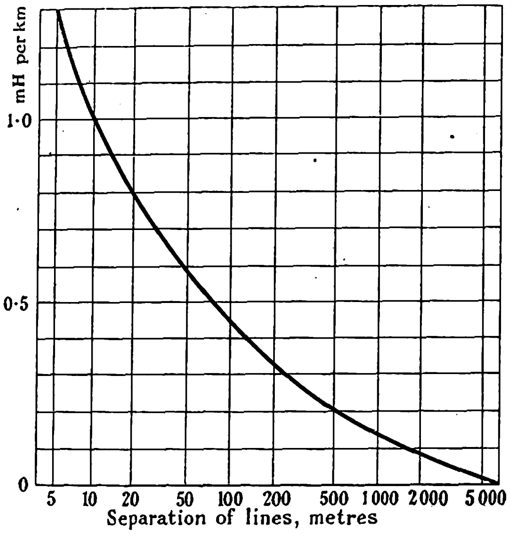

FIG. 13.—Mutual inductance of earth-return circuits, millihenrys per km.

MAGNETIC INDUCTION.

It is not directly clear from the formulæ given how the physical dimensions of the configuration affect the induction coefficients. Due to the relatively great depth of the return current in the earth the induction coefficients due to voltages decrease much more rapidly with increase in horizontal separation than those due to currents. Jäger (88) has given a curve (Fig. 13) which shows the mutual inductance M due to a single interfering line as a function of the separation.* It is based on numerous unspecified experiments at many places and for various lengths and separations of parallels involving earth-return communication lines. In the "French Rules" a formula is given for M as determined from results made at frequencies from 15 to 50 cycles per second as follows:—

$$M = \frac{4}{\sqrt{a}} \times 10^{-3} \text{ henry per km}$$

The relation $M \propto \frac{1}{\sqrt{a}}$

holds quite well over the curve given by Jäger between $a = 20$ and $a = 2\,000$ metres. It is possible that the same series of tests is the source in each case.

TABLE 3.

Formulæ for Induced Voltages due to Magnetic Induction.

Balanced currents.

$$E_4 = K\omega I \sqrt{\log^2 \frac{d^2{}_{14} D_{24} D_{34}}{D^2{}_{14} d_{24} d_{34}} + 3 \log \frac{d_{24} D_{34}}{D_{24} d_{34}}}$$

Single-phase current:

$$E_4 = -j\omega K 2 I_S \log \frac{d_{24} D_{34}}{D_{24} d_{34}}$$

Residual current:

$$E_4 = -j\omega \frac{2K}{3} I_R \log \frac{d_{14} d_{24} d_{34}}{D_{14} D_{24} D_{34}}$$

or approximately

$$E_4 = -j\omega 2 K I_R \log \frac{d_{04}}{D_{04}}$$

Approximations can be made under certain conditions. If the induced voltage due to the residual current is required, it is permissible to replace the three power conductors by one single conductor, the error incurred being usually small. (The accuracy of this approximation increases as the power conductor spacing decreases.)

The formula then becomes $E_4 = K\omega I_R M_{04}$, where M_{04} is based on the mean dimensions of the power wires.

---

* This curve is in fairly close agreement with results calculated according to Rüdenberg's formula using an earth resistivity of 20 000 ohms per cm cube. The latter formula will be considered in the Supplement.

APPENDIX 4.

EARTHING OF NEUTRAL POINTS.

The information given in this Appendix supplements that given in Section 3 of the résumé.

Bartholomew (32) has given details concerning tests carried out on the power systems of the north-east coast in order to determine the increase in interference to the telephone system due to the provision of more than one earth connection to the power system.

It was pointed out by the power company concerned “ that whilst the provision of more than one earth connection might increase the interference from normal working of the power system, it would certainly decrease the possibility of serious trouble arising out of momentary disturbance of larger magnitude and would reduce the risk of these latter continuing for any appreciable time. It was agreed that it would not be wise to have more than one earth on a circuit directly connected with a generator the neutral point of which was earthed, but it was contended that with delta-star transformers feeding a system the triple-frequency currents would be small and would not be likely to increase to any extent the normal interference.”

During the tests which were carried out currents in the earth connections at the various points were measured. The results are shown diagrammatically in Fig. 14 attached to this Appendix, which has been redrawn to show more clearly the main results given in Fig. 43 of the paper referred to above.

With the system earthed at Philadelphia only, the current in that earth connection is 0·6 ampere, which increases to peak values of approximately 3·5 amperes when three or four other points (North Tees, Dunston and Carville), and these three points together with Bowden Close, are earthed in addition. The communication circuits were under observation during these tests, but no effect was observed on the telegraph circuits, “ and although there was an increase in telephone interference this was inappreciable ”: . . . “ the routes of the communication circuits under observation were not favourable for interference.”

Note.—Philadelphia is earthed through a resistance.

FIG. 14.

In this test measurements were apparently taken at only one-quarter of the combinations possible with a maximum of five earthing points. Without further data regarding the lay-out of the systems and the distribution, analysis and phase of the triple-harmonic currents, this test seems to be insufficient to enable indiscriminate multiple earthing to be advanced as desirable.

Dewey has found (*Journal A.I.E.E.*, 1923, vol. 42, pp. 589–600) that the normal current interchange on many large extensive systems with several neutral points earthed is usually so small that interference only occurs in a few cases.

GENERATORS CONNECTED DIRECT TO LINE.

Where generators are connected directly to the line, it is possible to reduce the triple-harmonic residual capacity currents by earthing the neutral of the machine having the wave-form which has the smallest triple harmonics, considered from the viewpoint of interference.

The use of a transformer to provide the neutral to be earthed eliminates the triple-harmonic currents due to the corresponding voltage harmonics in the generator wave-form. In order to prevent third-harmonic components appearing in the line due to these transformers, the secondary winding should be connected in closed delta, or an interconnected star primary winding used.

PETERSEN EARTH COIL OR NEUTRAL EARTHING REACTOR.

Earthing the neutral of power circuits through reactance coils has been adopted in many cases in Europe and a test installation has been tried out in the U.S.A. (see W. W. Lewis, *Journal A.I.E.E.*, vol. 42, 1923, pp. 467–484, and Oliver and Eberhardt, *ibid.*, pp. 904–914). In this method, originally described by Petersen (*E.T.Z.*, 1919, January 2nd and 9th), the neutral of the system is earthed through an inductance which is in resonance at the fundamental frequency with the total direct capacity of the system to earth. The effect of this method of earthing is to tend to extinguish arcing faults to earth. The earth current is small when a fault exists to earth, but according to Conwell and Evans (*Trans. A.I.E.E.*, vol. 41, 1922, pp. 75–93) difficulties are introduced in obtaining selective relay protection.

In the U.S.A. test installation it was arranged so that the reactor was short-circuited if the earth fault remained on the circuit more than a few seconds. The service interruptions due to flash-over were mostly eliminated.

Bekker has shown (*Journal I.E.E. Japan*, 1922, No. 409, p. 595, Synopsis in English) that the effect of magnetic induction is rendered independent of the position of the earth fault. For a particular case when a parallel exists over a quarter of the length of the power line at the receiving end and an earth fault occurs at the receiving end, figures are given showing that the magnetic induction with an earth coil is 10 per cent of that occurring with the neutral earthed through a non-inductive resistance equal in value to the reactance of the coil.

The voltage out-of-balance with the Petersen earth coil is three times that of the voltage unbalance of solidly earthed systems. According, however, to L. P. Ferris in the discussion of the paper by Conwell and Evans, theory and experience indicate that induced voltages with one phase earthed are more severe with solidly earthed than with insulated systems, except perhaps on long parallels with very high-voltage systems.

For normal conditions, the effect of the earth coil system has been investigated by H. M. Trueblood (70). Considerable reduction in the triple-harmonic residual voltages and currents occurring with solid or low resistance earthing is indicated, this reduction increasing with the order of the harmonic. Residual currents of non-triple harmonics are reduced to practically the same values which would be present with the system insulated. Fundamental residual components may be increased if the line unbalance be too great. Lewis (see reference above) gives results of tests on the U.S.A. installation, which agree with part of these conclusions. On the system tested, with the neutral dead earthed, a small residual current flowed containing 5th and 7th harmonics; with the neutral earthing reactor, the total residual current was increased 20 per cent, but these particular harmonics were eliminated.

It appears that the earth-coil system is at present limited to high-tension lines up to 60 kV of medium length and up to 100 kV for short lengths.

While a thorough investigation into this question has not been made, it was thought desirable to include the above information in view of several references which have been made of late to this system of earthing, hinting at the possibility of the desirability of its adoption in the future in this country. In this connection Bekker (see above) states that as a remedy for interference, which is a serious complaint in Japan, the Petersen earth-coil seems promising.

APPENDIX 5.

SHIELDING EFFECT OF EARTHED BODIES.

Earthed conductors in the neighbourhood of either the inducing or induced wires tend to shield the induced conductors from both electric and magnetic induction. Shielding is usually assumed to be of importance only in connection with electric induction. "For effective electromagnetic shielding, the shielding circuit should be of low resistance and closely coupled with either the disturbed or disturbing circuit."

Earth wires, as commonly employed for lightning protection on power lines, exert a shielding effect with respect to inductive effects from residual voltages and currents. They may increase, however, the intensity of the induction from balanced voltages and currents, by distortion of the electric and magnetic fields about the power circuit.

It is possible to calculate the amount of shielding without further assumptions, but the increase in labour involved is considerable and only isolated simple cases have been considered. A case where a single power line parallels two communication wires, one of which is earthed, has been worked out by the present investigators. These calculations, which are filed with the original digests (cf. the *résumé*), show that the reduction depends for a given communication wire only upon the proximity of the earthed wire to the communication wire. In the example considered the reduction factor, i.e. the amount by which the induced voltage is reduced, is 44 per cent.

The shielding effect of earth wires of three-phase power lines was considered in Technical Report No. 68 of the Californian Commission.

CALCULATED RESULTS.

Calculations were made for two relatively simple cases, using the methods explained in Appendix 2 when shielding effects were not considered.

The cases were chosen in order to simplify calculations as far as possible.

Table 1 to this Appendix gives the values with the earth wires present as a percentage of the values which would exist were the earth wires not present. This table is of use in indicating that the shielding effect of earth wires cannot be stated simply as a definite percentage. The shielding effect varies with types of induction, separation and other factors.

TABLE 1.

Effect of Earth Wires on Induction from 3-Phase Power Circuits.

Induction with earth wires as percentage of induction without earth wires.

Configuration	Characteristic residual voltage	Horizontal separation, ft.	Induction				
			Balanced voltages	Residual voltage	Balanced voltages and characteristic residual voltage	Balanced currents	Residual currents
o	120	30	102	86·0	104	84·0 124*	95·9
o o o		600	50·1	78·2	33·9	18·4 161*	95·9
o o	35·6	65	82·4	75·6	82·6	91·4 120*	94·1
o o o		1 040	223	70·1	392	74·4 141*	94·1

* Magnitude depends on phase rotation of balanced currents. The smaller value occurs when current in conductor nearest communication circuit leads current in intermediate conductor by 120°.

† Sum of voltages to earth of energized conductors only.

TEST RESULTS OBTAINED BY THE CALIFORNIAN RAILROAD COMMISSION INVESTIGATION.

A number of tests were carried out by the Californian Commission in the course of which the effects of shielding were observed.

In its Technical Report No. 54 an account of tests to determine the coefficients of longitudinal induction at 50 cycles is given. From measurements on induction due to residual voltages, earthing one of the telephone conductors of a telephone circuit supported on the power-line poles reduced the voltage induced in the other by 33 per cent, when all three power conductors were energized. If one power conductor is earthed, reduction amounts to 17 per cent; if two are earthed the value is 33 per cent. In the case of induction due to residual currents, the corresponding figures are 2 per cent, 28 per cent and 41 per cent. The larger values denoted by the latter two figures are due to the relatively low resistance of the power conductors compared with the smaller iron telephone conductors.

From Technical Report No. 56, in which coefficients of induction were determined over a short length of the parallel concerned in the tests in Technical Report No. 54, further figures are available. For induction due to residual voltages, Table 2 gives the shielding effect when the two idle power conductors are earthed. The effect on the transverse induction is seen to be small but increases to 19 to 38 per cent for longitudinal induction.

COMPARISON BETWEEN TEST AND CALCULATED FIGURES.

In the same report calculations were made in order to compare test and calculated figures. For the special cases of residual voltage and residual current with a single conductor of the power circuit energized, the shielding effects of earthing the idle power conductors were calculated. Tables 3 and 4 give the results obtained. Table 5 compares the shielding, measured and calculated for the case of induction from residual voltage, one power conductor being energized and the other two earthed. The calculated values for transverse induction take into account the capacitance out-of-balance of the telephone circuit.

OTHER PUBLISHED RESULTS.

Tests made on the Lancaster–Heysham section of the Midland Railway (21) showed a reduction of 15 per cent due to the shielding action of an earthed wire mid-way between the inducing and the induced circuits, combined with that of earthed telegraphs on the same poles as the circuit under test. The separation was of the order of 12 ft.

Tests on the Lake Coleridge (New Zealand) Transmission System (24) showed reduction factors varying from 55 per cent to 25 per cent due to the remaining five of a group of six communication conductors being earthed. The distance from the power line was about 26 ft.

The above tests only concern electric induction.

The opportunity of tests on induction between a h.t. system and German Imperial Telegraph and Telephone Lines (119) led Brauns to draw certain conclusions regarding the shielding effects of earthed wires. For a vertical configuration and separation varying from 7 to 10 metres he suggests a reduction factor varying from 30 to 60 per cent according to the position of the earthed wires.

In a later article (95) Brauns considered the shielding effect of neighbouring rows of trees by replacing them by an equivalent earthed conductor, the size of which is apparently arbitrarily chosen. The reduction factors so calculated vary from 80 per cent to 25 per cent depending on the position of the trees relative to the lines concerned. No test data is available in this connection.

Jäger in a more recent general article (88) apparently has summed up this question by stating that earthed objects, which include rows of trees and earthed wires, near either power or communication lines exert 25 per cent to 30 per cent protection on the electric induction. An earthed wire screen is stated to reduce the charging current in the protected wires to about one-third, i.e. a reduction factor of 33 per cent.

APPENDIX 6.

REMEDIES APPLICABLE TO TELEGRAPH CIRCUITS.

The information given in this Appendix is taken from a very comprehensive discussion by Devaux-Charbonnel (36) except where otherwise stated. The classification adopted for the various remedies is that given by Leboucher and Villeneuve (61).

APPARATUS FOR REDUCTION OF THE INDUCED CURRENT.

Increase of circuit impedance.—By the insertion of inductance in series with the apparatus, the disturbing a.c. is reduced. The value of the inductance is limited by the permissible time-constant of the apparatus—an important factor since it determines the limit of transmission speed.

Proceeding from the statement that the disturbing current should not exceed 20 per cent of the working current, it is shown that, for a maximum speed of 15 signals per second (say 70 words per minute), the maximum permissible value of an induced voltage at a frequency of $16\frac{2}{3}$ cycles per second is 60 per cent of the working d.c. voltage. For higher frequencies the permissible limit is increased.

Arrangements comprising an inductance placed at each end of the line, termed the Carat method, were in service over a year on lines paralleling the Midi Railway (then a single-phase system) and worked perfectly if the induced voltage did not exceed 100 volts.

Increase in impedance of apparatus due to eddy currents.—It had been suggested that by placing metal in the magnetic field the effective resistance of the apparatus to a.c. would be increased due to eddy currents. Drouet placed a copper ring for this purpose on a relay-type sounder. The relay has functioned correctly with 20 mA working current, when the disturbing current is 8 mA at a $16\frac{2}{3}$-cycle frequency and 12 mA at a 25-cycle frequency. The apparatus has the disadvantage that it is of a special type.

Insertion of a series rejector.—Latour and Bethenod suggested the insertion of a parallel resonant circuit in series on the line and tuned to the disturbing frequency so as to form a rejector for that frequency. This arrangement suffers from the disadvantage that resistance is inserted in the circuit. Leboucher and Villeneuve (61) state that Latour used this rejector in conjunction with a resonant shunt placed across the receiving apparatus, and with both circuits tuned to a frequency of $16\frac{2}{3}$ the arrangement was satisfactory with induced voltages up to 300.

APPARATUS SHUNTING THE INDUCED CURRENT.

Resonant shunt.—Latour's apparatus employs a resonant shunt connected between the line side of the receiving apparatus and earth. The usefulness of this arrangement is shown to be greatly increased by the insertion of series impedances on the line side and on the apparatus side of the connection to the shunt. Leboucher and Villeneuve mention a similar arrangement which was in service for 18 months on a line paralleling the Midi Railway. The method was found to be efficacious up to certain values of induction for high-speed telegraphs. Tests at Tarbes showed that Hughes' apparatus was working with an induced voltage of 100.

Bartholomew (32) states the greatest success has been achieved with resonant shunts and shows the connections for simplex and duplex circuits in this country, where apparently series impedances are not used in conjunction with the shunts. The design of the shunt is limited in both directions since a high capacity will seriously affect signals on certain types of circuits which are worked by condenser impulses, while a high inductance makes the shunt less effective due to its associated resistance. With automatic working it is pointed out that the protection afforded by the shunt fails when the speed of working (Wheatstone automatic being cited) results in alternations approaching the resonant frequency of the shunt or multiples thereof. In an actual case of a circuit fitted with a shunt, a disturbing pressure of 22 volts caused interference when working on a 50-volt battery. The figure corresponding to this case, as calculated from formulæ derived by Devaux-Charbonnel on certain assumptions, is of the order of 30 volts for the maximum permissible disturbing voltage. With series impedances in conjunction with the shunt and a battery voltage of 150 volts, the limit is given as 500 volts.

Bridge connections.—Brouquier has proposed a bridge connection with the receiving apparatus connected across two arms so that no disturbing current of the frequency for which the bridge is balanced passes through the receiver. This type of protection does not appear to have been developed.

APPARATUS COMPENSATING THE EFFECT OF THE INDUCED CURRENT.

Girousse apparatus.—This method involves the use of a relay with two equal windings differentially connected. One winding of the relay is connected to the line through an inductance and capacity in series arranged to be resonant at the frequency of the disturbing voltage; the other is connected to the line through a resistance equal to the equivalent resistance of the resonant part of the first path. The disturbing current then divides equally between the two windings and its effect is neutralized.

The relay works well if the disturbing current does not exceed 80 mA. Since the circuit impedance with apparatus in circuit is 2 500–3 000 ohms, this apparatus is useful for induced voltages up to 200–250 volts. It is stated to work well in certain departments of France, but was not maintained in the Midi region, partly because of the complication introduced.

The Latour apparatus, considered above, was preferred by the Midi Company. Leboucher and Villeneuve (engineers of the Midi Railway) state, however, that beyond about 150 volts protection is not given. Condenser discharges tend to distort signals. Girousse (56) states that this apparatus has given good results on lines paralleling the 10-kV Haute-Vienna and the 6·6-kV Maritime Alps tramways and the Pyrenées–Orientales Railway. Voisenat (51) deals with the disadvantages of this method.

Apparatus involving the use of a transformer.—The method involving the addition of a transformer, by means of which a current is induced in the receiver in opposition to the disturbing current in the line, is due in its simplest form to Delcamp, and has been modified by Brouquier. Tests have proved satisfactory but the apparatus is of a special type and the method has not been used. Arrangements using transformers have been proposed by Lavallée and Hébécourt, but are not of interest.

METHODS BASED ON MECHANICAL MODIFICATION OF RELAYS.

These methods have the disadvantages that special apparatus is required and they have not been adopted on this account. In addition, as Leboucher and Villeneuve point out, for a particular modification, such devices do not discharge the line (presumably in comparison with previous methods, considering magnetic induction). These modifications are therefore not described.

Effect of frequency variation.—Methods involving the use of resonance devices are most severely affected. In the case of the Girousse apparatus, a frequency variation of the fundamental to the extent of 1 cycle in $16\frac{2}{3}$ allowed 5 per cent of the disturbing current to pass in the particular case calculated. Hence with a permissible limit of 4 mA disturbing current through the relay the permissible induced voltage is approximately 170 volts.

The Latour apparatus using a resonant shunt is affected more since the effective resistance is small. With the same frequency variation, the permissible disturbing voltage is reduced to an amount of the order of one-third of the permissible value at resonance.

In the case of the method employing a series rejector the increase in impedance is of the order of 7 per cent with the above frequency variation and a time-constant of approximately 0·03, so that its effectiveness is not much impaired.

APPARATUS TO TRANSMIT AT A HIGHER VOLTAGE THAN THE INDUCED VOLTAGE.

Leblanc proposed an arrangement in which the signal impulses were transferred to the line by a 10/1 step-up transformer, and a special modified Baudot relay was used as the receiving apparatus. Results were satisfactory, but trouble was found due to static charges, since the impedance to earth of the apparatus was high (of the order of 100 000 ohms), while, due to the high voltage, leakage effects trouble the transmission.

APPARATUS TO TRANSMIT AT A HIGHER FREQUENCY THAN THE INDUCED FREQUENCY.

Magunna evolved a method in which a vibrating tuning fork produces vibrations at a frequency of 500 which are employed for signalling, a receiver being used which only responds to this frequency, according to Leboucher and Villeneuve. Results obtained are good, according to Devaux-Charbonnel, while up to 12 channels of communication are possible over one wire. The only disadvantage appears to be the necessity of altering existing apparatus and the method has not been applied. Leboucher and Villeneuve only state, however, that the apparatus is too complicated for small telegraph offices.

APPARATUS TO TRANSMIT A.C.

Leboucher and Villeneuve refer to tests made in 1914 by Gratzmüller in which a.c. was permanently transmitted, signals being sent by interrupting the a.c.

More definite information regarding transmission by a.c. is given in an article (115) in which a system, which has been in use on the Italian State Railways, is described. Spinelli-triplicators were used to supply the a.c. at a frequency of 126 or 150 which is relatively high compared with the traction fundamental frequency. Special receiving circuits were used. Tests made in service showed that communication was not affected on a line on which the induced voltage was more than 100 volts with maxima up to 250 volts, while on a normal circuit the relay armature vibrated continually.

The transmission voltage was 110 volts.

The conclusions drawn regarding this method are:—

(1) Ordinary working with normal apparatus is possible.
(2) Induction by the a.c. on other telegraph circuits has no influence on the working of Morse apparatus.
(3) Induction on metallic telephone circuits is, in the cases observed, of the same order as that produced by other telegraph circuits when a coil-type generator is used; it is quite insensible when a smooth wave is used.

The system might also be applied to high-speed apparatus such as the Hughes apparatus by employing suitable transmission frequencies.

This system has, apparently, been adopted for lines alongside railway routes which are being electrified.

APPENDIX 7.

REMEDIES APPLICABLE TO TELEPHONE CIRCUITS.

INTERFERENCE DUE TO TRANSIENT CONDITIONS ON THE POWER LINE.

Induction from short-circuits on the power line is apt to cause acoustic shock through the non-simultaneous operation of the over-voltage protectors connected to the telephone lines. Jäger (88), in an extensive summary of investigations carried out by the German Telegraph Administration and published in 1924, states that although attempts have been made to produce a protective device which will give simultaneous operation, e.g. the vacuum-tube protector with three electrodes, presumably one connected to each line and one earthed, a successful device has not been constructed. A British Patent Specification (99), taken out in 1922, describes an improved form of protective device which, it is claimed, considerably reduces the acoustic disturbance. If similar results to those claimed in the Specification have been obtained commercially, the protector will go a long way towards solving the problem of eliminating acoustic shock from transient conditions on the power line.

Apparatus shunting receiver.—The German Telegraph Administration has made extensive experiments with "rare gas" devices connected across the receiver to avoid noises, according to Jäger (88). A device consisting of a "cartridge" (presumably a tube) filled with argon at a pressure of 5 mm and provided with basket-formed electrodes containing potassium mixture meets the case if placed in parallel with the receiver. This "shunt" protector operates on the average at 150 volts. Operation is satisfactory when induction is due to transient conditions, but when acoustic shocks are due to normal induction this protector is no use. The protector continues acting and produces a crackling noise in the receiver.

Jäger also mentions that the most satisfactory devices are of the coherer type although they are not always reliable. These devices are shunted across the receiver similarly to the "rare gas" protector and operate with quite low voltages. This can easily be a disadvantage as they cannot be maintained permanently on the line, for they would short-circuit speech currents.

The same article states that experiments have been made to reduce acoustic shock by adopting a different receiver construction.

Jäger also points out that acoustic shocks could not originate if over-voltage protectors could be dispensed with, assuming perfect insulation so that a breakdown would not occur. He foresees that in the future German cable system there will be no over-voltage protection, and mentions a figure of 2 000 volts which the cable and telephone transformers should withstand. In the proposed French Rules (102) it is laid down that "if underground lines terminate on transformers and arresters between wires and earth are absent, the maximum values expressing danger in case of short-circuit are considered to be the breakdown voltage between cable conductors and sheath, between transformer windings and between transformer windings and their metallic covering."

REDUCTION OF EFFECTS DUE TO LONGITUDINAL INDUCTION.

Insulating transformers.—The use of insulating or telephone transformers in separating sections of a circuit with different degrees of unbalance has been mentioned in Section 6.

Drainage coils.—A drainage coil consists of a high-impedance coil connected across the conductors of the telephone circuit and earthed at its mid-point. The halves of the winding are so connected that the impedance to currents flowing from wires to earth is small, being the resistance of the coils only if the coil is perfectly balanced; at the same time the impedance between the telephone conductors is high. The use of such coils was mentioned by Schrottke (35), who pointed out that by connecting a regulating resistance across the halves of the coil, so arranged that the coil could be earthed at any point along the resistance, it would be possible to neutralize any unbalance in the telephone line due, say, to insulation faults. As Stein (*E.T.Z.*, 1912, pp. 844–847), however, shows, this regulating resistance is useless for this purpose, since the earth current through the coil due to electric induction is only slightly affected by the value of the earthing resistance. In addition, the unbalance may vary due to a sudden change in line resistance due to bad joints.

Jäger (118) mentions the results of connecting discharge coils to communication circuits. The most satisfactory results were obtained with coils with a low resistance of 22 ohms per winding which were applied to telephone lines carried on power-line poles. Coils with windings each having a resistance of 200 and 1 100 ohms were correspondingly less satisfactory. From measurements made of the impedances of the windings of these coils, differences of the order of 1 to 2 per cent were found between windings of the same coil.

Jäger points out that if the windings of a coil are unbalanced, a portion of the current to earth will flow round the apparatus. The unbalance of the telephone circuit also needs to be taken into account. Telephone lines carried on power-line poles have a fairly well-balanced insulation, as they are far from trees and are often insulated with h.t. insulators. In comparison, an unbalance of 5 to 10 per cent must be looked upon as an average figure, according to Jäger, for public service circuits in Germany. This figure takes into account all electrical constants, including the mutual unbalance with respect to the power line. It is then shown that the effect of connecting a discharge coil to a telephone circuit may result in a charging current through the receiver due to the circuit unbalance. Similarly, it is shown that when two discharge coils are connected to a circuit, unbalance currents will flow through the receivers due to magnetic induction.

In conclusion it is stated that discharge coils can, therefore, only be used for the purposes of the R.T.V. (German Imperial Telegraph Administration) in exceptional cases and should by no means be looked upon as sufficient protection for strongly influenced lines.

Kellogg (52) mentions that drainage coils practically eliminate noise from longitudinal induction due to insulation leakage, but sometimes increase the trouble due to defective joints. Increased susceptibility to noise from irregularities in the series impedances of a circuit is also pointed out by Warren (59). Telephone transmission efficiency is impaired also. Warren remarks that these coils are helpful for reducing electrostatic effects on power companies' lines carried near h.t. lines, but they have not proved to be adapted for general use on commercial systems. Leboucher and Villeneuve (61) confirm that attempts to allow for unbalance of the circuit by varying the relative number of turns in the windings of the coil were unsuccessful.

So far the use of discharge coils on public telephone lines in this country has not been found to be necessary.

It is shown from the above that discharge coils are not a general remedy for public service lines, but they may be used with good effect on strongly induced lines, such as private lines carried on power-line poles. Successful application is reported by Bennett (4) and Gillespie (104).

Latour system of transmission.—Costabel (84) gives an account of experience with this system in which the telephone current is amplified at the sending end and reduced at the receiving end. Disturbing effects are, therefore, reduced at the same time. Several circuit arrangements are given employing ordinary valve amplifiers.

Tests carried out on the Midi Railway showed that these arrangements overcome disturbances due to single-phase traction lines without a return feeder. The conclusion is drawn that this system is for circuits carried on power-line poles.

Bartholomew (32) points out that this system would be satisfactory on single-circuit routes, " but overhearing would occur on lines carrying two or more circuits owing to the greater power used."

Use of cabled circuits.—The consequence of earthing the lead sheath is to bring into play a compensating effect which reduces to some extent the longitudinal induced voltage. A number of writers have considered this effect in particular connection with induction due to single-phase railways. Amongst these are Kühle (6), Krause and Zastrow (116), Zastrow (80) and Jäger (88). It will be clear that short-circuit conditions on earthed power systems will produce similar effects to those present with single-phase traction systems. The vector diagram shown in Fig. 15 has been re-drawn from a similar diagram given by Jäger in order to cover both cases. Since the lead sheath is earthed at various points a sheath current flows due to the longitudinal voltage induced therein, and a partially compensating e.m.f. is induced in the cable conductor.

FIG. 15.

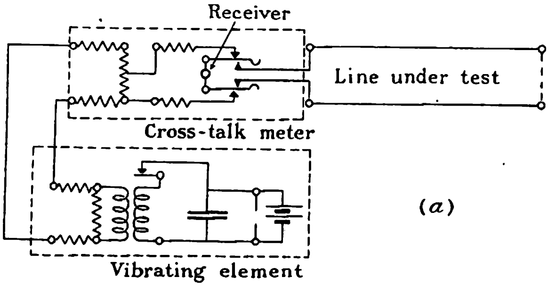
APPENDIX 8.

NOISE MEASUREMENTS.

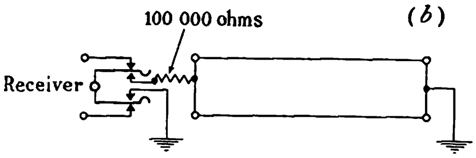
In interference problems, the deciding test as regards disturbance to telephonic transmission is the amount of noise produced in the subscriber's receiver.

The 1-*A* noise-measuring set has been developed in U.S.A. so that the noise on any circuit can be directly measured in terms of an arbitrary noise unit. A description of this apparatus is given in a paper by Erikson and Mack (*Journal I.E.E.*, vol. 62, 1924, pp. 653–687). The circuit of the noise-measuring set is given in Fig. 16. It is a portable instrument including a standardized vibrating element or noise standard generating a noise of comparatively low fundamental tone very rich in harmonics. The receiver is connected alternately to the circuit under test and to the standard and the potentiometer setting is adjusted until the noise in the receiver is judged to be the same in both cases as regards disturbance to conversation.

The noise-measuring circuit used in connection with the Californian Commission investigation has been superseded by the 1-*A* noise-measuring set.



(*a*) Measurement of line noise.



(*b*) Measurement of earth noise.

FIG. 16.—Circuit of noise-measuring set.

The 2-*A* noise-analysing set is another U.S.A. development which is used for determining the frequencies of the different tones in a noise. In conjunction with the 1-*A* noise-measuring set it may be used for obtaining an approximate estimate of the relative magnitudes of these tones. The circuit of the noise-analysing set consists of a resonant circuit with a receiver in series, which can be caused to resonate at any frequency between 150 and 2 500 cycles per second by varying the value of the condensers. Whenever resonance points occur the corresponding frequency can be read from a calibration chart.

It is stated in this paper that " the effect upon transmission efficiency of various amounts of noise has been closely studied, so that an estimate can now be made of the reduction in intelligibility in any given case due to the presence of a given amount of noise."

A flicker-type noise meter in which the unknown noise is balanced against a known sound from a current of definite frequency has been tried by the Post Office (32) but has been found unsatisfactory.

Another method, which was also being investigated, consists of amplifying the noise so that the current in the circuit can be measured and by means of a potentiometer comparison made between the amplified and line currents; thus the line noise can be expressed as a voltage. Filters are necessary to cut out frequencies outside the audible range to ensure that the current measured includes only that producing noise.

The vibrating element type has been widely employed in America and Europe, and is specified for use in the French Rules.

APPENDIX 9.

EFFECT OF PHASE-CHANGE AND ATTENUATION.

The effect of phase-change and attenuation has been discussed in Technical Report No. 66 of the Californian Investigation.

Considering a uniform exposure of a telephone conductor to a three-phase power circuit forming one

C = " Continuous " type barrels.
H = " Halting " type barrels.
H–R = " Halting-reversing " type barrels.

complete barrel, there are equal exposures of the three different phase arrangements. If it is assumed that no phase-change or attenuation occurs in the balanced voltages and currents along the power circuit, these components induce waves in the telephone conductor which are 120° apart in phase and at points one-third of the length of the barrel apart. These three waves would be at every point and the resultant would be zero if the waves travelled along the telephone conductor at an infinite speed. Since in the time for the waves to travel to a particular point a change of time-phase occurs, then considering a point at one end of the parallel the waves from points in the middle and further section one-third of the barrel length apart arrive there $120° + \phi$ and $240° + 2\phi$ out of phase with the wave from the first section. The change in time-phase ϕ is that occurring while a wave travels along one-third of the barrel length. It is shown in the above-mentioned report that the unbalance U is given approximately by

$$\frac{2\pi f L^2}{9V}\left[1 + 2/\underline{120 \pm \tfrac{1}{2}\phi}\right]$$

When ϕ is small, it is evident that the unbalance varies directly as the frequency, as the square of the length L of the barrel, and inversely as the wave-speed V. The alternative sign allows for the two possibilities, namely, whether the power transpositions cause a lead or a lag of 120°, depending on the point in the parallel considered.

It is shown from a consideration of a 6-mile barrel at 1 000 cycles that the effect of attenuation can be neglected for the range of frequencies and distances met with in practice, and that the approximate formula shown above is sufficiently accurate for all ordinary purposes. " For the rather extreme case of a 24-mile barrel at 1 500 cycles " this " equation indicates an unbalance of 6·5 miles which is about 6 per cent too high."

" The speed of propagation is generally from 170 000 to 180 000 miles per second in power circuits and in non-loaded metallic telephone circuits," open-wire circuits being considered.

Considering the phase-change of the waves also present in the power circuit, the effect on the unbalanced exposure may be either additive or subtractive with respect to the effect of the phase-change occurring in the telephone circuit, depending on the position chosen on the telephone line. Therefore, at one end of the telephone line the total effect of phase-change is zero assuming the same wave-speed in both circuits, while at the other end the total effect would be double that which would occur were there no phase-change along the power line.

Hence if the phase-change along the telephone circuit is alone considered, the average effect is obtained, although the worst effect will be roughly double this value.

Reflection of waves from the communication circuit is not considered in the above discussion.

In Technical Report No. 68 are shown some curves giving the unbalances for various frequencies and lengths of barrel. The curves show that unbalances of 0·1 mile occur as follows:—

Frequency, cycles per second	Length of barrel, miles
300	6·1
900	3·6
1 500	2·8

Owing to the large unbalance with long barrels it becomes necessary to use more than one barrel in long uniform parallels.

As mentioned in Section 7 of the *résumé*, where more than one barrel is necessary, three different arrangements may be used having barrels of equal length. Table 1 to this Appendix shows the unbalance for each of these three types of transposition in a 24-mile parallel when the frequency is 1 000 cycles per second.

The advantage of both types of halting barrels over continuous barrels is clearly shown. With " continuous " barrelling the unbalances of successive barrels add nearly in phase, while with " halting " and " halting-reversing " barrelling the unbalances nearly balance each other every three barrels and two barrels respectively.

Such arrangements enable the unbalances to be reduced " to a point beyond which it is probable that minor irregularities will control the result."

APPENDIX 10.

METHOD OF CALCULATION OF LENGTHS OF UNBALANCED EXPOSURE.

Since the method of obtaining the amounts of unbalanced exposures in an actual parallel is practically unknown to power engineers, the details of the procedure necessary for the calculation are given here as outlined in Appendix 1, Technical Report No. 66 of the Californian Investigation. The example considered is taken from this Appendix and involves telephone circuits transposed on the cross-over system. A diagram of the telephone transpositions showing the exposures of each circuit for a complete transposition section is required. In order to distinguish between the two possible positions of each circuit relative to the power circuit, the terms positive and negative exposures are used. Diagram 1 in Fig. 17 shows this diagram for the example to be considered. Another diagram, termed the " Transposition Distance Chart," is necessary, on which is shown the actual distances between successive telephone transposition poles and the distances from the nearest telephone transposition poles to all power transpositions and points of discontinuity. Diagram 2 on the same Fig. 17 shows such a chart for the example chosen. The parallel may be divided into a number of zones or uniform parallels and the unbalance exposure determined for each circuit in each zone or uniform parallel.

The three different phases of induction from a transposed three-phase circuit of uniform construction are termed A, B and C. B is assumed to lag by 120° behind A, and C to lead A by 120°. Transverse induction is positive or negative, depending on the position in the telephone transposition section.

The sample record sheet given below shows the type of form used, with figures entered for circuit 7–8, zone 2 being considered. The distances correspond to + *A* − *A*, + *B*, etc.; exposures are set down as shown and totalled. The sum of the positive *A* total and negative *A* total gives the longitudinal *A* exposure, while the difference of these totals gives the transverse unbalances. The *B* and *C* figures are treated in the same way. The transverse residual unbalance is given by the algebraic sum of the *A*, *B* and *C* transverse unbalances. The transverse and longitudinal unbalances to balanced components of currents and voltages are then obtained

− 790	A	12 510
− 420	$-\frac{1}{2}(B + C)$	− 14 330
− 1 210	$x = A - \frac{1}{2}(B + C)$	− 1 820
+ 15 220	$B - C$	+ 8 240
+ 13 180	$y = 0{\cdot}866(B - C)$	+ 7 140
13 240	$U = (x^2 + y^2)^{\frac{1}{2}}$	7 360

by adding vectorially the three transverse and longitudinal unbalances.

In order to combine the unbalance exposures in several zones, the relative magnitude of the induction per unit length and the phase difference must be calculated for each zone.

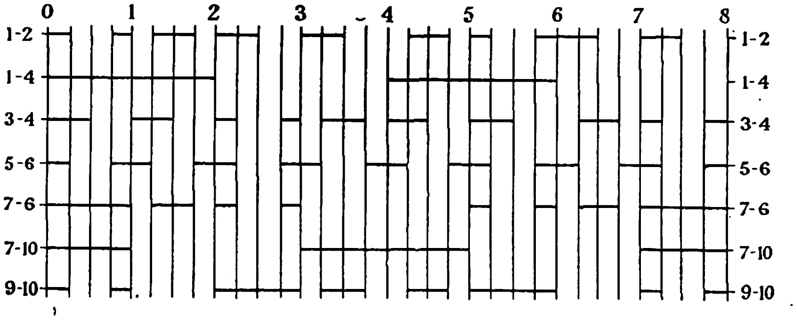

Diagram 1.—Telephone transposition diagram.

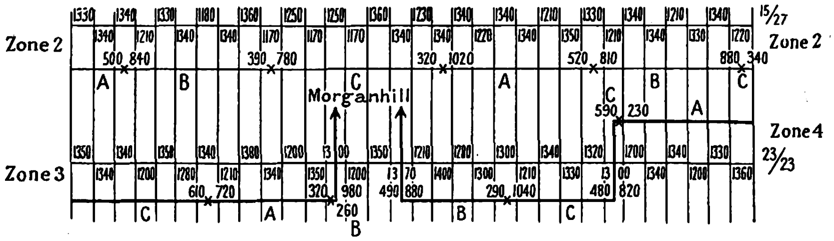

Diagram 2.—Transposition-distance chart. San Jose-Gilroy parallel.

FIG. 17.

For the example considered it is seen that the residual transverse unbalanced exposure is + 50 ft. while the balanced transverse and balanced longitudinal unbalanced exposures are 13 240 ft. and 7 360 ft. respectively, the length of the zone being 41 170 ft. (approximately 8 miles).

APPENDIX 11.

TELEPHONE TRANSPOSITION SCHEMES.

This Appendix gives a more complete description than is contained in the *résumé* of the special methods developed by the American Telephone and Telegraph Co. of transposing telephone lines exposed to induction from other circuits.

An outline of the methods of design involved is given by H. S. Osborne (78). A systematic consideration of all possible arrangements was necessary to obtain the maximum economy and efficiency.

THE "E" SECTION.

An endeavour was made to develop a new section having a nominal length of 8 miles (actually 8 miles or less), which should give balance within short lengths for all circuits for induction from balanced and residual components, and should properly co-ordinate with power barrels of several lengths.

"Investigation of $\frac{1}{2}$, $\frac{3}{4}$, 1, $1\frac{1}{2}$, 2, 3, 4 and 6-mile continuous barrels in relation to the 64 fundamental types of telephone transpositions indicated that economical telephone transposition systems could not be developed to co-ordinate with barrels other than those $\frac{1}{2}$, 3 and 6 miles in length."

Other variations of power barrels were also considered.

"The system evolved has the following characteristics:—

"Balance to non-transposed foreign circuits in each mile; balance to three-phase power circuits transposed for $\frac{1}{2}$ and 3-mile barrels (and to barrels the length of which is any multiple of 3 miles) in each mile." "The system of $\frac{1}{2}$-mile barrels, halting at mile points only, having five transpositions (with the same direction of rotation) between mile points, was chosen on account of the greater economy found to obtain therewith." From information given in Osborne's paper mentioned above, continuous barrels can be used for the 3-mile barrels.

For 4-cross-arm, 40-wire lines, 32 transposition poles per 8-mile section are required when physical circuits are alone present. When phantom circuits are present 64 transposition poles are required. Drawings showing the system of transpositions for these two cases are given in Technical Report No. 66. For further cross-arms, 64 transposition poles are required for physical circuits and the most commonly occurring phantom circuits.

The E section can be used for line lengths shorter than 8 miles, but below 4 miles it is more economical to use the L transposition section.

THE " L " SECTION.

This section was designed on the same general principles as the E section, but is arranged for a section length of 4 miles or less. This section has the following characteristics:—

Balance to non-transposed circuits in each mile.
Balance to three-phase power circuits transposed for 3-mile barrels.

" It is frequently possible to include points of discontinuity within sections by so placing the telephone transposition sections that the discontinuities occur at mile-points, which are neutral points with respect to external sources of induction." This statement applies to both E and L sections.

" It is desirable to use these transposition sections wherever possible in parallels on account of the combination of good cross-talk balance, frequent balance to foreign circuits and provision for co-ordination with power transpositions, and they are the normal means to be used where uniformity and length of parallel justify."

CONSECUTIVE " X " SECTIONS.

" Where parallels contain numerous points of discontinuity separated by short distances, and where short lengths intervene between ends of longer sections and points of discontinuity, consecutive X sections are very convenient."

An X section comprises a section $\frac{1}{2}$ mile or less in length containing three transposition poles at its quarter points. "The use of X sections in parallels often involves the use of several in succession, each X section having transpositions added so as to secure balance within itself to non-transposed parallel foreign circuits." " Junction points of sections are placed opposite power transpositions and points of discontinuity. It is not necessary, though desirable, that successive sections be of the same length." " Consecutive X sections are decidedly inferior to the E and L sections on account of the relatively poor cross-talk balance and the greater cost for a given length."

" WHOLE-LINE " TRANSPOSITIONS.

When physical circuits only are concerned, the cross-talk balance of the existing telephone transposition system is not disturbed by inserting transpositions in all the circuits at any point, that is, transposing the " whole-line." " It is thus possible in such cases to place extra transpositions wherever required to balance the exposures to power circuits."

This method may be employed in some cases, where phantom circuits are present on the telephone line, without increasing the cross-talk to excessive values.

" The best use of this method is obtained in very short parallels or in short portions of long parallels where it is inconvenient to use the exposed line sections and where otherwise a long section of line outside the parallel would have to be transposed.

" The method is a very simple and economical solution of the problem of co-ordination of transpositions, where it is applicable."

PRACTICAL APPLICATIONS.

In order to appreciate fully the foregoing information it is necessary to consider an actual parallel and work out a co-ordinated scheme of transpositions.

In actual cases " the length and character of transposition sections and barrels is usually determined by the location of the points of discontinuity." In a long uniform parallel, the length of power transpositions required to obtain adequate balance is limited by the unbalance arising due to phase-change.

Where there are several power barrels in succession, it is better to use barrels of either of the two " halting " types. Where the number of barrels is a multiple of three, " halting " type barrels should be used; and where the number is a multiple of two, " halting-reversing " type barrels are better.

It is considered in Technical Report No. 66 of the Californian Investigation that 3-mile barrels in a long parallel may be expected to give a degree of unbalance such that configuration irregularities will control the unbalances. " For large separations, usually giving small coefficients of induction and with good wave-form, 6-mile barrels should be sufficiently effective."

Griswold and Mastick (71) state that 6-mile barrels have been found satisfactory in some cases in practice. They consider that 3-mile barrels give a satisfactory solution, except under severe exposure conditions.

Both opinions date from 1916–1917.

APPENDIX 12.

MEASUREMENT OF HARMONICS.

Whenever interference problems arise, knowledge of the harmonics present is, in general, required. The desired extent and accuracy of this information will depend on the type of problem. When it is necessary to locate the origin of harmonics causing interference, exact measurements of the magnitudes of the harmonics will not be required so much as the determination of their frequencies. When the harmonic is traced to the apparatus producing it, a quantitative measurement is necessary to determine whether the magnitude of the harmonic is normal or excessive and, in consequence thereof, where to apply the remedy. Again, when it is necessary to test new apparatus in order to decide whether interference might arise when such is placed in service, it is probably desirable to measure the total effect of all the harmonics present. There is, therefore, a need for apparatus, which will give and give alone the particular information required.

OSCILLOGRAPH.

Where the fundamental is small and the harmonics are prominent, as is usually the case for oscillograms of residual voltages and currents, it is possible to make an accurate determination of the values of the harmonics. Where the fundamental is proportionally large, as in the case of line voltages and currents:

(i) The harmonics may be magnified,
(ii) The fundamental may be neutralized or otherwise suppressed, leaving as a residue the harmonics only.

Under method (i) a condenser may be used in series with the vibrator and will produce magnification in proportion approximately to the frequency of the harmonic, provided that the impedance of the remainder of the circuit is small in comparison with the impedance of the condenser. This arrangement was used, where necessary, during the Californian investigation for voltage-wave measurements. Distortion of harmonics in oscillograms of currents, particularly line currents, was obtained by the use of an inductance coil shunted across the vibrator in series with a condenser. With this arrangement a magnification greater than the square of the frequency is obtainable.

From the constants of the oscillograph circuit and the values of the harmonics obtained by analysis of the oscillogram, the magnitude of the harmonic in the circuit under test can be calculated. The circuit arrangements used in the above investigation are described in Technical Report No. 41.

Method (ii) was under consideration by the British Engineering Standards Association in 1920 and subsequently.*

RESONANCE METHODS.

These methods employ essentially a circuit comprising inductance and capacity in series which can be tuned to any particular frequency.

RESONANT SHUNT.

The method used during the Californian investigation embodied such a circuit with a low-impedance telephone receiver in series. When the shunt is tuned for the harmonic whose magnitude is to be measured, the sound in the receiver will be largely due to this harmonic. By connecting the receiver in turn to an auxiliary comparison circuit capable of supplying current of any desired frequency and adjusting its value until the same sound is heard at the particular frequency, the value of the current through the resonant shunt is obtained from the known circuit constants.

This method is useful for determining high harmonics of small amplitude for which the oscillograph is not suited. While the value of each harmonic has to be determined separately, the process is quicker than the oscillograph.

FREQUENCY ANALYSER.

An analyser has been developed in the Research Laboratories of the American Telephone and Telegraph Company and the Western Electric Company (89) in which a variable-tuned circuit is employed, the natural frequency of which may be altered continuously over the whole range. The current in the resonant circuit is amplified and recorded on a moving photographic strip. Two frequency ranges of 20–1 250 and 80–5 000 cycles respectively are provided, and it is stated that the record is delivered five minutes after the mechanism has been set in operation.

No details concerning the accuracy obtainable with this instrument are given in the description (89), but even if the error is considerable the possibility of obtaining a complete analysis in such time should be of great value.

DYNAMOMETER METHODS.

In a paper by Cockcroft, Coe, Tyacke and Miles Walker (*Journal I.E.E.*, vol. 63, 1925), a modified dynamometer method is described which has been developed in both laboratory and commercial forms, which will enable wave-forms to be analysed up to at least the 23rd harmonic with considerably greater accuracy than with the oscillograph. It is stated that it should be possible to analyse e.m.f. waves to within 2 per cent of the harmonic itself, and to detect harmonics of less than 1/1 000th of the amplitude of the fundamental, thus enabling the approximate amplitude of harmonics to be determined which are not visible on an oscillogram. A more recent modification of the dynamometer analyser in portable form is described in the *Journal of Scientific Instruments*, vol. v, No. 10, October 1928, page 320.

TELEPHONE-INTERFERENCE FACTOR METER.

The simplest method so far suggested of determining the deviation of a wave from the equivalent sine wave is by devising a network such that the current in one branch resulting from a complex voltage wave at the terminals of the network is an indication of the distortion of the voltage wave in question. The harmonics of the wave may be given a desired relative weighting by using a suitable network. Davis (11) suggested that the harmonic weighting should be proportional to the frequency by using a simple condenser as the network. The American I.E.E. Sub-Committee on Wave-Shape Standards considered the possibility of modifying the network to obtain a satisfactory standard, based on this method of measuring wave-shape, so that errors due to the impedance of the machine under test and of the measuring instrument would be negligible, and so that it would be possible to use standard condensers, coils and meters. " It was the conclusion of the Sub-Committee, based on a large amount of experimental work, that whatever form of network might be adopted it would need to be set up as a special piece of apparatus with the constants carefully specified." " It was also found necessary to use with the apparatus a highly sensitive indicating instrument, such as a vacuum thermocouple with a d.c. milliammeter or a very sensitive a.c. dynamometer milliammeter."

EXPERIMENTAL WORK.

In order to determine the detrimental effect on communication systems, experiments were carried out to determine the relative effect of harmonics of different frequencies in producing interference in telephone systems.

Two methods have been used. In each case currents of different frequencies were in turn injected into the telephone receiver of an ordinary telephone circuit.

Method 1.—Observers compared the reading of ordinary news matter over the noisy circuit and over a quiet circuit of greater length and indicated the better circuit.

Method 2.—Articulation tests were made wherein the excellence of transmission was measured by the percentage of syllables correctly understood.

---

* One of the most practical ways of using this method is that which has been proposed by Belfils (see *Révue Générale de l'Electricité* of April 3, 1926, page 523).

The results give curves as shown in Fig. 18 which represent the relative variation with frequency of the combined sensitiveness of the telephone receiver and of the human ear, the shape of curves obtained being due, to a great extent, to the resonant diaphragm of the receiver. This receiver was typical of all receivers in general use in the U.S.A.

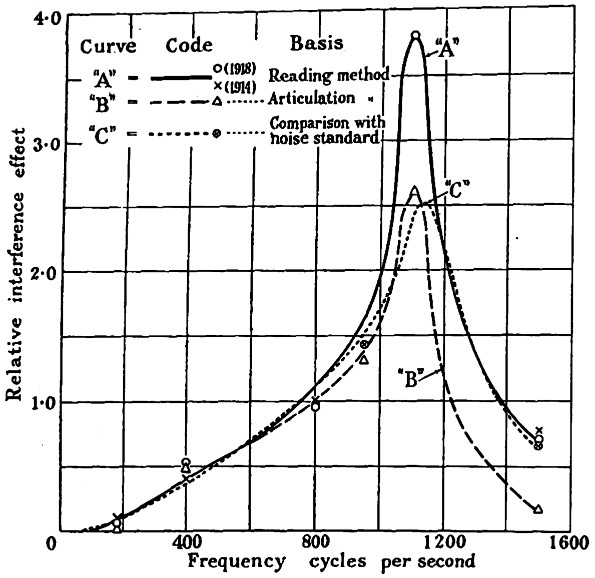

FIG. 18.—Relative interfering effect of single-frequency currents in a telephone receiver.

The difference shown by the curves of Fig. 18 between the results obtained by the two methods indicates that the factor of annoyance to the subscriber, which is not taken into account by the articulation tests, is included in the reading tests and becomes of more importance with high frequencies.

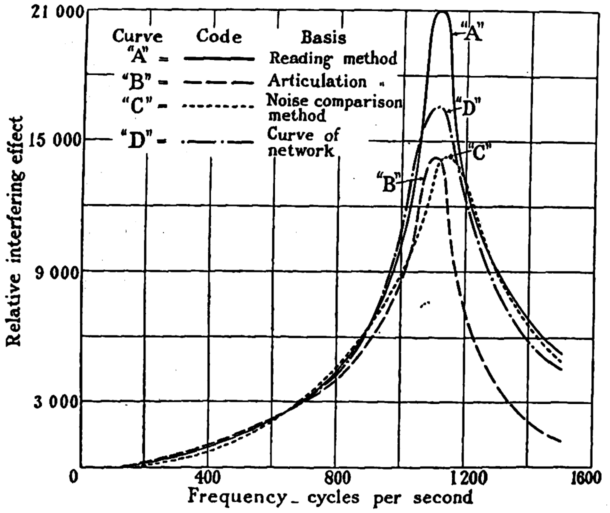

FIG. 19.—Comparison of frequency weighting curves.

These tests were carried out by the American Telephone and Telegraph Co. at different times, the first series of reading tests being made in 1914 at the request of the Californian Joint Committee.

DEVELOPMENT OF INTERFERENCE WAVE FACTOR FROM EXPERIMENTAL DATA.

The relative amount of noise caused by generator voltages and currents of different frequencies depends on additional factors to that obtained by the above experiments. The frequency weighting curve for the interference wave-factor is given in Fig. 19, and is based on the sensitivity-frequency relations and, in addition, on the fact that the current induced in telephone circuits by magnetic or electric induction is approximately proportional to the frequency. It neglects the effects of:—

(*a*) The attenuation of the current harmonics along the power and telephone circuits varying with the frequency. This effect is usually relatively small.

(*b*) Some forms of telephone apparatus acting as filters or rejectors for certain harmonics, e.g. loaded lines, do not transmit currents above about 2 500 cycles, while with some forms of apparatus low frequencies are eliminated. Usually the effect on the noise volume of these frequencies is small.

A network was developed, as shown in Fig. 20, in which the ratio of the current through one branch of the network to the voltage applied at its terminals gives an indication of the telephone interference factor of a voltage wave, corresponding to the weighting curve. The measuring instrument of the apparatus consists of a vacuum thermocouple connected to a d.c. milliammeter. When a number of harmonics are present in the voltage wave applied to the apparatus a reading is given which is proportional to the square root of the sum of the squares of the effects of the individual harmonics (root-sum-square value). Data obtained on the summation law of a number of noises of various frequencies indicate that this law varies under different extreme conditions.

"It seems probable that the root-sum-square law best represents the average condition and it is far more practicable for use than any other law because of the characteristics of measuring instruments."

				R_5 = 43 „ ±1%

FIG. 20.—Network for measurement of interference wave factor.

Fig. 21 shows the relative interference to the telephone circuit per volt of harmonic in the power circuit for harmonics of different frequency.

It has been pointed out (18) that, since the effect of increased impedance and leakance of the line at the higher frequencies is neglected in determining the interference factor, the curve in Fig. 21 will give values too large when the interference is caused through magnetic induction. This effect only affects the usefulness of the T.I.F. meter when applied to machines not yet placed in service.

Since by definition the interference factor is the ratio of the root-sum-square of the weighted values of the harmonic components to the R.M.S. value of the wave, it is necessary to multiply the values given by the T.I.F. meter for voltage and current waves by the R.M.S. value of the wave in order to determine the degree of disturbance in the telephone receiver

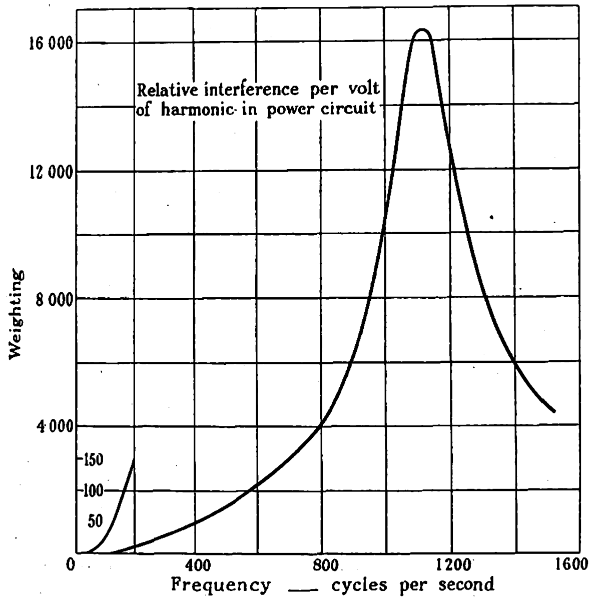

FIG. 21.—Frequency weighting curve for interference wave factor.

T.I.F. values have been obtained for a number of machines (9) and may serve as a basis for future work.

APPENDIX 13.

SOURCES OF HARMONICS.

The object of this Appendix is to present a brief general summary of the features which bear upon the production of harmonics in so far as they affect interference.

ROTATING MACHINERY.

The two groups of harmonics obtained in machines may be termed

(a) Spacing ripples or harmonics.
(b) Tooth ripples or harmonics.

SPACING HARMONICS.

Considering the special case of the smooth surface armature, the shape and content of the flux-curve is unvarying in time. With a non-sinusoidal distribution of the flux, the e.m.f. induced in a turn will, therefore, contain harmonics, the orders of which will be those present in the flux-space wave. The phase e.m.f. will be the sum of the e.m.f.'s induced in coils connected in series, modified by the distribution factor for each harmonic.

Effect of distribution factor and phase-spread.—The importance of the harmonics in the flux wave is determined by the values of the distribution factor for the various harmonics.

Table II, page 150 of the "Electromagnetic Machinery" section, Whittaker's Pocket Book (5th edition), gives values of this factor for uniformly distributed windings and various phase spreads. Fig. 474, vol. 3 of *The Dynamo*, 6th edition, shows a curve of distribution factors for uniform distribution over one-third of the pole-pitch.

Whole number of slots per pole.—With a whole number of slots g per pole, the distribution factor for the xth harmonic holds also for harmonics, the orders of which are any multiple of $2g \pm x$. Harmonics of the orders $2g \pm 1$ have the same value of distribution factor as the fundamental; similarly, harmonics of the orders $2g \pm 3$ and the third harmonic have the same distribution factor. Fig. 473, vol. 3 of *The Dynamo*, shows distribution factor curves for different numbers of slots per pole per phase for phase-spread $\sigma = \frac{1}{3}$.

For harmonics of the order $2g \pm 1$ in the flux wave, therefore, there is no reduction factor for the resulting harmonics in the phase e.m.f., and they will reappear with the same percentage value. Harmonics of the order $2g \pm 3$ reappear in the e.m.f. wave with a percentage value reduced by about one-third.

Relative importance of harmonics of the orders $2g \pm 1$ and $2g \pm 3$.—Since harmonics of the orders $2g \pm 3$ are triple harmonics, i.e. their order is an odd multiple of 3, their inductive effect is relatively more serious. They form a residual component which will appear in the line with a star-connected neutral earthed winding. On the other hand, harmonics of the orders $2g \pm 1$ do not suffer any reduction in their percentage value of the fundamental in the original flux-space curve, but their inductive effects are not normally so serious, since they form part of the balanced component of the line voltage.

Therefore, harmonics of the orders $2g \pm 3$ are specially undesirable and, in general, are most to be avoided.

Effect of coil-span factor.—While in single-layer windings the coil-span is equivalent to a full pole-pitch, in double-layer windings the coil-span may be any whole number of slots or winding spaces on the smooth armature. The phase e.m.f. is therefore modified by the coil-span factor. From the expression for the reduction factor due to the coil-pitch for the nth harmonic given on page 76, vol. 3 of *The Dynamo*, Table 1 has been worked out showing values of this factor for each harmonic for various values of coil-pitch for the case with 9 slots per pole.

C. C. Hawkins states (vol. 3, p. 51, *The Dynamo*) that the expression on which this statement is based is only strictly true for smooth armatures and is to be regarded "as a guide only when toothed armatures are in question." The values obtained upon the assumption that the flux curve is constant are, however, close to the truth until we come to harmonics of frequency connected with the presence of the teeth.

Hawkins shows (p. 77, vol. 3, *The Dynamo*) that if the coil-pitch = $2k/n$, where k is an integer, the pitch factor for the nth harmonic is zero; "on a smooth core a fractional pitch (as recommended by Prof. Comfort A. Adams, *Trans. A.I.E.E.*, vol. 28, p. 1077) of about 0·833, as given e.g. by 5 out of 6 slots or 10 out of 12 slots per pole, would, by the combined action of the coil-span and distribution factors, reduce the 5th, 7th, 17th and 19th harmonics to about one-quarter of their value in full-pitch coils. If the multiples of 3 are cared for by star-connection, the 11th and 13th are left as the most prominent harmonics."

TABLE 1.

Coil Reduction Factors for Various Values of Coil-Pitch for the Case with 9 Slots per Pole.

Coil-pitch ..	1	8/9	7/9	6/9
Order of harmonic n				
3	1	0·87	0·5	0
5	1	0·65	− 0·18	− 0·87
7	1	0·34	− 0·81	− 0·5
9	1	0	− 1·0	—
11	1	− 0·34	—	—
13	1	− 0·65	—	—

Fractional number of slots per pole per phase.—With a fractional number of slots per pole per phase in either single-layer or double-layer windings, the total reduction factors can be considered as nearly the same as for a uniformly distributed winding. When the number of slots per pole-pair $2g$ is an odd integer, harmonics of the order of multiples of $2g$ cannot appear in the phase e.m.f., due to the effect of the coil-span, when the armature is smooth, and they may be much reduced when the armature is slotted.

Effect of rotor slots.—Owing to the slotted rotor of non-salient pole turbo-generators, the distribution of flux over a pole-pitch does not follow a smooth curve. Ripples occur in the flux-density space curve, coinciding with the rotor slots, due to the spacing of the exciting winding. A second ripple due to variation of the gap reluctance also exists; but this is, in general, "negligible compared with that due to the spacing of the existing winding, since wide open slots without magnetic wedges are seldom used nowadays on the rotor."

Smith and Boulding have shown that since the amplitude of the ripple due to the concentration of the exciting winding can be assumed to fall off sinusoidally towards the centre of the pole, the spacing ripple can be replaced by two harmonics of the orders $2R \pm 1$, where R is the number of rotor slots per pole.

These harmonics will be greatly reduced in the phase e.m.f. due to the distribution factors, except when R is nearly equal to g. If $2R \pm 1 = 2g + 1$ or $2g - 1$, no diminution occurs when g represents a whole number of stator slots per pole. It should be pointed out that if one of the two harmonics is a triple harmonic, its distribution factor will be about 0·66. This may be of great importance, as already indicated.

TOOTH HARMONICS.

In connection with spacing ripples a fixed space-flux wave is assumed, but with a toothed armature such a fixed wave-shape of flux does not exist. It passes through a complete cycle of shapes as the poles move through a tooth-pitch relatively to a stationary armature or vice versa (see Fig. 487, vol. 3 of *The Dynamo*). "The e.m.f. induced in a loop is accordingly a complex phenomenon in the presence of teeth and slots."

It may be considered that two effects are present:—

(i) Due to the relative movement of the teeth under the pole the rate of change of linkages, i.e. the e.m.f. induced, in a loop fluctuates with time around the values which would occur if the armature were smooth. This effect is due to the differences in the permeances at the two ends of the pole-pitch according to the position of the teeth.

"The origin of tooth-ripples has often been assigned to 'flux-swing' upon the supposition that the weakening of the fringe at one edge of a pole and its strengthening at the other edge in the unsymmetrical positions of teeth and pole causes a corresponding amount of flux to travel backwards and forwards across the slots under the pole, cutting the conductors therein and virtually either increasing or reducing the normal rate of cutting such as would occur in an equivalent smooth armature with the same constant relative velocity of movement."

According to C. C. Hawkins, however, the growth and decay of the flux density in the teeth is to be regarded as occurring in the path along the direction of the flux without passage of any lines from the teeth across the slots; the phenomenon would not, therefore, appear to be so correctly explained by ascribing it to flux oscillating backwards and forwards in the above manner.

It is shown that the loop e.m.f. may have a crest of a ripple at its centre or a hollow, or any intermediate figure depending on the width of the interpolar gap; "but it must not be supposed that one will necessarily pass gradually into the other by gradual shortening of the polar width, although it is the case that as the curve of the flux per tooth-pitch becomes more rounded or sinusoidal, the less the amplitude of the tooth-ripple."

"The exact shape is dependent on *all* the circumstances, including the maximum density and reluctance of the teeth under the pole as compared with their almost negligible reluctance in the inter-polar gap." In fact no general rules or precise conditions for the pole width to contain a whole, even or uneven, number or a fractional number of tooth-pitches can be laid down as obviating tooth-ripples.

It has been shown by Smith and Boulding for the case when the basic flux-density space-wave is sinusoidal, that a ripple of frequency $2g$ is produced, the amplitude of which itself varies sinusoidally over the whole pole-pitch. This ripple can be analysed into two odd harmonics of the order $2g \pm 1$. This deduction holds in a general way for any flux distribution, "the condition presupposed implying a maximum tooth-ripple at the crest of the e.m.f. wave of the loop, is often fairly well reproduced in actual cases," according to Hawkins. Therefore, "in general, it may be said that harmonics of the orders $2g \pm 1$ may be expected to be pronounced in the toothed machine." Since the distribution factors for harmonics of the orders $2g \pm 1$ are the same as for the fundamental, the tooth-ripple occurs undiminished in the phase e.m.f.

(ii) Due to pulsation of the total flux or of the permeance of the pole-pitch during a tooth cycle, a loop e.m.f. is induced by transformer action which is a maximum when the loop e.m.f. due to cause (i) is zero. "The amplitude of the pulsation, even when undamped. will be found in all practical cases to be very small."

Effect of rotor slots.—The addition of rotor slots makes the consideration of tooth-ripples of still greater complexity.

Effect of damping bars in the shoes of salient poles.—Damping bars may cause ripples "if the number of '*amortisseur*' slots in the field bears a certain relation to or comes too close to the number of slots in the armature." Numerous tests have been made, chiefly by the General Electric Company of U.S.A., to remove the ripples due to d.c. machines and convertors. Information as to these is contained in the original digests (28), (39), (44), (46), which are filed at the offices of the Research Association.

STATIC TRANSFORMERS.

The theory of the cause of transformer harmonics has been treated by numerous writers. As pointed out in the *résumé* the distortion of the magnetizing component of the current wave, or of the induced e.m.f. wave if the current wave is sine shaped, is due to the variation in permeability of the iron at different flux densities.

Figures given by O. G. C. Dahl (90) for single-phase transformers at normal saturation show that—

The fundamental of the magnetizing current = 90 per cent of the equivalent sine wave.

The 3rd harmonic of the magnetizing current = 45 per cent of the equivalent sine wave.

The 5th harmonic of the magnetizing current = 15 per cent of the equivalent sine wave.

Other harmonics of the magnetizing current = 0–3 per cent of the equivalent sine wave.

Fig. 22 shows the variation of these figures with the flux density.

With transformers connected for three-phase working, a path may be provided enabling the necessary third harmonic of current to flow. Such paths may occur due to the type of connection chosen.

Stigant and Lacey have made a study of the conditions obtaining with different arrangements for 3-phase service (chap. 16, "The J. and P. Transformer Book"). Table 2 is taken from this book. The conclusions in this table apply to single-phase transformers of both shell and core-types and to three-phase shell-type transformers. With three-phase core-type transformers any third harmonic fluxes must find their return path outside the core. Such a path is of very high reluctance and consequently the third harmonics in the flux and induced pressure waves are very small. In modern rotary convertor transformer design, the magnetic shunts are so designed that their use does not lead to the production of any appreciable third-harmonic fluxes (see also F. P. WHITAKER, "Rotary Convertors, with Special Reference to Railway Electrification," *Journal I.E.E.*, 1922, pages 501–525 and 835–844).

The above remarks, which apply to third harmonics, also apply to other harmonics, which are odd multiples of three.

As regards harmonics other than triple harmonics, there is always an external path enabling corresponding currents to flow. The voltage harmonics remaining depend on the impedance of such paths.

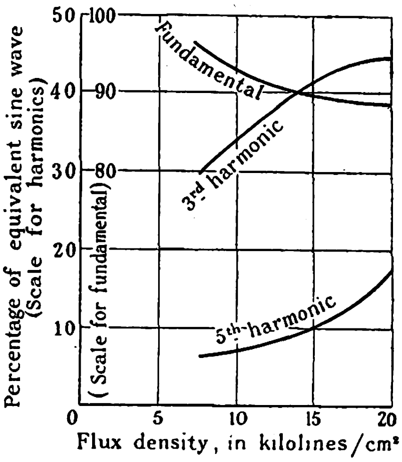

FIG. 22.—Components of magnetizing current of single-phase transformers.

The relation of triple-harmonic residuals to the magnetic-flux density is the subject of a technical report (No. 59) of the Californian Railroad Commission investigation, based on experimental and theoretical work. It is pointed out that, as shown by Nickolson and by Tackley (*Journal I.E.E.*, vol. 53, 1915, p. 248 and p. 521), at high densities the magnetization curve of iron can be represented by the equation $H = KB^m$. The tests in question showed that the B/H curve for the transformer iron could be represented fairly well by $H = KB^{10}$ above 13 000 gausses.

In this report one of the general conclusions states that "with increasing simple harmonic (i.e. sinusoidal) impressed voltage, the higher harmonics of the exciting current of a transformer increase at first more rapidly than the fundamental, but for high magnetic densities the wave-shape becomes constant." For modern transformer iron the ultimate value of the third harmonic is said to be about 54 per cent of the equivalent sine wave. Curves are given in this report which show that the magnitude of the harmonics increases very rapidly as the iron approaches magnetic saturation.

In the second edition of Vidmar's *Der Transformator* an exhaustive study is made of the harmonics produced by saturation of the transformer iron. The oscillating

I.N. means " isolated neutral."

N. to G. means " transformer primary neutral connected to generator neutral."

* In all these cases the third-harmonic component is less than it otherwise would be if—
(*a*) The circulating third harmonic flowed through a closed delta winding only, or
(*b*) The neutral point were isolated.

potential of the neutral is one of the chief dangers to be feared in a star-connected three-wire system. This is eliminated with the delta connection.

MERCURY RECTIFIERS.

For ideal conditions D. C. Prince (*General Electric Review*, September 1924, pp. 608–615) has shown that the amplitude of the voltage pulsation harmonic of frequency mNf, where m is an integer, is

$$ln = \pm \frac{2}{N^2m^2 - 1} \text{(constant component } E\text{)}$$

Hence, for a six-phase rectifier, there will be present harmonics of frequencies 6, 12, 18 . . . times that of the supply frequency, and with amplitudes ± 5·7 per cent, ± 1·4 per cent, ± 0·6 per cent . . . respectively of the constant component E. A later contribution by L. B. W. Jolley (*Journal I.E.E.*, vol. 63, 1925, pp. 588–592) gives formulæ from which the above figures are also obtained. Figures given by Professor E. W. Marchant in an Appendix to a paper by Bartholomew (32), are about 70 per cent higher for the sixth harmonic. This increase may be due to harmonics in the a.c. supply voltage.

The actual figures obtained in this case for a 50-cycle supply were:—

6th harmonic	± 9·5 per cent
12th harmonic	± 2·5 per cent
18th harmonic	± 0·8 per cent
24th harmonic	± 0·83 per cent
30th harmonic	± 0·42 per cent

APPENDIX 14.

LEGAL ASPECTS.

This Appendix is intended to give an indication only of the legal questions relating to inductive interference.

GREAT BRITAIN.

The P.M.G. has very wide powers under Acts of Parliament. In practice, co-operation between supply authorities and the Post Office frequently enables satisfactory compromises to be arrived at.

With regard to the earthing of h.t. power systems:—

(i) In cases where the Electricity Commissioners deem earthing to be necessary for the safety of the public, authority can be given by them for such earthing without any reference to the P.M.G.

(ii) In cases where the Electricity Commissioners do not deem earthing to be necessary for the safety of the public, authority can be given by them for earthing, subject to the P.M.G.'s concurrence (see Section 10 of the Schedule to the Electric Lighting (Clauses) Act, 1899). "Permission has never been withheld to such earthing, subject to it being made at one point on each distinct circuit, and subject also to a proviso that the P.M.G.'s concurrence may be withdrawn at any time."

(iii) According to Section 69 of the 1899 Act it is made incumbent upon undertakers to arrange that their lines and works shall not harmfully affect the communication circuits of the P.M.G.

ABROAD.

The information we have found regarding legal aspects in countries abroad is contained in four articles, (55), (68), (69), (103), which refer entirely to the U.S.A. Beyer (68) indicated the general trend of the law relating to interference up to 1917. He summarized the question by stating that the various utilities are licensees of the public and priority does not give an exclusive privilege, but certain well-defined rights which must be respected, except by utilities connected with public travel. Presumably, priority to occupancy of roads is referred to here. The telephone is considered theoretically as a substitute for travel and has, therefore, greater fundamental rights than electric light and power lines.

Proceeding from the principle that the use of public highways is for travel, telephone companies have no remedies against tramways when negligence is not an issue. No supreme court has dealt with the question of who shall pay the cost of measures taken to avoid interference on prior-established lines and what relief may be granted for increased maintenance.

In a majority report of the Iowa Railroad Commission in 1917 (55) it was held that the Commission would not prohibit h.t. lines on roads where substantial interference could be eliminated by changing the location or the construction of the telephone lines at reasonable expense. If metallic circuits and transpositions or re-locations of the telephone lines be required the power company must pay the cost. If the telephone lines be in bad condition, the telephone company must pay the cost of putting them in order; or, in the case of re-location, or of conversion to metallic working, part of the reconstruction costs.

In the Homer inductive interference case (103), in which application was made to the Illinois Public Utilities Commission for permission to erect a h.t. power line serving property owners along a road on which local and long-distance telephone lines were prior occupants, the Commission stated that the growth of rural communities demanded that roads be used by other utilities and, therefore, all must operate so as to prevent undue interference one with the other.

With equal highway rights, the prior occupant cannot exclude others, but he may have superior rights which are limited to protection from interference, substantial in character. It was accordingly directed that the power line should be three-phase instead of single-phase and that a co-ordinated system of transpositions should be carried out on both systems. An opinion as to the allocation of the costs of such extra transpositions was not given.

DISCUSSION ON

"THE CAPACITY EFFECT AND NATURAL FREE PERIOD OF A D.C. ARMATURE."*

Prof. W. Cramp (*communicated*): The subject of this paper is of great interest, extending far beyond the limits to which the author has confined himself. Moreover, the mathematical expressions are here developed in a manner more lucid and thorough than that of previous investigators, and the experimental apparatus which the author has devised is original, ingenious and effective for teaching purposes. Since, however, some years ago a considerable amount of research work was carried out on somewhat similar lines in my laboratory, I wish to place on record some of those results and, in particular, to mention another experimental method of examining the same problem. Referring first to equations (6) and (7), the author's assumptions are not very explicit. Since E has disappeared from the equations it would seem that he is assuming a motor with constant separate field excitation whose armature, having been run up to a speed such that the counter e.m.f. exceeds the supply p.d., is then disconnected from the supply and short-circuited. If this is not his meaning, it is not clear why E is omitted. And if it is his meaning, then his solution shows that, if R is small enough, the armature will experience velocity oscillations as its average speed falls. This may be true, though no experimental proof is given. But then, if true, would this not happen whether the armature were "accelerated above its normal running speed" or not? On the other hand, if E be added to the left-hand side of equation (6) the system is still oscillatory (R being small) and my calculation of its period agrees with equation (8), even when a constant-load torque is added to the right hand of equation (7). I conclude from my analysis that generally the inherent value of L for a d.c. armature is too small to produce practical effects, but that if a separately excited armature were switched on to constant p.d. mains, with a large inductance in series, oscillation should result. This was confirmed by experiment on February 26th last year. Clearly, energy was alternately stored in the rotating armature and the series inductance, and this exchange between kinetic and magnetic energy lies at the root of all the author's work. There is a further more telling experiment which I occasionally show to students and which depends upon the author's equations (6) and (7). Choose a machine with small armature resistance and brush friction and separately excite it, having a large value of L placed across the armature with an ammeter in series. Then in the author's notation

$$aM\frac{d\theta}{dt} = L\frac{di}{dt}$$

or, if $\theta = 0$ when $t = 0$, $i = aM\theta/L$. In other words, if the armature be uniformly turned round, the ammeter needle will register the angle through which it has been turned. This generally causes surprise, since it seems so contrary to the ordinary dynamo equations, but it works well experimentally. For example, in one experiment, the armature having moved through 90°, the ammeter read 0·12 ampere, and after another 90° it read 0·22 ampere, and so on. The proportionality is not exact on account of unavoidable resistance, but the principle is the same as that of the Grassot fluxmeter. It is interesting to notice that on releasing the armature the stored energy in L is distinctly evident as a "restoring torque."

I turn now to the author's section on instability and can confirm his comments concerning the solution of equations (15) and (16), upon which I have spent many hours. Here, again, I included a constant-load torque, and, like the author, arrived at a solution by neglecting smaller quantities. My solution, however, is in terms of flux and current, and is not better than equation (18). The practical importance of this instance arises from a fact that the author does not mention. It is seldom that a motor or generator is differentially compounded, but interpole motors are frequently built with shunt speed-regulation. Now the author's equations (15) and (16), when armature reaction is taken into account, apply ultimately to all shunt motors, but oscillations are not usually experienced because the reaction is not sufficient at normal loads, unless the field is abnormally weak. When, however, interpoles are employed, it can be shown, both theoretically and by measurement, that the resultant field flux per pole, and therefore the induction factor, is of the form $(M-Ki)$ as given by the author for the differentially compounded machine. Therefore shunt interpole machines oscillate when the shunt field is weak and the speed high, especially if the brushes be given a small shift backward, though this is not essential. Fig. A shows the result of a test obtained by F. M. Aust, M.Sc., in my laboratory in March, 1924. The machine to which it refers was a 50-h.p. 4-pole shunt interpole motor, intended for a variable speed of 450 to 750 r.p.m. It has a wave-wound armature with 318 conductors, and the normal shunt currents for the above speeds are from 5 to 3 amperes. In order to make the machine oscillate, the brushes were given three segments backward lead and the field current was reduced to 1·1 amperes, the load torque (a friction brake) being 16·7 lb.-ft. The torque equation was obtained by separate tests and gave

$$\mathbf{T} = 0{\cdot}735 \times 10^{-6}\,\Phi_0 i - 0{\cdot}00353\,i^2$$

which corresponds to the author's equation (16). the values of $\mathbf{T}$ being in lb.-ft., and Φ_0 being the flux per pole corresponding to the shunt field amperes. This equation expresses, for different constant values of Φ_0, a family of curves each having two values of i for a given torque, except when $i = 104 \times 10^{-6}\,\Phi_0$, which is the maximum value of **T**, and in this instance $\mathbf{T} = 0\cdot00353\, i^2$. Such torque curves are common to all shunt motors, but for normal excitations the curve is approximately a straight line up to the safe limiting armature current. When the shunt current, however, is reduced, the value of Φ_0 falls, and at 1·1 amperes is nearly $1\cdot36 \times 10^6$. Thus for Fig. A, $\mathbf{T} = i - 0\cdot00353\, i^2$, having its maximum at $i = 142$ amperes. The figure shows the phase relationships between field current, field voltage, armature current, armature voltage, speed and acceleration. The periodic time is 8·5 seconds. A comparison of these results with the author's equations (17) and (18) suggests the following remarks:—

---

* Paper by Mr. J. C. PRESCOTT (see page 185).

(1) Equation (17) seems to have a term missing, for the current does not oscillate about zero but about a value corresponding to the steady conditions, i.e. 47·2 amperes in Fig. A.

(2) The angle between current and speed is approximately 90°, which is the difference between the author's angles β and β'.

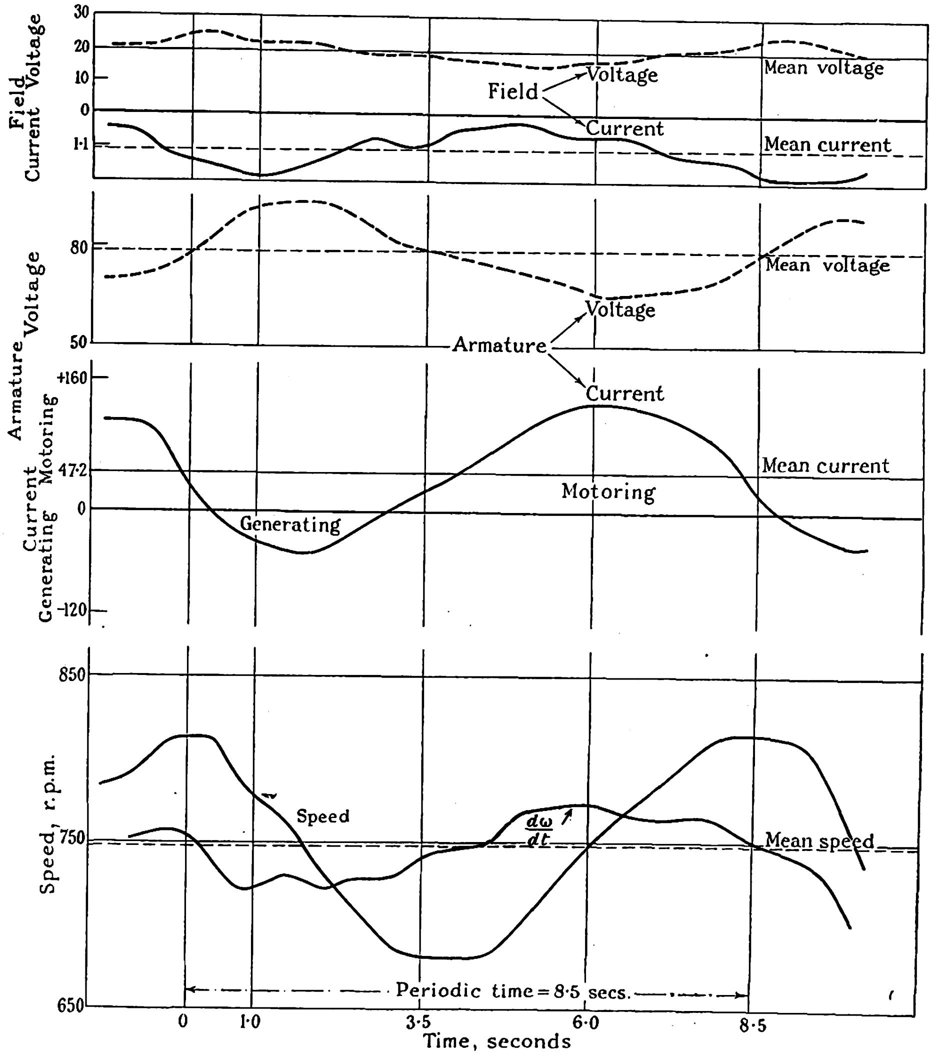

Fig. A.

(3) No. 2 is confirmed by the acceleration curve, which is shown to be in phase with the current.

(4) The armature voltage is not in phase with the speed, but nearly in phase with the current.

(5) Although the field was separately excited, a considerable variation was induced which is not in phase with current, voltage or speed.

The effect of the variation in the field is not referred to by the author, but it must modify equations (17) and (18). It may be of interest to explain the method by which the curves of Fig. A were obtained. It was desirable to record simultaneously the five quantities shown and also the readings of the spring balances for the torque arm. All were varying and no two were absolutely in phase. To obtain results even with one observer to each instrument proved impossible, and Mr. Aust finally adopted a kinematograph method. The instruments necessary for the measurements mentioned above and, in addition, a seconds clock were all fitted on a frame in the same plane. The machine having been set oscillating, films 1 in. by $\frac{3}{4}$ in. were exposed at about the rate of 12 per second. These, after development and fixing, were projected one by one on a screen by a stereopticon. The instrument pointers were then quite clear, but the finely divided scales were difficult to read; exact reproductions of the dials, therefore, were made and fixed to the screen, the stereopticon being adjusted until the image was the exact size of the dials. Thus the readings could be taken off as accurately as on a stationary instrument. These results were then plotted, as shown in Fig. A. This method may be recommended to any observer having a number of variables to record, as being convenient, accurate and inexpensive. It has already been remarked that the oscillations which are the subject of this paper are only one example of a large number, all of which depend upon certain general principles. Remembering that work or energy may always be divided into an intensity factor and a quantity factor, and that power may similarly be resolved into intensity and quantity per second, the first principle may be enunciated as follows:—

Where a system includes two alternatives for the storage of energy, a double energy transient will always arise if the natural characteristic intensity-quantity slope is negative and less than the corresponding slope of the supply system.

Besides the instability of electric motors, this principle covers organ pipes, violin strings, the shrieking of brakes, the swinging of a loose belt on a shaft and the oscillation of a pendulum fixed to the shaft of an induction motor. As regards the interchange of various forms of energy, the following principles are also of interest:

(*a*) In electrical and magnetic systems there are five possible variables, i.e. mass, elasticity, inductance, capacitance and resistance.

(*b*) Since in a given medium inductance and capacitance can only be changed by relative motion, self-sustaining oscillations supplied from a constant source of power cannot arise except by the intervention of mechanical motion—of these the synchronous motor is the standard example.

(*c*) Since change of resistance is not dependent upon mechanical displacement, self-sustaining oscillations, similar to those under (*b*), can arise without mechanical motion—the standard example is the oscillating arc.

Mr. J. C. Prescott (*in reply*): I am indebted to Prof. Cramp for his appreciation of my paper and for his criticism. As he points out, equations (6) and (7) are somewhat ambiguous. They are intended to express the oscillation of the angular velocity about the normal running speed of a motor, considered to have an induction factor M (which is constant, in accordance with the footnote on page 135), and operating on a constant e.m.f. The variation in angular velocity is, in these equations, expressed in terms of the resulting variation in armature current, but, as Prof. Cramp suggests, it would have been better to write the equations in the form

$$\left.\begin{aligned} E &= aM\frac{d\theta}{dt} + Ri + L\frac{di}{dt} \\ bMi &= \mathbf{I}\frac{d^2\theta}{dt^2} \end{aligned}\right\}$$

which will give as a solution, if $\dfrac{abM^2}{L\mathbf{I}} > \dfrac{R^2}{4L^2}$,

$$\theta = A\epsilon^{-Rt/2L}\sin\left[\left\{\frac{abM^2}{L\mathbf{I}} - \frac{R^2}{4L^2}\right\}^{\frac{1}{2}} t + a\right] + \frac{E}{aM}t + B$$

where A, B and α are constants. The experiment described by Prof. Cramp, in which an inductance is placed across a d.c. armature, is new to me and is of considerable interest as bringing out the fact that, whilst a d.c. armature connected across an ohmic resistance experiences a torque proportional to its velocity, when the same armature is connected across a pure inductance the torque is proportional to the angle by which the armature is displaced; for, neglecting resistance,

$$aM\frac{d\theta}{dt} = L\frac{di}{dt}$$

and i is therefore proportional to θ. Since the induction factor is constant, the torque is also proportional to i and therefore to θ.

The instability of uncompounded shunt motors with weak fields was known to me before I began the investigations described in the paper, and the reason why the fields of the motors used in the experiments were kept at nearly a normal value was that I wished to ascertain whether equations (15), (16) and (17) (which were evolved before the measurements were actually made) could be given a physical interpretation in a machine having the axis of its main field more or less rigidly fixed in space. The curves given by Prof. Cramp for the oscillation of a d.c. machine are very interesting and, speaking from my own experience, I should say that very careful adjustment of the circuit conditions would be necessary in order to obtain such excellent results, even with the method of recording used by Mr. Aust. With regard to the remarks of Prof. Cramp upon equation (17), here, again, the current specified is intended to be the extra current flowing due to the oscillation. Constant terms were omitted, with a view to simplifying the equation as much as possible.

DISCUSSION ON

"LOW-TEMPERATURE CARBONIZATION OF FUEL, WITH SPECIAL REFERENCE TO ITS COMBINATION WITH THE PRODUCTION OF ELECTRICITY." *

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 20TH JANUARY, 1930.

Mr. E. M. Hollingsworth: From the particulars given in the papers it is evident that the processes are technically successful, but little definite information is given as to the financial side of the question. In the paper dealing with the German process figures of the capital expenditure for stations with and without carbonization plant are given; apparently, the adoption of such plant almost doubles the expenditure and results in a high figure per kilowatt installed. At the World Power Conference in London in September 1928 reference was made to the high capital cost and probable short life of such plants. Mr. McEwen's experience shows that there is less difficulty in America than in this country in connection with the disposal of the gas produced. There also appears to be a more satisfactory market for the semi-coke for domestic and trade purposes in that country; this is an aspect which is not considered in the papers. With regard to the use of semi-coke on mechanical grates and for pulverized firing, I should like to know whether difficulty is experienced in grinding and burning this fuel. I have in mind the case of a large power station where good-quality coke breeze mixed with slack is fired on chain-grate stokers; experience shows that to obtain the best possible results the proportion of coke must not exceed 16 per cent.

Mr. R. E. Gibson: The gas industry is naturally interested in problems connected with the carbonization of coal, but it is something of a novelty to find that electrical supply companies are now concerned with problems of the same kind. Although I am glad to see that power engineers are giving some attention to carbonization I cannot understand why they should be interested in low-temperature processes. High-temperature carbonization is being ignored despite the fact that it is firmly established, commercially sound and of high thermal efficiency. In one of the papers reference is made to the fact that coke produced by high-temperature carbonization is not favoured as a fuel by power engineers. The reason for this is probably that the price of coke is, in general, considerably higher than that of slack. Gas coke has been successfully used, however, in several power stations where the boiler furnaces have been adapted for the purpose; this appears to be a suitable fuel, as it is smokeless, burns at a high temperature and has a substantial calorific value. Those responsible for the development of the gas industry have been accused of apathy and unwillingness to recognize the advantages of low-temperature systems, in spite of the fact that they are capable of exploiting them most easily. It should be understood, however, that they have been following closely the progress of low-temperature schemes and that these will be adopted as soon as it is clear that they have definite advantages. At the present time 6 of these plants are being tested in London gasworks and the records of their performance are awaited with much interest. In all these processes the yield of gas is less than half that which is obtained from high-temperature carbonization and, as this is the criterion with which the gas industry is primarily concerned, any process which reduces the output of gas is regarded with disfavour unless it can show compensating advantages. It is also feared that the special fuel and other liquid by-products may not realize prices sufficiently high to compensate for the loss of the gas and for the extra capital outlay. With regard to low-temperature carbonization as applied to electricity, Mr. McEwen states that, to make the process profitable, gas must be sold for town supply. Dr. Rosin agrees with this and also points out that unless the tar products and the gas are sold at prices sufficiently high to reduce the cost of the semi-coke below that of the fuel generally used in power stations, the scheme presents no financial advantage. The success of low-temperature processes for the production of domestic fuel has largely depended upon the ratio of the price of that fuel to the price of coal. It is difficult to see how any such process can be financially advantageous to the electrical industry unless it is worked in conjunction with a gas supply authority which is able to distribute the gas, dispose of the by-products, and perhaps sell a portion of the semi-coke at a comparatively high price. Messrs. Smythe and Weeks describe a system in which the gas is not sold but is burnt along with coke in the furnaces. They state that the proportion of volatile matter left in the coke must be 12 to 14 per cent to ensure ease of ignition. This seems to be a waste of good material, as coke with 3 to 5 per cent of volatile matter will ignite fairly easily. They emphasize the importance of the liquid by-products, which they value at 8s. 11d. per ton of coal carbonized. This is a high figure, and although it may be a correct estimate of the value under certain circumstances no statement is made as to the cost of installing and working the special plant necessary for refining the products. The quantity as well as the calorific and marketable values of the gas produced are not mentioned nor is any financial statement of the process as a whole included in the paper. I agree with the view expressed in the paper by Mr. McEwen, that low-temperature processes associated with the generation of electricity have a smaller margin of profit than similar processes applied to the production of high-grade fuel for domestic purposes. This is sold at a price in excess of that which supply companies can afford to pay. In view of his statement that the quality of gas with a calorific value of 275 to 300 B.Th.U. per cub. ft. is not high enough for use in a public service, it may interest Mr. McEwen to know that there is a town in England where gas of a lower calorific value is distributed. The paper describing German practice has rightly drawn attention to the problem of waste liquor disposal, a matter of some difficulty in this country. I agree that the large fluctuations in the prices of tar products and oils since the War have seriously affected the financial results of carbonization processes.

---

* Introductory Papers by Mr. S. McEwen, Prof. P. Rosin, and Messrs. E. H. Smythe and E. G. Weeks (see pages 205–236).

Mr. J. Hamilton: The application of low-temperature carbonization seems to be attractive and practical, but we have to assume that it is economically sound. Messrs. Smythe and Weeks have told us that the semi-coke from their process has a heat value of 76 per cent of that of the coal treated, so that to get an equivalent heat value it would be necessary to treat approximately 1¼ tons of coal. This would cost, say, 13s. 9d.—an additional charge of 2s. 8d. The sum realized from the sale of by-products has therefore to exceed the capital charges on the plant plus the cost of production (including increased freight charges) by an amount sufficient to show a profit on the cost of the coal if burned untreated. Whilst it may be possible to attain such a result with coal at 11s. per ton, the prices ruling in this district would necessitate higher receipts from the by-products than those given in the paper. It would be interesting if the authors would indicate the financial results on the Dunston plant. A plant with a through-put of 160 tons per day is given as a typical example of modern practice, but such a plant would prove too small for modern boilers, in view of the need for a bunker reserve, where the process takes an appreciable time. Will the authors state their views on the relative merits of stoker and pulverized-fuel firing and their experience of arch settings and wear on pulverized mills with semi-coke? Is the stripped gas which is at present used in the boiler furnace suitable (possibly enriched) for supplying the combustion products to the retorts? From Mr. McEwen's paper it will be noted that in the American plant the process is accelerated by pulverizing the fuel at the outset. This is an advantage, but it would appear possible, in view of the percentage held on the 48-mesh, that further pulverizing might be necessary and this would increase the costs. Prof. Rosin's paper supplies figures as to the capital cost of German installations; the interest payable upon such costs would counterbalance any gain which might accrue from the adoption of the process. Reference has been made to the national aspect of the question and the need for more effective use of the constituent elements contained in coal. Messrs. Smythe and Weeks state that this should now be attempted by the electrical supply industry, in view of the co-ordination which is being effected by the Electricity Commissioners and the Central Electricity Board. If low-temperature carbonization is an economic success it should, in my opinion, be exploited by these authorities in certain districts, the semi-coke should be supplied as fuel to selected stations, and the profits derived from the process should be used to equalize freight charges. The selected stations would then be provided with raw material at the same price and competition in operating efficiency would result, with a beneficial effect upon the industry as a whole.

Mr. H. E. Stone: I am glad to find that the electrical industry is at last realizing the serious waste of our natural resources which is a consequence of their practice of burning raw coal. Destructive distillation and by-product recovery, as described in the papers, are obviously in the experimental stage and it is difficult to estimate their value on the small amount of evidence given. The paper on English practice is, I think, unduly optimistic for it gives the price of coal as 11s. per ton—a very low figure for fuel delivered to the plant. Further, the marketable value of the by-products is, in fact, not above 6s. per ton, compared with the figure of 8s. 11d. in the paper. The cost of working the tar would not be less than 3s. for the quantity mentioned, even with large-scale operation and up-to-date plant. This charge does not appear in the paper. The method of distillation used, that of internal heating, gives a low-grade gas heavily charged with inert constituents and is inefficient. I think that the process suffers by reason of the fact that one of the most profitable products of coal (gas) is eliminated. External heating would be more effective as it would provide gas of a saleable quality. It must be remembered that the high sulphur content of poor coal causes the sulphur content of the tar products and motor spirit also to be high. This point should receive careful consideration when the advisability of reducing the cost of the raw material is under discussion. I agree with the conclusion, arrived at in Mr. McEwen's paper, that gas and electricity undertakings must combine in order satisfactorily to solve the problem. The former fully understand the destructive distillation of coal and the working up of by-products. They have a good market for the gas and are themselves able to produce a large amount of cheap steam by the use of waste-heat boilers and coke-cooling plants. I believe that it would be quite possible for the gas industry to supply a coke or breeze suitable for combustion on boiler grates. Recent research work has shown that the reactivity and ignition temperature of coke are those of its most easily combustible constituent. A reactive coke could thus be produced by blending, and this would still leave the gas undertakings free to sell the larger coke for domestic and industrial purposes. Furthermore, if it can be demonstrated that low-temperature carbonization is a paying proposition the gas industry will certainly adopt it.

Mr. T. H. Byrom: The paper by Mr. McEwen shows, in Table 2, an item on the revenue side which allows $0·375 for the ammonium sulphate recovered. In low-temperature carbonization processes generally, however, it is doubtful whether the comparatively small yield of ammonia is worth recovery, in view of the present condition of the market. The disposal of the ammoniacal liquor may actually be a matter of some difficulty and cost owing to the restrictions upon stream and river pollution; I therefore consider that the value assigned to it should be diminished, if not ignored. On page 207 of the same paper a figure of 30 cents per 1 000 cub. ft. is given for the gas obtained in the process. Although this may be its value in America such a price could not be realized here; a certain coke-works in this country has agreed to supply coke-oven gas of a minimum calorific value of 520 B.Th.U. at 6½d. per 1 000 cub. ft., and this is not an isolated instance. In the paper by Messrs. Smythe and Weeks it is stated on page 220 that when coal is burnt in the boiler furnace no use is made of the "high-value" heat units contained in its volatile constituents. It is, however, very unlikely that these volatile constituents, which are driven off when the coal is first heated, can traverse the whole range of the heated zone under the boiler without undergoing at least partial combustion. On the same page it is stated that the optimum content of volatile matter in the semi-coke is from 12 to 14 per cent—a figure which is, in my opinion, unnecessarily high seeing that in many processes a volatile residue of 3 to 4 per cent is found to be satisfactory. It is noteworthy that the ash content amounts, in this case, to 16·4 per cent, so that the calorific value and combustibility of the coke will be low. This may explain why it is necessary to retain so high a percentage of the volatile constituents. With regard to the economic possibilities of low-temperature carbonization, there is no doubt that a market must be found for the tars and oils produced and that, even though certain products are recoverable from the former, they have to be sold at a price which is liable to considerable fluctuations. It is likely, however, that they may be utilized in hydrogenation processes and this appears to be a very promising outlet. In a paper on low-temperature carbonization, by Dr. Lander and Dr. Sinnatt, which was read at the World Power Conference in 1928, it was stated that the true commercial test of such processes could only be provided by plants which had been worked for a long period, throughout which the products had been sold on the open market and definite profits had been produced. Prof. Rosin's paper suggests that the product of low-temperature carbonization of brown coals is liable to spontaneous combustion unless suitably quenched. It is clear, therefore, that great care is necessary in cases where the product has to be stored for any length of time.

Mr. R. G. Devey: After inspecting the Dunston plant I came to the conclusion that low-temperature carbonization was a practical possibility and that it only remained to show it to be a commercial success. A paper * on this subject which was read some years ago drew attention to the fact that many types of pulverized-fuel systems exist; I am glad that only a few of the most practical of these have been described. American practice cannot but differ from that adopted in this country on account of the difference between the positions with regard to the supply of fuel oil. Whereas in the U.S.A. an abundance of the latter is provided by nature, England imports about 600 million gallons of spirit yearly and as she consumes, in addition, some 600 million tons of coal per annum the two countries must take widely different views of the commercial advantages of low-temperature carbonization. With regard to the paper on English practice, I should like to ask what percentage of coal is used and whether this is screened. Is the dust problem less serious as a result of the use of coke fires? I gather that less than 100 per cent of the fuel is distilled; it would be interesting to hear whether the quantity of sulphur, and the nuisance with which it is always associated, are at all reduced during the distillation process. Should not the plant which is used for this purpose be placed in a separate building near to the boiler house? That equipment would probably be subject to a good deal of corrosion arising out of the low-temperature conditions. What rate of depreciation on the capital charges would this involve? The authors' opinions as to whether coke firing, either by stoker or by pulverization, has been an entire success, would be of interest. As no statement of initial costs has been given, some indication of the capital charges on, for example, a distillation plant for 100 000 kW would be welcome.

Mr. E. W. Ashby: I notice a difference between the American and English systems in that in the former the coal is pulverized before treatment. It seems clear from the diagram that in the English system the coal is not crushed; I should have thought that this would not have been such an efficient process as low-temperature carbonization of coal which has been already pulverized.

* "Pulverized Fuel and Efficient Steam Generation," *Journal I.E.E.*, 1924, vol. 62, p. 385.

THE AUTHORS' REPLIES TO THE LIVERPOOL DISCUSSION.

Mr. S. McEwen (*in reply*): It is natural that the question of general interest when considering the possible application of low-temperature carbonization of coal in conjunction with power generation should be a financial rather than a technical one. Mr. Hollingsworth gave expression to this in drawing attention to the fact that little definite information is given in the papers on the financial side of the question. In an industry, however, which is in process of development it is practically impossible to give definite financial figures which would be of any real value. The matter, in my opinion, has to be approached in an entirely different way. Thus, if it be accepted that by the carbonization of coal at low temperatures products of a considerably higher value than that of the coal from which they were extracted may be recovered, the procedure should be to apply the skill of engineers, chemists and financial experts to the study of the precise conditions which would obtain where a combined carbonization and power plant could be installed. The equipment could then be so planned as to secure profitable operation. Knowing the cost of the coal available for treatment and the minimum realizable values of the various products, it is possible to predetermine what amount of money may be expended as capital, what operating charges are permissible and what profit is essential in order to make the project worth while. This is the manner in which the installation at Milwaukee was undertaken. The revenue which could be obtained from a satisfactory gas and from the sale of the solid fuel was known. In the case of the revenue from the tar and light oil a minimum value could be fixed, but it was realized that, following careful investigation and research work, it would be possible to secure a higher rate of income. A prospective balance-sheet was prepared and it then remained for engineers to design the equipment, keeping within the limits of the estimated expenditure for capital and operation. At this early stage in the development of the industry it is inconceivable that figures relating to a plant erected in one district would apply with equal accuracy to a plant erected elsewhere. A careful study of local conditions will determine what financial results are possible, and it then remains for the combined effort of those skilled in engineering, chemistry and finance to convert into reality that which was shown to be possible.

The reference in my paper to the importance of securing an adequate revenue from the sale of gas was commented upon by several speakers, including Mr. Gibson and Mr. Byrom, it being pointed out that conditions for the sale of gas in America were obviously different from those which existed in England, but in this connection there is one point which is apt to be overlooked. A misapprehension has arisen with regard to the value of gas, as a result of the low prices which have in the past been realized for the surplus gas produced in high-temperature coke ovens. The cost of manufacturing the gas which is sold for supply to a town is well known (the figures are published every year), and it is apparent that there is little, if any, relation between the actual cost of manufacture of gas to a gas company and the price which such a company is willing to pay for surplus gas supplied from a high-temperature coke-oven plant. The justification for the low price paid lies in the fact that the gas company has the responsibility for public service and its supply must be available at all times, whereas the operation of the high-temperature coke-oven plant is dependent upon the fortunes of one industry. There is no guarantee of the continuity of the supply from the latter, and consequently the gas manufacturer must maintain his equipment, his staff and his whole organization in readiness to manufacture the gas in substitution for that purchased from the coke-oven plant should the latter supply fail. In considering the combination of carbonization with power generation, the question of continuity of supply does not arise; the electricity company is just as much a public service company as the gas company; the demand for electric power is not dependent upon the fortunes of any one industry, in fact the demands for electricity and gas bear a very definite relation through all the seasons of the year. Therefore, the value of the by-product gas should be represented by the actual cost of manufacture at the gasworks.

Mr. Byrom refers to an item on the revenue side of Table 2 in my paper, relating to the realizable value of the ammonium sulphate recovered. It will be seen, however, on further reference to Table 2, that the results given are not from low-temperature carbonization but from high-temperature carbonization. It is fully realized that in low-temperature carbonization the ammonium sulphate recoverable is of such small quantity as to make it valueless. In Table 4, which gives the revenue from low-temperature carbonization, no credit at all is given for ammonium sulphate. At the bottom of page 207 it is distinctly stated that no revenue is obtained from the sale of ammonium sulphate with low-temperature carbonization.

Mr. Devey asks for an expression of opinion as to whether coke firing by stoker or by pulverization has been an entire success. Presumably the question refers to semi-coke, and so far as combustion of semi-coke in pulverized form is concerned it has been very definitely established that combustion is entirely successful. Powdered semi-coke is very easy to ignite, it is sufficiently soft to prevent unusual wear in the handling equipment, the rate of combustion per cubic foot of furnace capacity is higher than with raw coal, and a very high percentage of CO_2 can be maintained.

Mr. Hamilton refers to the sizing test on the semi-coke resulting from carbonization at Milwaukee, and suggests that further pulverization might be necessary before combustion. In this connection, however, it is important to remember that rapidity and completeness of combustion are dependent upon the surface area exposed. A particle of semi-coke, although it fails to pass through a 48–mesh screen, can still expose as much surface for combustion (for its weight) as a very much finer particle of solid coal. The semi-coke particle is cellular, it is extremely reactive and it has been found in practice that relatively large particles delivered to a furnace by the standard pulverized-coal burner will burn completely and satisfactorily.

Dr. P. Rosin (*in reply*): I referred in my paper to the essential difference which exists between the carbonization of pit coal and of brown coal. The profit on the carbonization of pit coal must come from the higher price of the coke, which, however, the power stations will not pay, and for this reason I believe that there are no prospects in Germany for the combination of the carbonization of pit coal with the generation of electricity. Coke obtained from brown coal cannot be used in any great quantity for house fuel and has therefore a lower value. The sale of the tar and gas obtained from the carbonization of such coal is so profitable that coke is a cheaper fuel than raw coal for power stations. Therefore, in spite of the high capital charges associated with the carbonization of brown coal as compared with German pit coal, the process results in considerable economy.

Messrs. E. H. Smythe and **E. G. Weeks** (*in reply*): Replying to Mr. Hollingsworth, the paper dealing with the Babcock process is admittedly concerned with the technical side and no attempt has been made to give any detailed information as to finance. Such information would involve a hypothetical plant concerning which a number of assumptions would have to be made. We frankly consider that the Dunston distillation plant is on too small a scale to give a representative idea of the financial results to be obtained in large-scale working. Although the paper makes no mention of the production of semi-coke for household use, the process is well adapted for this purpose and in our opinion there is an even better market in this country than in America for the high-grade smokeless fuel, owing to the more general use in England of open fires and coke-fired domestic boilers. In America oil firing has now been extensively adopted for domestic heating installations.

No difficulties have been experienced in using semi-coke on chain-grate stokers. As far as our experiments have gone, the semi-coke has presented no difficulties either as regards grinding or burning in pulverized form, but we shall be in a position to give more information on this point when we have had some experience with the working of the new retort which has been purposely installed for the firing of a pulverized-fuel boiler. The possibility of having to blend coal with coke does not arise if semi-coke of the type made at Dunston is used, and this complication is therefore avoided. Semi-coke containing about 12 per cent of volatile constituents forms a very satisfactory boiler fuel.

Mr. Gibson mentions that the gas industries are naturally interested in coal carbonization, but as far as low-temperature distillation is concerned any practical interest they may have taken is of comparatively recent date; it is the result of endeavours made by those associated with certain low-temperature processes, or is due to Government assistance. Even so, the number of processes now under test by the gas companies is confined to only 3 or 4 large-scale plants in the London area, so that Mr. Gibson's estimate of half a dozen is rather too optimistic. On the other hand, the electrical industry has up to now taken no general interest in the problem except in the instance which forms the subject-matter of this paper. It is, however, a fact that the possibilities of combining low-temperature distillation with the production of power were first considered by electrical engineers about 12 years ago in some experiments which they instigated in order to discover a more economical method of utilizing our coal resources, combined with the home production of oils. High-temperature processes were not taken into consideration; firstly, because the gas industries make use of a different type of coal from that normally used for power-station work; secondly, because the coke produced is more expensive than coal and less suited for use in modern steam-raising plants; and thirdly, because high-temperature carbonization gives a lower yield of tar oils than that obtainable by low-temperature processes. Although it is reassuring to know that the gas companies are watching and will take advantage of the improvements in low-temperature carbonization, this is rather different from taking an active part in the work of development. Presumably they are content to leave the task to those already engaged upon it; this is encouraging, provided that their co-operative support is likely to be forthcoming in the commercial development of a method of carbonization with which their own industry is so closely allied. It is true, as Mr. Gibson says, that the production of gas from low-temperature distillation is considerably less than that from high-temperature carbonization, but at no time has it been claimed that one industry would supplant the other. Rather should one be complementary to the other, and while the gas industry may be primarily concerned with the production of gas it is also interested to a considerable extent in the sale of coke. For instance, some gas companies have of recent years devoted attention to the supply of a special type of coke suitable for use in domestic boilers. We hope, however, that they will soon recognize that low-temperature semi-coke is even more suitable for household purposes than high-temperature coke and that the production of this fuel should therefore be of immediate interest to them. The gas produced by the Babcock process could either be used to meet the heat requirements of the process, or else it could serve as a diluent for the rich gas produced by high-temperature retorts. As Mr. Gibson suggests, co-operation between gas and electricity undertakings on these lines would greatly facilitate developments, and it is our contention that the results already achieved at Dunston give a very fair indication of the possibilities. Mr. Gibson thinks that, from the gas-makers' point of view, it is wasteful to burn semi-coke containing 12 to 14 per cent of volatile material, but from the general economic point of view it is far less wasteful than the combustion of raw coal containing, say, 30 per cent of such material. In our experience, it is essential that the volatile content of the semi-coke should not be less than about 12 per cent and we do not agree that coke having 3 to 5 per cent of volatile matter is a fuel suitable for firing boilers. It is open to question as to whether it would support combustion when used as a pulverized fuel, apart from the fact that such coal is difficult to pulverize. It is altogether unsuitable for use as domestic fuel. The prices given for the by-products were obtained from actual sales figures of the products made at Dunston, and these prices compare very favourably with those quoted in the market at the time when the paper was written. This remark also refers to the point raised by Mr. Stone. We realize that by-product prices are liable to considerable fluctuations, but it is generally considered that these are at present exceptionally low. It is obviously necessary to install a refining plant in order to realize the full value of the by-products: this was carried out at Dunston in order also to obtain practical experience in refining low-temperature tar oils. As far as we were aware, no practical investigation into the commercial values of low-temperature tars had been carried out by the gas or the tar-refining industries. It was therefore necessary for us to do this work ourselves, with the result that we have been able to market the various products mentioned in the paper. The quantity of gas produced is about 33 000 cubic ft. per ton of coal treated, the calorific value being about 80 B.Th.U. per cubic ft. of gas. At Dunston, this gas is used in the boiler furnace and is therefore only valued at the same price per therm as the semi-coke supplied to the boilers.

In reply to Mr. Hamilton, we agree that it would be necessary to treat approximately 1⅓ tons of coal in order to obtain a ton of semi-coke, but this larger quantity treated would also proportionately increase the quantity of by-products available and, incidentally, if all industrial fuel were so treated considerable assistance would be given to the coal-mining industry. We agree with Mr. Hamilton that a plant with a through-put of 160 tons per day is too small for modern boilers, and for this reason we have evolved a design for a unit capable of handling 300 tons per day which will work on the same lines as the new 60-ton retort at Dunston. As regards the use of semi-coke on chain-grate stokers, the plant at Dunston has definitely proved that there are no difficulties and that the fuel is entirely suitable for this purpose. The brick arch required for the combustion of semi-coke may be made shorter and higher than is general with chain-grate stokers burning highly volatile raw coal, and thereby the first cost and maintenance of the brick arches is reduced. No special arrangements are required for draught regulation, beyond those usually provided on modern chain grates. Regarding the use of semi-coke in pulverized form, we shall be in a better position to give useful information after the new retort has been in operation for some time, but our preliminary experiments have not led us to anticipate any special difficulties in connection either with the grinding or the combustion of the pulverized semi-coke. It is for this reason that the new retort has been designed to work in conjunction with the pulverized-fuel boiler. The stripped gas from the retort could, as Mr. Hamilton suggests, be used for making the distilling medium and, incidentally, for pre-heating the coal. It is possible that it would be an advantage to enrich the gas if the foregoing arrangement were adopted. From the point of view of thermal efficiency, however, and in order to facilitate control of operation it is, in our opinion, preferable to utilize waste flue-gases from the boiler for pre-heating the coal and to have an independent source of heat for the retorts. The gas made in the latter can either be fed into the boiler furnace or sold for use as a diluent for gas of high calorific value. At Dunston, the gas from neighbouring coke ovens is used for producing the distilling medium, and this is the most economical method. A producer has also been installed as an alternative means of supply; this would come into action if for any reason the supply of gas from the coke ovens were cut off. Mr. Hamilton's suggestion that the Electricity Commissioners and the Central Electricity Board should investigate the possibilities of applying the process to selected stations is one which we warmly welcome: we have always maintained that power stations afford one of the best examples of correct application of the principle, owing to their continuity of operation and to the large quantity of coal which is utilized at one point.

We agree with Mr. Stone that the total of 8s. 11d. available per ton of coal from the sale of by-products has to cover interest on capital, maintenance, depreciation and operating expenses. With large-scale operation this figure is sufficient to show a profit on the process. In cases where coal is dearer, prices of by-products may be correspondingly more favourable. It is therefore clear that each application of the process must be accompanied by a careful study of the local conditions in regard to possible outlets for the products of the plant. Mr. Stone expresses the opinion that internal heating of the retort is inefficient owing to the amount of low-grade gas which it produces. We have already explained that, in this country at any rate, we do not think that great importance should be attached to low-temperature carbonization as a means of producing gas, at least as far as the requirements of gas undertakings are concerned. We therefore do not agree that external heating is preferable to the method we employ, firstly, because slow heat transference and the resultant losses greatly reduce its thermal efficiency, and secondly, because under this system it is difficult to treat large quantities of coal in one unit. This necessitates the use of a multiplicity of units. Many small retorts are therefore necessary and this increases the capital expenditure; in addition, the life of the retorts is not so great if they have to be subjected to high temperatures in order to effect complete carbonization. As an example of the effects of internal heating it may be mentioned that the walls of the new retorts at Dunston, which have now been in operation for 3 years, show no signs of deterioration or distortion. Mr. Stone believes that the gas industry could produce a type of coke suitable for boiler firing or for use as a domestic fuel, but the fact remains that hitherto the industry has not done so. Though this might be achieved by blending we doubt if the gas companies would be able to add this to their ordinary business of producing gas, and it therefore seems more reasonable to expect them to take an interest in low-temperature distillation, which will produce fuel suitable for both these purposes.

In reply to Mr. Byrom, we wish to explain that by high-value heat units we refer to those heat units available from the coal, which are more valuable when used in some other form than when they are burnt in the furnace. Thus, although it is certainly the case that in a boiler furnace the volatile constituents undergo combustion and add to the generation of heat, they would none the less be far more valuable in the form of motor spirit, creosote or some other liquid by-product. Our experience of boiler firing with coke containing only 3 to 5 per cent of volatile constituents has shown that this proportion is far too small for ordinary use, and we are certain that such coke would not be suitable as a pulverized fuel. We agree that the ash content of the coke is increased by distillation, but our avowed object is to treat the type of coal which is normally used in power stations. The fact remains that we are able to produce a semi-coke of equal calorific value, pound for pound, to that of the raw coal, without experiencing any difficulty in disposing of the ash. We note that Mr. Byrom agrees with our contention that the price obtainable in this country for gas produced by low-temperature plant is far lower than in America, and it should also be noted that in Great Britain a considerable number of gas companies are supplying gas of calorific value lower than 500 B.Th.U. per cubic ft. In this connection, there is the possibility of using the low-grade gas made by this process as the diluent for the rich gas made by high-temperature processes, and thus of creating another useful link between the two industries. As regards the quotation from Dr. Lander and Dr. Sinnatt's paper, we should like to know what period of working constitutes a true commercial test. The Dunston plant has now been in operation for 3 years and throughout that period the yield of by-products has been sold on the open market. This should be sufficiently long to show that the process is a practical proposition, though it must be admitted that the cost of developing and working a small-scale plant, such as the one at Dunston, gives no indication of the profit to be made from large-scale operation. As Dr. Lander points out, there are undoubtedly local conditions under which a plant can be expected to be a commercial success—it is only a matter of finding the right conditions in order to apply the process commercially. If time alone can tell how far low-temperature distillation can influence the utilization of coal, then it is high time that a start was made to show what can be done.

In reply to Mr. Ashby, the Babcock process is designed to treat ordinary small coal and to produce semi-coke either in lump form or as a pulverized fuel. The distillation of crushed coal is in a different category and is outside the scope of our investigations.

Mr. Devey aptly summarizes the essential differences between conditions in America and in this country from the point of view of low-temperature distillation, and we are in full agreement with what he says. In answer to his question, we would point out that the process described is not designed to treat duff and that it is preferred not to use coal with a proportion greater than about 20 per cent below ¼-in. sieve, so that to this extent screening may be necessary. The amount of sulphur present in the semi-coke is largely dependent upon whether the sulphur in the original coal was combustible. There are only isolated instances in which the amount of sulphur is reduced by distillation; in most cases the sulphur content of the semi-coke is equal to, or possibly greater than, that contained in the coal. Generally speaking, low-temperature distillation affords no solution of this problem. The distillation plant should, if possible, be housed in or alongside the boiler-house so as to make use of existing coal-bunkering arrangements, and also because the operation of the retorts can thus be controlled by the boiler-house staff. It should, however, be understood that the retorts will not be linked up direct to the boiler furnace, but will supply the semi-coke to separate bunkers for storage and subsequent use. In this connection, we have made some investigations which tend to show that the risk of spontaneous combustion is less with semi-coke than with coal. The distillation plant can be housed in a separate building, but this may necessitate the installation of separate coal-handling plant. The tar storage-tanks and any tar-refining plant should be at a convenient distance from the power station. Regarding Mr. Devey's remaining questions, we have already referred in previous replies to the fact that there is no difficulty in firing boilers with semi-coke, at any rate so far as the use of chain-grate stokers is concerned; we hope to prove by continuous working that pulverized semi-coke is equally satisfactory. We have also previously referred to the almost complete absence of corrosion; and the fact that the temperature in any part of the plant is no higher than 500 to 600° C. accounts for the good condition of the retort walls after 3 years of continuous operation. We consider that 5 per cent would be an ample figure to allow for depreciation.

ANNUAL DINNER, 1930.

The Annual Dinner of the Institution was held at the Hotel Cecil on Thursday, 6th February, 1930, when the President, Col. Sir Thomas F. Purves, O.B.E., presided over a gathering numbering 651 persons. Among those present were: Mr. G. M. Gillett, M.P. (*Secretary, Department of Overseas Trade*); The Rt. Hon. The Earl of Bective; The Rt. Hon. The Viscount Falmouth; The Rt. Hon. Lord Monk Bretton, C.B., D.L. (*Chairman, London County Council*); The Hon. Sir C. A. Parsons, O.M., K.C.B., F.R.S. (*Honorary Member*); Sir George Sutton, Bart.; Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S. (*Past-President; Honorary Member*); Sir G. Evelyn P. Murray, K.C.B. (*Secretary, General Post Office*); Sir John Rose Bradford, K.C.M.G., C.B., C.B.E., M.D., F.R.S. (*President, Royal College of Physicians*); Col. Sir Charles Close, K.B.E., C.B., C.M.G., F.R.S. (*President, Royal Geographical Society*); Sir Arnold B. Gridley, K.B.E.; Sir Cyril W. Hurcomb, K.B.E., C.B. (*Permanent Secretary, Ministry of Transport*); Sir Joseph E. Petavel, K.B.E., D.Sc., F.R.S. (*Director, National Physical Laboratory*); Sir J. R. Brooke, C.B. (*Electricity Commissioner*); Sir Ambrose Fleming, M.A., D.Sc., F.R.S. (*Honorary Member*); Sir H. Haward (*Vice-Chairman, Electricity Commission*); Sir J. H. Jeans, D.Sc., LL.D., F.R.S.; Sir David Milne-Watson, LL.D., D.L. (*President, Institute of Fuel*); Sir Archibald Page (*Past-President*); Sir Walter Raine, J.P. (*President, Association of British Chambers of Commerce*); Sir Ernest Rutherford, O.M., P.R.S. (*President, Royal Society; I.E.E. Faraday Medallist*); Mr. C. T. Allan (*Hon. Secretary, Western Centre*); Mr. H. V. Ashley (*Vice-President, Royal Institute of British Architects*); Mr. Ll. B. Atkinson (*Past-President, I.E.E.; Chairman, Royal Society of Arts*); Mr. G. Balfour, M.P.; Mr. J. R. Beard, M.Sc. (*Member of Council*); Capt. J. F. C. Bennett, J.P. (*Mayor of Westminster*); Major B. Binyon, O.B.E., M.A. (*Member of Council*); Mr. J. K. Brydges (*President, Incorporated Municipal Electrical Association*); Mr. R. A. Chattock (*Past-President*); Mr. A. E. L. Chorlton, C.B.E. (*Vice-President, Institution of Mechanical Engineers*); Col. D. S. Collins, D.S.O. (*Asst. Director of Works, War Office*); Mr. A. R. Cooper (*Member of Council*); Col. R. E. Crompton, C.B., R.E. (*Past-President; Honorary Member*); Mr. W. Cullen, LL.D. (*President, Institution of Mining and Metallurgy*); Mr. W. R. Davies, C.B. (*Principal Asst. Secretary, Technical Branch, Board of Education*); Capt. J. M. Donaldson, M.C. (*Vice-President*); Dr. C. V. Drysdale, O.B.E., F.R.S.E. (*Director of Scientific Research, Admiralty*); Mr. R. N. Eaton (*Hon. Secretary, Irish Centre*); Dr. W. H. Eccles, F.R.S. (*Past-President,* *I.E.E.; President, Institute of Physics; President, Physical Society of London*); Lieut.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (*Past-President*); Mr. H. Cecil Fraser (*Hon. Secretary, North Midland Centre*); Mr. N. G. Gedye, O.B.E. (*Chairman, Association of Consulting Engineers*); Mr. T. G. N. Haldane, M.A. (*Member of Council*); Mr. S. Harcombe, M.A., B.Sc. (*Member of Council*); Mr. T. E. Herbert (*Chairman, North-Western Centre*); Mr. J. S. Highfield (*Past-President*); Mr. F. S. G. Hinings (*Past-Chairman, North Midland Centre*); Mr. H. Hooper (*Hon. Secretary, South Midland Centre*); Mr. P. V. Hunter, C.B.E. (*Vice-President*); Mr. J. M. Kennedy (*Member of Council*); Mr. L. J. Kettle (*Past-Chairman, Irish Centre*); Mr. J. E. Kingsbury; Prof. T. M. Lowry, F.R.S. (*President, Faraday Society*); Mr. W. McClelland, C.B., O.B.E.; Mr. H. Marryat (*Member of Council*); Mr. C. H. Merz; Col. R. K. Morcom, C.B.E. (*Member of Council*); Mr. W. M. Mordey (*Past-President*); Brig.-Gen. Magnus Mowat, C.B.E. (*Secretary, Institution of Mechanical Engineers*); The Very Rev. W. Foxley Norris, C.V.O., M.A., D.D. (*Dean of Westminster*); Col. William Parker, D.S.O., T.D. (*President, Chartered Institute of Secretaries*); Mr. H. Parodi (*President, Société Française des Electriciens*); Mr. C. C. Paterson, O.B.E. (*Member of Council*); Mr. R. W. Paul (*Chairman, British Electrical and Allied Industries Research Association*); Mr. F. W. Purse (*Member of Council*); Dr. A. H. Railing (*Vice-President*); Mr. B. A. Robinson (*Chairman, North-Eastern Centre*); Mr. T. Roles (*Chairman, North Midland Centre*); Dr. A. Russell, M.A., LL.D., F.R.S. (*Past-President*); Mr. E. E. Sharp (*Member of Council*); Mr. E. H. Shaughnessy, O.B.E. (*Member of Council*); Dr. F. E. Smith, C.B., C.B.E., F.R.S. (*Secretary, Department of Scientific and Industrial Research; Secretary, Royal Society*); Mr. Roger T. Smith (*Past-President*); Mr. James Swinburne, F.R.S. (*Past-President*); Prof. J. F. Thorpe, C.B.E., D.Sc., F.R.S. (*President, Chemical Society*); Mr. H. T. Tizard, C.B., F.R.S. (*Rector, Imperial College of Science and Technology*); Mr. V. Watlington, M.B.E. (*Chairman, British Electrical and Allied Manufacturers' Association*); Mr. R. S. Whipple (*Member of Council*); Mr. J. Harcourt Williams (*Past-Chairman, North-Western Centre*); Mr. T. P. Wilmshurst, M.B.E. (*Electricity Commissioner*); Prof. E. Wilson (*Member of Council*); Mr. M. F. G. Wilson (*Chairman, British Engineering Standards Association*); Mr. W. B. Woodhouse (*Past-President*); Mr. H. T. Young (*Member of Council*); and Mr. P. F. Rowell (*Secretary*).

The toasts of "His Majesty the King" and "Her Majesty the Queen, His Royal Highness the Prince of Wales, and the other members of the Royal Family," were proposed by the President and loyally received.

Sir James H. Jeans, D.Sc., LL.D., F.R.S., in proposing the toast of "The Institution of Electrical Engineers," said: "I suppose we all feel that electrical science occupies at the present time a very special and peculiar position both in the scientific life and in the technical life of this country. I remember once trying to imagine what would have been the impression of visitors from another planet, if they had visited us at intervals of a century to report on our world and its habits. For many thousands of years during the Stone Age the changes would have been slight. In the century which ended in 1830 they would find more to report on, but that would be nothing compared with the changes which have taken place in the century between 1830 and 1930. Now when we look for the causes of the great change which has taken place in our habits of life during the last century, I suppose that the largest single item would be Faraday's discovery of electromagnetic induction, made just 99 years ago. Such small practical use was at first made of that discovery that when your Institution was founded 40 years later it did not begin as a society of electricians but as the Society of Telegraph Engineers. I think I am right in saying that in 1870 nobody imagined that electromagnetic induction could have anything to do with telegraphy as then understood. Ten years later, in 1880—just half a century ago—your Institution took electromagnetic induction and similar subjects under its wing, and became the Society of Telegraph Engineers and Electricians. Until then the electromagnetic side had, I think, been in charge of the societies concerned with pure science—the Royal Society, the Physical Society, and so on. From that time development has been rapid and one might fairly say that, as the result of the development of electromagnetism alone, human life has changed more in the last half-century than throughout the whole duration of the Stone Age. I think it may fairly be said that all the developments of electrotechnics have been for the good of the human race: one cannot make that statement about all sciences. On the purely scientific side the science of electricity has developed, I suppose, at a greater rate than any other pure science, largely under the guidance of great men of science who have specialized in electricity and all of whom have, I think, been connected in some way with your Institution. Partly as a result of this, your Institution has always been in very close touch with pure science, and we on the purely scientific side are extremely glad of this. For one thing, it gives the pure scientist a very strong argument when asked to justify the expenditure of money, time and energy on research in pure science. All he has to say is, 'Think of the financial value to the country of Faraday's discovery of electromagnetic induction.' In a sense your Institution has been obliged to keep in touch with abstract science and theory. A man may be a very clever civil engineer or a very clever mechanical engineer without knowing very much about the differential calculus, but he cannot be a good electrical engineer without knowing something both about the differential calculus and about pure science. If he thinks that he can, he is making a great mistake, for which he will have to pay very heavily in his profession. At the same time, it has been a great satisfaction to pure scientists that there has been this close contact between pure science and applied science. One of the real honours which has come to me during my scientific career was the invitation from your Council some years ago to deliver the Kelvin Lecture. I remember that on that occasion I was requested not to deal with technical matters but to talk about one of the most abstract branches of mathematical physics. The Council showed extreme breadth of view in suggesting the subject for the Kelvin Lecture; and that attitude has characterized the history of your Institution and, to my mind, accounts for a very large part of its greatness and success. I am much impressed by a remark made by Mr. C. F. Varley in 1872 at one of the earliest meetings of your Institution, before its title had been changed, when he boldly prophesied that electricity would take within its purview the whole of nature. It was really the concept of the electrical structure of matter which brought the whole of nature within the scope of electrical science, yet that idea did not come until later. In 1872 even the electromagnetic theory of light was not established; Clerk Maxwell was discussing it, but had not at that time published the first edition of his work " Electricity and Magnetism," and there was no reason in 1872, apart from pure insight and breadth of view, for supposing that the whole of nature would ultimately come within the purview of electricity. Yet Varley used those words, which have since been justified by the advance of science. Again, to come to more modern times, I was more than ever impressed by the breadth of knowledge of the electrical engineer when this year I read the address of your President, Sir Thomas Purves. Before I read that address I should not have imagined that abstract mathematical astronomy and electrical engineering could have anything in common, and yet I found your President dealing with abstract ideas about the galactic system and the number of possible universes, and such numbers as 10^{177}, which I had hitherto looked on as the special preserve of astronomers. It made me wish that I could invade your realm of electrical engineering with the same facility as your President invaded the realm of abstract astronomy. It gives me great pleasure to propose the toast of 'The Institution of Electrical Engineers,' and to couple with it the name of your President."

The President, in responding, said: "It is a pleasure and an honour to respond to the toast of this Institution, which has been so graciously and so pleasantly proposed to us by Sir James Jeans. I feel that to give anything like an adequate reply for the great groups of the electrical industry which the Institution represents would be a very considerable task; but I think that I am absolved from one of the duties which, I understand, sometimes devolves on the individual who has to reply to a toast of this kind—the duty of gracefully calling attention to various nice things about the subject of the toast that the proposer may have unfortunately omitted to mention. There is no need for me to do that; Sir James has done us full justice in a thoroughly comprehensive way. I am rather glad he has done so, because I must confess that the professional activities of some of the members of this Institution are still rather mysterious to me, in spite of the fact that I have already had the pleasure of attending a good many dinners of its Local Centres up and down the country, and have in this way had the advantage of listening to a very fine selection of speeches on the subject—speeches of the kind which, I believe, are often the main sources of information from which Presidents of great organizations such as this learn things about them that they ought to have known before. I shall not attempt, therefore, to stand here as an expert dispensing information. I have heard an expert defined as merely an ordinary man away from home, so here at our headquarters I am not able to put up even that claim. Besides, I once heard Sir Oliver Lodge remark, in one of those delightful conversational soliloquies with which he sometimes entertains his friends, that experts in one's own line of business require to be placated rather than informed. At all events if I should ever feel inclined to pose as an authority on the great subject of electrical engineering it would certainly not be in the presence of an audience such as I have the honour of addressing to-night, an audience so much more fully informed on all aspects of the subject than I am, or can ever hope to be. Occasions after dinner are not, perhaps, the best occasions on which to speak in any detail of the work and of the manifold functions of this great Institution, and yet one feels it appropriate to make a brief reference to some of its aims and activities. It exists to serve an industry which already covers a very wide and diverse field, and one which is continually developing and reaching out into new spheres of action; and it has deliberately adopted the policy of standing for, and endeavouring to cater for, the whole of that industry. Other great engineering institutions have in some cases adopted the alternative policy of allowing more or less specialized groups of interests, coming within their ambit, to form themselves into separate institutions or societies, in some cases affiliated to the parent body but with an independent constitution and a separate government. We, on the other hand, have thought that a profession based upon electrical research and electrical knowledge, however wide and varied its interests may be, is capable of being treated from this point of view as one profession. We think it will reap advantages from keeping together and that the general public interest, as well as the interests of the electrical industry and of its professional *esprit de corps*, will be better served by one powerful Institution of a national character than by a number of separate electrical societies. From this standpoint we have had to sectionalize our membership, and we have tried to do it in such a way that members who are interested in the same special subjects may be able to meet and act together for the advancement of their sectional interests, with as much effect and, for all practical purposes, with as much freedom as if they were independent bodies. So far as I have been able to judge, this system is working well and is giving satisfaction. Our constitution has so far proved to be sufficiently flexible to provide both the necessary freedom and the necessary government, and I think that the main body of opinion in the Institution favours the continuance of development along those lines. Our policy is, therefore, to offer the ægis of the Institution to any distinctive group of qualified workers in the electrical field who wish to act together for the advancement of their science and art, in a wider sense than the interests of one particular firm or concern, and I think I might describe our idea of the status that such a special section should hold in the Institution by saying that it corresponds more or less to what we know as Dominion status within the British Empire. Up to the present we have not evolved a satisfactory system of caring for the whole of the natural adherents of such groups. I have been very much impressed by the fact that electrical societies which have transformed themselves into sections of the Institution have been called upon to make the very great sacrifice involved in shedding the large proportion of their membership not individually qualified by professional education and experience for membership of the Institution. Any relaxation of the standard of qualification required for corporate membership is of course quite out of the question; the movement of the future is much more likely to be in the opposite direction. But I feel sure that we shall, in due time, devise methods of meeting this difficulty which will enable the Institution to extend its usefulness among the classes which have at present to stand outside it, in ways which will not only benefit those immediately concerned but will react to the benefit of the electrical industry as a whole, and to the benefit of the nation. As Sir James Jeans has very pointedly put it to us, anything which tends to spread and to make more universal the ideals of science and engineering is an object worthy of support. As he says, we are living in a great age. I do not suppose that ever since this world began has any generation of men witnessed such a panorama of scientific progress as that which has unrolled itself before our eyes during the past 30 or 40 years, and which has led to developments entering intimately into the whole social and commercial structure of the world. Many of us can remember the days when there was no electric light or electrical machinery, no Parsons steam turbines, no internal-combustion engines or motor-cars, no phonographs, no cinematographs, no radio, no flying machines, and I might add —though perhaps this may be counted as a blessing— no telephones! And this wonderful technical progress has been accompanied by a kind of lifting and widening of the whole intellectual horizon of mankind; a real mental revolution accomplished by science and by the exercise of the scientific spirit, the significance of which has yet been seen and appreciated only by relatively few. Science is, of course, the spear-head of engineering, and there is no more pressing material need to-day than the increase of science, and the inculcation of the methods of science and engineering in the education of the nation as a whole. What, after all, is engineering but the optimum use of available means to secure the desired end? What is the constructive statesman or the director of a great business but an engineer? What is Rutherford, sitting here with us to-night—our Faraday Medallist of this year—the man who first began to take atoms to pieces in order to show us how they are made, and who, with Dr. Jeans and others here, has carried the banner of English science into the very highest places of the world's honour—what is he but an engineer? Every true engineer is a builder, and I think that the converse is equally true: every man who builds for the future, with a just appreciation of permanent values, is a true engineer. There is urgent need for great numbers of men with the scientific and engineering turn of mind to come forward and take their places in industry, and to give industrial leading. Fortunately, their capacity to do it is becoming more and more widely accepted as time goes on, and I hope that such mentality and training will before long be looked upon as essential for the efficient direction of British effort. One could no doubt enlarge on that theme, but I must leave it and return to my more immediate objective, the subject of this Institution and of the graceful and generous way in which the toast of its success has been put before us to-night. Once more I thank Sir James Jeans most sincerely—and I know that in doing so I speak for every individual here—I thank him for the kind way in which he has presented the toast, and I thank you all, my lords and gentlemen, for the very hearty manner in which you have responded to it."

Captain J. M. Donaldson, M.C., (Vice-President) then proposed the toast of "Our Guests," to which **Sir John Brooke, C.B.,** (Electricity Commissioner), responded.

A reunion was subsequently held in the Victoria Hall of the Hotel.

INSTITUTION NOTES.

Professional Engineers' Act (Queensland).

Corporate membership of the Institution is one of the qualifications entitling to registration as a Professional Engineer under the above Act.

The Benevolent Fund.

The Committee of Management of the Benevolent Fund desire to draw the attention of the members to the last page of the cover of this issue of the *Journal*, on which will be found particulars of certain publications, etc., which are offered for sale on behalf of the Fund.

Elections and Transfers of Members.

At the Ordinary Meeting held on the 13th February, 1930, the following elections and transfers were effected :—

ELECTIONS.

Member.

Arendt, Otto.

Associate Members.

Cameron, Charles James.
Campbell, Harold Gordon, B.Sc.
Cunningham, Bertram Tweedale.
Damant, Eric Louis B.
Hunter, Francis Grant, Lieut.-Commander R.N.
Jolley, Ernest Harris.
Maxwell, Robert Gibson, B.Sc.(Eng.).
Nowacki, Friedrich-August.
Pallot, Charles Frederick.
Pullan, Arthur Hubert.
Saunders, Norman Clement J.
Symonds, Alfred Edward J.
Tudball, Fergus Campbell, B.Sc.
Washington, Albert Bryan, B.Sc.
Wheatley, Mervyn Savile.

Companion.

Gray, Robert Cochran, M.A., D.Sc.

Associates.

Cater, Clinton.
Chapman, Gerald Sidney.
Narayanan, Kannanur, B.A.
Stave, Cecil Herbert.

Graduates.

Adley, Arthur George, B.A.
Burke, Anthony, B.E.
Clifford, Cecil Frank, B.Sc.
Crowe, Henry Eyre.
Evans, Trevor.
Floyd, Geoffrey.
Guha, Hem Chandra, B.Sc.
Lambert, Austin Edmund, B.E.
Robson, Oswald Murray, B.A.
Rossler, Albert.
Smail, George Grey, B.Sc.
Whiteley, Joseph William, B.Sc.Tech.

Students.

Allen William Kenneth.
Arnott, Arthur Walter.
Ashworth, James Lewis.
Balean, John Hermann.
Barker, Harold.
Barr, James.
Beaton, Robert Frederick.
Bedil, Shams Din.

Students—continued.

Bilton, Stanley Maurice.
Blair, David Charles.
Blewett, Harold Stuart.
Bowie, Sydney Herbert.
Brewer, Sydney Roy B.
Bridge, Hugh John.
Bridger, William.
Brooks, John Frederick.
Burton, John Shepherd.
Caddy, Bernard Charles.
Carte, Humphrey John C.
Combridge, John Hayden.
Cook, Arthur.
Cooper, Lawrence Henry H.
Creasey, Frank Raymond.
Damany, Lax Michand Mansingbhai.
de Lestang, Marie Clement, R.
Dreyfus, Henry Benfey.
Farren, Leslie Ivan.
Fitzer, Herbert Clyde.
Forster, Edward.
Freebody, John William H.
Gadkari, Narayan Laxman.
Gatehouse, Harry William C.
Groom, Leonard William.
Hadlow, Loris Ivor.
Harris, Thomas Alfred.
Hartley, Alfred William E.
Harvey, John Philip.
Haslam, John Robert.
Hedley, John Arthur J.
Higgins, Stanley George.
Hodges, Philip George L.
Holt-Jones, Cecil.
Hughes, Claude Samuel G.
Inglis, Felix Stevens.
James, David Edward.
Jarvis, Charles McKechnie.
Jewsbury, Thomas.
Jobling, Hugh Beresford.
Kelly, Richard Gould.
Kennedy, Philip William.
Khosla, R. D.
Knott, Harry Cleal.
Lacey, Ronald Edgar.
Lewis, Hexell Arthur.
Lissimore, John Philip.
Little, James.
Lucas, John Harold.
McIlvride, Keith Jack A.
MacKenzie, Murdo.
McKinlay, John Finlay.
MacMaster, Ian James.
Mansell, Frederick Raymond W. K.
Marshall, Philip Henry.
Mathur, Suraj Jang B.
Meeres, Alfred Shirley.
Miller, Andrew Hugh.
Miller, Henry Arthur.
Moore Frederick George.
Nasib, Mohd.
Naylor, Arthur Edgar.
Newsam, Harold, B.Sc. (Eng.).
Onslow, William George.
O'Sullivan, Barry Joseph C.
Pafford, Wilfred Clive.
Page, Harold.
Parshad, Sital.
Patel, Natverlal Lalaji.
Pathak, Chun Chun.
Peak, Charles Harrison.
Pinto, David Joseph, B.Sc.
Ramana, Jagdhir Singh, B.A., B.Sc.(Eng.).
Randell, Wilbur Horatio.
Reeve, John Polden.
Richardson, Dennis Eric O.
Ritchie, David Findlay.
Roddan, Robert Alexander
Rousell, Sydney Michael E.
Rowe, Ernest George.
Searby, Norman Halifax.
Sherwood, George Eliot C.
Shuttleworth, Harry.
Stephens, William Henry.
Strathmann, Robert Christian.
Thadani, Shamdas Tharumal, B.Sc.
Tucker, Edward William.
Underwood, Leonard Edwin.
Vernon, John Russell D.
Wakeford, Robert.
Walker, Alexander Frederick.
Walker, Frederick Alfred S.
Watkins, Thomas Peter.
Winstanley, Kenneth Charles.
Young, James Ernest.
Young, Robert Eric.

TRANSFERS.

Associate Member to Member.

Platt, Frank Cuthbert.
Roxburgh, Andrew Kean.
Sarsfield, Leslie Gerald H., M.Sc.(Eng.).

Graduate to Associate Member.

Anderson, Frank Cordue K.
Beaufoy, Samuel, B.Sc. (Eng.).
Beynon, John Henry.
Brook, Salomon.
Buckley, Cornelius Francis.
Charlton, Thomas Hadwen.
Davies, Edgar Wilfred.
Evans, Alan Wainwright, B.Eng.
Fleming, David Crawford, B.Eng.
Geernaert, Sidney Glorieux.
Grundy, Geoffrey Earnshaw.
Komarow, Alexander.
Mather, Frank.
Prickett, John Howard.
Richards, Ernest Montgomery, B.Sc.(Eng.).
Sahgal, Amar Chand, B.A., B.Sc.Tech.
Stahl, Henry Cecil.
Taylor, John Russell, B.Sc.
Templeton, William, B.Sc.
Thomas, Horace Augustus, M.Sc.
Uglow, John Curtice, B.Sc.

Student to Associate Member.

Preston, Geoffrey William.
Watkins, Donald John, B.Sc.(Eng.).

Student to Graduate.

Kirsten, Kenneth Haenart, B.Sc.

The following transfers have also been effected by the Council under the provisions of Bye-Laws 14, 15 and 18:—

TRANSFERS.

Graduate to Associate.

Adams, Herbert Leslie.
Ashton, Thomas James.
Atkins, James Walter.
Buckley, John Stanley.
Bulow, Vincent Alfred M.
Butler, John Henry.
Carrott, Herbert Edward.
Cope, William John L.
Durrell, William Henry.
Evans, Alfred Charles.
Galloway, James.
Gough, Howard Butler.
Grant, David Leslie.
Guthrie, Ernest Alfred.
Halliday, Harold Robertson.
Hambleton, Charles Ernest.
Hunter, Thomas Chalmers.
Jackson, Frederick Stanley.
Lash, Alfred Reeves.
Lewis, David.
McPherson, Angus.
Mittra, Binay Kumar.
Mukerjee, Nanigopal.
Patterson, William Herbert.
Pittaway, Kenneth.
Price, Arthur John.
Rac, N. Srinivas.
Sleigh, Charles Crofton.
Smith, John Albert.
Stonehill, David Hareven.
Sundar, Padma Malla.
Tandon, Ch. Parkash Laull.
Tydd, George Allan.
Vogel, Theodore Mathieu.
Wellingham, Herbert John.
Wheeler, Edmund Frank.
Wills, Maurice Alan.

Associate to Graduate.

Black, Richard Henry.
Clark, Ernest Cameron, B.Sc.
McKechnie, Alan Francis.
Phillips, John Douglas N.

Student to Graduate.

Batra, Rajindra Nath.
Beaumont, George Harold.
Bevan, Percy Archibald T.
Bickerstaffe, John, B.Eng.
Brickell, Robert Patrick.
Brockbank, John Bowman.
Brookes, Samuel Ernest.
Brown, James Connell, B.Sc.
Brown, James John.

Student to Graduate—continued.

Brown, William John.
Buchanan, Donald Geoffrey, B.Sc.(Eng.).
Calwell, James Edmonston M., B.E.
Castellan, Guy Edward.
Cheryan, Paruthiparambil B.Sc.(Eng.).
Christy, Geoffrey, B.Sc. (Eng.).
Collins, Wilfred John.
Cowlishaw, Alwyn.
Crofton, Robert Denis, B.Sc.(Eng.).
Daines, Sidney Arthur.
Dannenbaum, Arthur, B.Sc.
De Larue, Serge.
Dingwall, Ronald.
Dransfield, Tom.
Edwards, George William.
Ellwood, Percy.
Emery, Edward Thomas G.
Fielder, Cecil Redvers.
Fielding, Alfred Leslie.
Fitzpayne, Eric Richard L., B.Sc.
Flint, Ernest Frederick.
Gardiner, Stephen Maurice, B.Sc.
Gartside, Arnold.
Goodchild, Ronald Frank.
Gould, Charles Thomas.
Heath, Frederick Ernest.
Heyes, Clifford.
Hocking, Russell Charles, B.Sc.
Hollingsworth, John Edward R.
Horlock, Robert Pasifull, B.Sc.(Eng.).
Humphriss, Eric Allan, B.Sc.(Eng.).
Jephson, Peter Douglas.
Johnstone, Andrew Wauchope, B.Sc.(Eng.).
Jones, Harold Edward.
Just, Ernest James.
Kay, Edward John R., B.Sc.(Eng.).
Kelly, William.
Langley, Arthur Henry, B.Eng.
Laredo, Edward, B.Eng.
Lloyd, John Leslie.
Lusty, Harold Higson.
Marchant, Albert Edward, B.Sc.Tech.
Mare, Arthur John.
Matthey, Henry Albert.
Mildner, Raymond Charles, B.Sc.(Eng.).
Millward, Gerald Richard.
Mittra, Madan Gopal, B.Sc.
Mole, Franklin Henry.
Moore, William Herbert, B.Sc.
Morley, Cyril George L.
Moss, John Lawrence.
Mukerjee, Hemendra Nath.
Murdoch, James Barclay B., B.Sc.
Newton, John Burgess.
Olson, Andrew Hugh, B.Sc. (Eng.).
Page, Thomas Henry D.
Painter, William James A.
Palmer, Edward Barry.
Paterson, Allan, B.Sc.
Pearce, Donald John, B.Sc.
Phillips, John Waldron.
Pilfold, Charles William.
Pratt, Alan Anderson.
Raybould, Sidney.
Robertson, Alan Stuart.
Rose, Victor Reginald.
Rushton, James.
Sainsbury, Frederick Walter J.
Scriven, Vernon Colin.
Sears, Herbert William.
Sims, Robert Frank, B.Sc. (Eng.).
Snelling, Charles Arthur.
Stephens, Maurice Norman B.
Stewart, Ian, B.Sc.
Vickers, Harold Edwin.
Vine, Harry Albert E.
Vyas, Baldevbhai Motiram.
Wadhera, Chaman Lal.
Wallace, Leslie Macquestin, B.Sc.(Eng.).
Walters, Frederick.
Watthews, Herbert Thomas.
Watts, John Lea.
Whitworth, Gerald, B.Sc. (Eng.).
Willard, Leslie Albert.
Williams, Alan Cyril O.
Wilson, Kenneth Ellerby.
Woodroffe, Daniel Norman.
Young, Frederick Joseph, B.Sc.(Eng.).

Associate to Student.

Dinsmore, Harry.
Hall, Percival Henry G.
Hami, Mehemed Behaeddin.
Keay, Edmund McLaren.
Staddon, Edward Charles.

THE HEATING OF BUILDINGS ELECTRICALLY BY MEANS OF THERMAL STORAGE.

By Lieut.-Col. S. E. Monkhouse, R.E. (T.R.), and L. C. Grant, Members.

Summary.

Considerable progress has been made with electrical heating in recent years. The higher cost of electrical energy as compared with the cost of solid or liquid fuels is compensated by the advantages of cleanliness, convenience and efficiency.

The authors advocate the more extended use of electrical heating by adopting thermal storage, thus enabling energy to be used during off-peak hours. They contend that such a system is economical to operate, and they show that, for large buildings, electrical heating can compete with systems employing other forms of fuel.

Introduction.

During the past few years there has been considerable development in the electric heating of buildings, in which radiators and other types of direct heating appliances have played the principal part; but as the energy supplied for such apparatus must be unrestricted and must always be available for use, it follows that the price charged for such supplies is governed largely by the same factors as apply to any ordinary supply of electricity.

Continuous availability necessitates that any such supply must bear its proper proportion of the overhead charges of the power system, and as these are usually largely influenced by the shape of the supply undertaking's load curve and by the load factor of the system, it seems logical to conclude that, for supplies of constant load taken regularly each day but confined to off-peak hours only, there could be an appreciable reduction in the prices charged. It is the main purpose of this paper to describe means whereby advantage may be taken of these conditions, by making use of an off-peak supply for the heating of buildings.

The inherent low load factor and thermal efficiency of steam-driven electricity generating stations necessitate that if heat units from such a source are to be sold at a price which can compete with that of heat units derived from coke or coal burnt in a central heating plant, then full credit must be allowed for the improvement in the load factor of the system which would result from the sale of such units, just in the same way as discrimination is shown in the allocation of capital charges when tariffs are designed for lighting, power and other supplies of widely divergent characters.

Factors Influencing Cost of Current.

The practice of allocating to supplies for power or heating by radiator the same proportion of capital charges as is allocated to a lighting supply, is one which would be discountenanced by most supply engineers, as such a course, if followed, would throttle further development. Similarly, when supplying off-peak load, provided it is taken regularly throughout a certain portion of the year, the overhead charges should be lower for at least three reasons, namely :—

(1) The supply makes use of available power-station and system capacity at a time when it would not otherwise be producing revenue.

(2) The amount of energy consumed by such apparatus is large in relation to the capacity of the apparatus connected.

(3) The night load for heating being regular in character and a known quantity to the supply undertakings, it is possible for them so to arrange the conditions of night operation that a smaller proportion of stand-by plant than usual is retained in use, which in turn results in an improvement of the plant load factor and in the general efficiency.

In spite of the manifest difficulties of supplying current at a competitive price for direct heating, e.g. by the use of radiators and convectors, considerable development has taken place, largely on account of the ease of installation and convenience and cleanliness in operation, but as most electrical methods of heating have similar advantages, irrespective of the size of the installation, it is evident that, with the energy supplied at a cost which should be possible with off-peak thermal storage, considerable developments in electric heating may be expected.

The subject of what should be charged for electricity supplied under these restricted-hour conditions is one on which there will naturally be a great diversity of opinion, as this charge must depend largely upon local conditions, cost of coal, method of production and relationship of generating and system capacity to sales; and the authors feel it to be a matter altogether beyond the scope of this paper.

For these reasons they have refrained from making any definite statement on this subject, being content, in giving data in regard to the cost of operating the electrical equipments they have described, to indicate the maximum cost of current at which it would be economical for the user to adopt electric heating for each scheme, leaving it to the suppliers to decide whether it would be economical to sell energy at a figure which would be competitive with local prices for other forms of fuel.

The authors would like, however, to express the opinion that, if proper allowance be made by the supply undertakings for the appreciable value attached to any load which assists to fill the valleys of the load curve, there should be neither difficulty nor hesitation on their part in quoting prices which would give rise to the extensive adoption of equipments such as those described in this paper.

It is important to recognize that the supply of electrical energy for a heating system means, fundamentally, the supplying of heat units, and it should be borne in mind that it is liable to be compared (perhaps erroneously) by the user, purely on a heat basis when in competition with the fuels generally used, such as oil or coke.

OFF-PEAK STORAGE.

To make use of off-peak supplies a system of storage is necessary, as usually the off-peak hours are the few hours on either side of midnight when the ordinary public services are not generally required.

A cheap and economical method now employed of storing heat from off-peak electrical energy is to heat water during the off-peak hours and to store it in tanks suitably lagged so as to enable them to retain the heat for use when required during the remainder of the 24 hours.

Systems operating upon this principle have the important advantage over systems making use of solid or liquid fuels, that flues and smoke stacks are dispensed with. This, particularly with a new building, is a point of considerable importance, and results in an appreciable saving in the first cost of the building and its subsequent cost of maintenance. It has also an appreciable value in making available, for office or other accommodation, additional space with possibly an increased rental value.

The operation wages costs for electrical installations such as are described in this paper can be eliminated by the adoption of automatic working, while the annual overhaul and renewal charges are almost negligible.

In spite of much propaganda the value of the smokeless city is still but little appreciated in this country. With a better appreciation of the value of a pure atmosphere, the scope of the electrical thermal-storage system of heating should be much enlarged.

STORAGE MEDIA.

Heat can be stored conveniently in many substances, e.g. water, iron and oil. Water has several advantages, not the least important being its relatively low cost compared with that of other storage media.

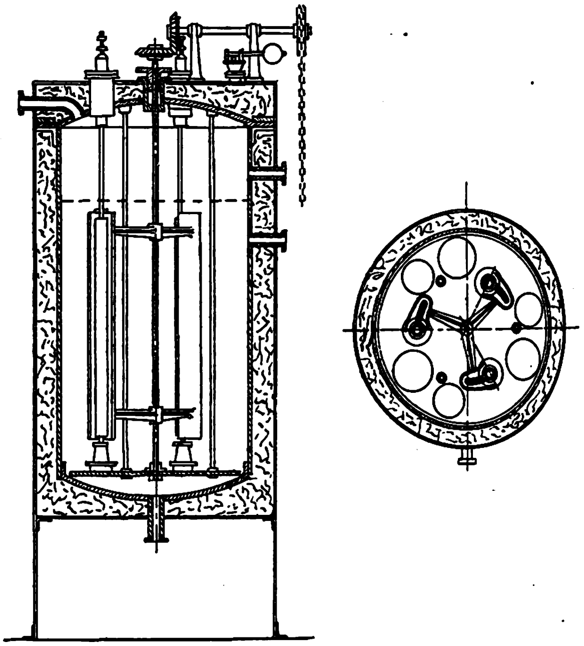

FIG. 1.—Electrode method of direct water-heating.

Water.—The specific heat of water is 1·0 and its specific gravity is also 1·0. It can be loaded under pressure to store heat up to 280° F. without boiling, thus giving a working range of 280° F.-120° F.

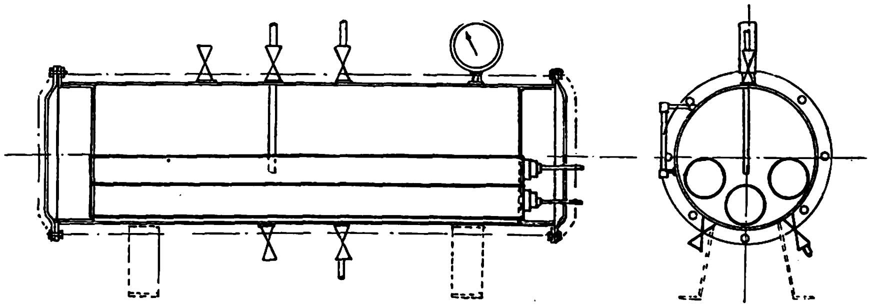

FIG. 2A.—Immersion-heater installation (large).

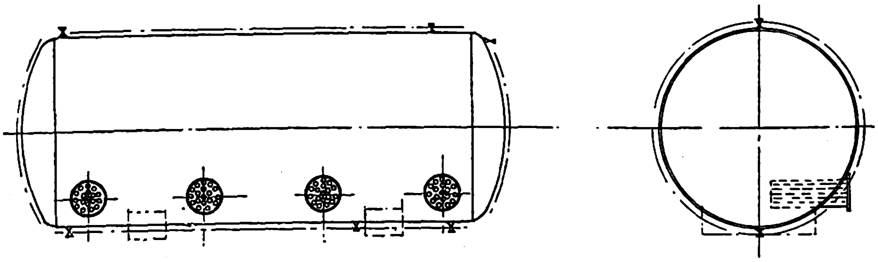

FIG. 2B.—Immersion-heater installation (small).

= 160° deg. F., which enables 160 B.Th.U. per lb. to be stored, or 160 × 62·5 = 10 000 B.Th.U. per cub. ft. The cost of water per 10 000 B.Th.U. stored is about 0·1d. with water at 1s. 4d. per 1 000 gallons.

Iron.—This material has a specific gravity of 7·2, but its specific heat is 0·13. It can be heated to a temperature of about 700° F., but cannot be worked much below 200° F., which gives an available temperature range of 700° F.–200° F. = 500 deg. F., giving 65 B.Th.U. per lb. or 65 × 62·5 × 7·2 = 29 800 B.Th.U. per cub. ft., i.e. considerably more than could be stored in water in a similar space. The heat-flow through iron is, however, such that it is rather difficult to secure the heat distribution desirable, and this, coupled with the fact that at the temperature mentioned the material would be working on the glow point and would necessitate expensive heat insulation, makes it doubtful whether the temperature range mentioned could be maintained economically under working conditions. The cost of iron castings at £14 per ton is approximately 18·8s. per 10 000 B.Th.U. stored.

Oil.—A suitable oil has a specific heat of 0·4 and a specific gravity of 0·92. It can be heated to a maximum temperature of 500° F., the working range thus being 500° F.–120° F. = 380 deg. F., giving 152 B.Th.U. per lb., or 152 × 62·5 × 0·92 = 8 753 B.Th.U. per cub. ft. The capital cost of oil per 10 000 B.Th.U. stored is thus 7·2s. with oil at 1s. per gallon.

Turning then to a consideration of heat storage in water, there are two ways of converting the electrical energy into heat, namely, by means of (*a*) electric water heaters, which are not, strictly speaking, boilers, and (*b*) electric steam boilers in which steam is produced and is subsequently utilized as a medium for transferring the heat to the storage system proper.

Both water heating and steam raising can be accomplished by means of either (*a*) equipment wherein the current is supplied to electrodes immersed in the water into which the current is led and in which heat is produced in proportion to the resistance of the water and to the current passed through it, or (*b*) resistance heaters, wherein the current is used to heat wire-wound or other forms of resistors which in turn heat the water.

Fig. 1 shows diagrammatically the electrode method of direct water-heating and steam-raising, while Figs. 2A and 2B show the resistance method similarly applied.

BOILERS OR WATER HEATERS EMPLOYING ELECTRODES.

In boilers or water heaters of the electrode type the loading of the equipment is determined by the area of electrode and the hardness of the water, care being necessary in the design of the electrodes to ensure that the current density is kept low, in order to avoid internal arcing between electrodes. Commercially pure water, that is, water of less than 1 degree of hardness, when used in an electrode boiler of 1 000 kW capacity passes a current of about 1 or 2 amperes at 6 000 volts. On the other hand, commercial town main water is frequently of 15 to 20 degrees of hardness, which results in something approaching a short-circuit in the boiler. Therefore, the water hardness must be adjusted to approximately 6 to 10 degrees, so as to pass full load at about half electrode immersion.

Various methods of load regulation are made use of. Messrs. Sulzer Brothers use movable deflectors which are hydraulically raised or lowered to the required degree of immersion, while Messrs. Siemens use movable electrodes which are kept at approximately earth potential.

In the Reyrolle electrode boiler, fixed electrodes are used and the load is regulated by varying the rate of feed. This method obviates the necessity for an awkward electric-cum-steam gland and enables the terminals to be completely encased in metal, a particularly important point in a boiler house.

The Oerlikon Co. use fixed electrodes and regulate the load by controlling the water-level in the boiler, but, owing to the variation in storage capacity which would result, this method is practicable only where the boiler is separated from the storage cylinder.

As electrode boilers are frequently of the 3-phase type, care must be taken to avoid phase unbalancing and the consequent neutral or earth current, though trouble from this source can be avoided by careful electrode adjustment.

It is an advantage in favour of the electrode boiler that it can be designed almost equally well for either high or low voltage, but the electrodes for the low-voltage boiler must naturally be correspondingly larger for a given load rating than for the high-voltage pattern, and it is worth noting that the extra electrode area for low-voltage work sometimes necessitates a complicated arrangement of electrodes which tends to increase the cost. It is on this account, therefore, and because of the somewhat greater difficulty of *applying* low-voltage electrode boilers to a low-voltage earthed-neutral system that the resistance heater method is frequently preferred when only a low-voltage supply is available (because the resistance heaters are completely insulated from earth and consequently avoid the formation of a short-circuit through earth to the network neutral).

RESISTANCE HEATERS.

These usually embody the storage cylinder and " boiler " in one unit, and the storage system usually takes the form of a horizontal drum with the resistance heaters placed along a horizontal axis.

In order to obtain the best circulation, the heaters should be fixed at a low level in the cylinder, as the water should be put into circulation in order to obtain an even temperature throughout the cylinder. If this were not done, there would be a temperature gradient throughout the water at the time of greatest storage, and this would result in a loss of heat-storage capacity.

With the object of improving the heat distribution in the cylinder it has on some occasions been considered an advantage to place some of the heating elements at different levels throughout the storage cylinder, or, as an alternative, to accelerate the circulation by means of a pump during the water-heating period so as to ensure a good circulation and an even temperature throughout the storage cylinder.

For medium-sized and large installations heater units are mounted in groups each of which has a capacity of about 50 kW. Heaters so arranged can be conveniently operated by means of thermostats and contactors so that the load taken during the water-heating period can be automatically controlled.

ATMOSPHERIC TEMPERATURE RANGE OF STORAGE CYLINDER.

The storage of heat in water depends upon the weight of water and the temperature attained, and as the atmospheric temperature of the water stored must not exceed atmospheric boiling point the upper temperature limit under these conditions is fixed at about 210° F. "Panel" heating installations require a normal circulating temperature of 120° F., therefore for such duty the temperature range is fixed at 210° F.–120° F. = 90 deg. F., and accordingly under atmospheric pressure 90 B.Th.U. can be stored per lb. of water. (Radiator systems generally require a higher circulating temperature.)

Storage under Pressure.—The heat storage for a given space can, however, be considerably increased by putting the storage cylinder under pressure, and a pressure of the order of 60 lb. per sq. in. (corresponding to 138 ft. of height) is often obtainable in modern buildings. It can be simply applied by mounting a small tank on the top of the building and piping it to the storage cylinder, thus stabilizing the head and consequently the boiling point, but it is advisable to keep the upper temperature limit rather below the boiling point, otherwise trouble with water vapour and steam formation may be experienced.

The boiling point at a pressure of 60 lb. per sq. in. is 292° F., so that the upper limit of temperature can be made as high as 285° F., the available temperature range thus becoming 285° F.–120° F. = 165 deg. F., or an increase of 75 × 100/90 = 83 per cent over that available at atmospheric pressure.

Large installations are now working in this country at atmospheric pressure and at higher pressures, actual examples of the latter being 30, 50 and 70 lb. per sq. in. Some of the smaller plants have been arranged to work at atmospheric pressure in order to avoid complication or because of the lack of a convenient method of obtaining the required head.

Heat Loss during Storage.—It is essential that efficient lagging should be used in order that the daily heat loss from the storage cylinder should not be excessive. A good commercial lagging of about 2 in. thickness is capable of limiting the heat loss to about 40 B.Th.U. per sq. ft. per hour with a temperature gradient of 145 deg. F. With carbonate of magnesia of 6 in. thickness, the loss can be reduced to about 15 B.Th.U. per hour and it is possible to reduce this loss to 5 B.Th.U. per hour if a heavier lagging be applied. About 12 to 15 B.Th.U. radiation per sq. ft. per hour seems to be the most economical figure for the majority of installations, taking a reasonable balance between the cost of lagging material and the cost of the B.Th.U. radiated.

There appears to be need for further development in laggings; the following table shows that the usual plastic boiler covering could be improved upon, particularly for low temperatures, by the adoption of some other form of heat insulation, although the first three materials shown in the table are considerably more expensive for a given weight. Cellular metallic laggings are promising in some respects.

ARRANGEMENT OF APPARATUS.

Combined Storage and Heater System.—The combined arrangement usually consists of one or more cylinders fitted with immersion heaters either of the withdrawable pattern or otherwise, the cylinder or cylinders being fitted with flanges for the circulating pipes, the filling and emptying pipes, the pressure tank and vent pipes, and also with thermometer and thermostat pockets. The circulating system is coupled to the top of the cylinder. A constant proportion of hot water is drawn off and added to the water in the circulating system, while an equal amount of cold water is returned from the circulating system to the cylinder, the relative proportions of water re-circulated and that drawn from the storage cylinder being regulated by means of suitably placed valves. In small installations these valves are sometimes arranged for hand control, but in large installations it is desirable to adopt servo-motor operated valves which are controlled automatically by a thermostat in the main flow pipe.

Thermo-siphon circulation can be used if great simplicity is of importance, but with automatic mixing a small pump has advantages and the cost is usually offset by the reduction which can be effected in the diameter of the pipework (see Fig. 3).

Separate Unit Scheme.—This arrangement, which makes use of a heater separate from the storage system, usually means that a steam-raising boiler will have advantages over a water heater, on account of its greater flexibility in operation. The use of such a boiler necessitates the introduction of a calorifier bank between the boiler and storage system.

The calorifier generally takes the form of a cast-iron drum tubed from end to end after the manner of a surface condenser, with a steam space outside the tubes. The steam from the boilers is passed into the outer space between the tubes, while through the latter the water from the storage cylinder is pumped and so warmed by contact with the steam-heated tubes. During this process the steam becomes condensed and passes from the calorifier through a trap system, thence to a feed or make-up tank to be re-pumped to the boiler.

A pressure-retaining valve is necessary between the boiler and the calorifier in order to control the steam flow; otherwise, if the boilers were connected direct to the calorifiers, excessive condensation would occur in these, priming would be set up in the boilers, and generally the system would become unstable in operation. The pressure-retaining valve may be worked by actual difference in pressure or by setting it for a minimum boiler pressure. Another method which may sometimes have advantages is to control the valve by an electric link so arranged that the steam output and electrical input just balance.

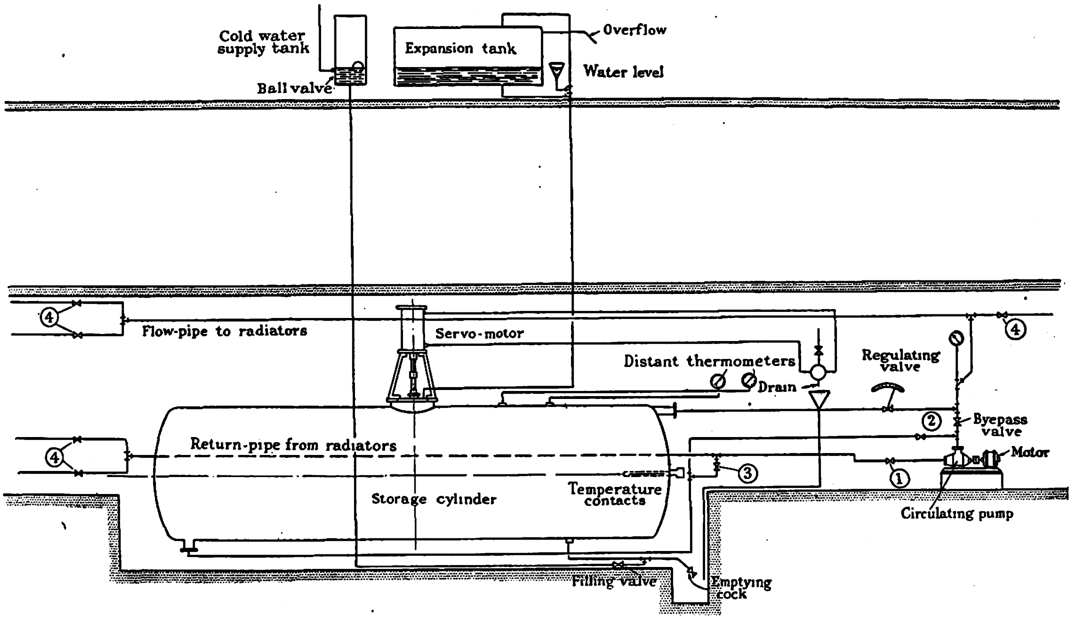

FIG. 3.—Pipe lay-out of electrode water-heater system.

ARRANGEMENT OF APPARATUS IN PRACTICE.

A description of some of the installations now in operation may be of interest and will show how the size of building, the location of apparatus and other considerations influence the general form of the heating installation.

Banca Commerciale Italiana di Roma.—In Italy, a large electro-thermal heating system was installed some 6 years ago at the Banca Commerciale Italiana di Roma, a building which occupies a ground area of 28 500 sq. ft. and has a total volume of 1 175 000 cub. ft. This installation, which was probably the first of its size and type in the world, consists of four Mascarini single-phase, 50-cycle boilers working at 450 volts. Current is taken during the period from 11 p.m. to 7 a.m., and the consumption during the first winter of operation was 0·08 watt-hour per cub. ft. per deg. F. rise in temperature. The cost of a set of 3 single-phase boilers suitable for this installation is about £1 200, plus £400 for one single-phase boiler to act as a stand-by.

Newcastle Motor Depot.—This plant, which was installed early in the year 1925, is believed to be the first of its kind to be used in Great Britain, and consists of a combined storage cylinder and " boiler," the latter being of the electrode type fed at 6 000 volts direct from a 40-cycle, 3-phase system. The normal load current is 20 amperes (equivalent to a load of approximately 200 kW), and the cylinder, which is under atmospheric pressure only, has a water-storage capacity of 6 000 gallons, giving a thermal-storage capacity of about 6 million B.Th.U. of useful heat.

The building has a capacity of 500 000 cub. ft. and is a difficult one to deal with from a heating point of view, because there are five large doors, each measuring 13 ft. by 10 ft., in frequent use, and a motor-driven ventilation system which is used to clear the building of carbon monoxide. Heat is supplied to the building continuously day and night for 7 days per week and about 8 months per annum. The building absorbs 210 000 kWh per annum, current being consumed only between the hours of 7 p.m. and 7 a.m.

There are no labour charges incurred in running this plant, as the only labour involved is the daily operation of closing the high-tension switch, which is opened automatically when the required amount of heat has been added to the storage cylinder.

Maintenance is practically negligible, as it consists only of opening the cylinder manhole once per annum for the ordinary annual inspection. It is expected that even this small item of cost will be reduced, as it would appear from the inspections already carried out that there is little object in having them so frequently.

The only other item of maintenance cost so far incurred has been the replacement of electrodes, and although one new set has been fitted as a precaution it was observed that only slight wear had taken place and the replacement was not really necessary.*

---

* For statement of costs see Appendix 1.

Carliol House Installation.

Heating System.—The authors believe that this installation is the largest of its kind in use in the world.

Separate boilers and storage cylinders are used with intermediate calorifiers. There are two 3-phase boilers each capable of dissipating approximately 1 200 kW at full load, and these are supplied with current at 6 000 volts from a 3-phase, 40-cycle system, each boiler taking approximately 120 amperes per phase.

The boilers deliver steam at 55 lb. per sq. in., the steam production being controlled by an electric regulating-valve system which balances the water input against the electrical input, in addition to which there is a pressure-retaining valve which maintains a fixed steam pressure on the boilers and opens only to pass steam to the calorifiers when the pressure exceeds this value.

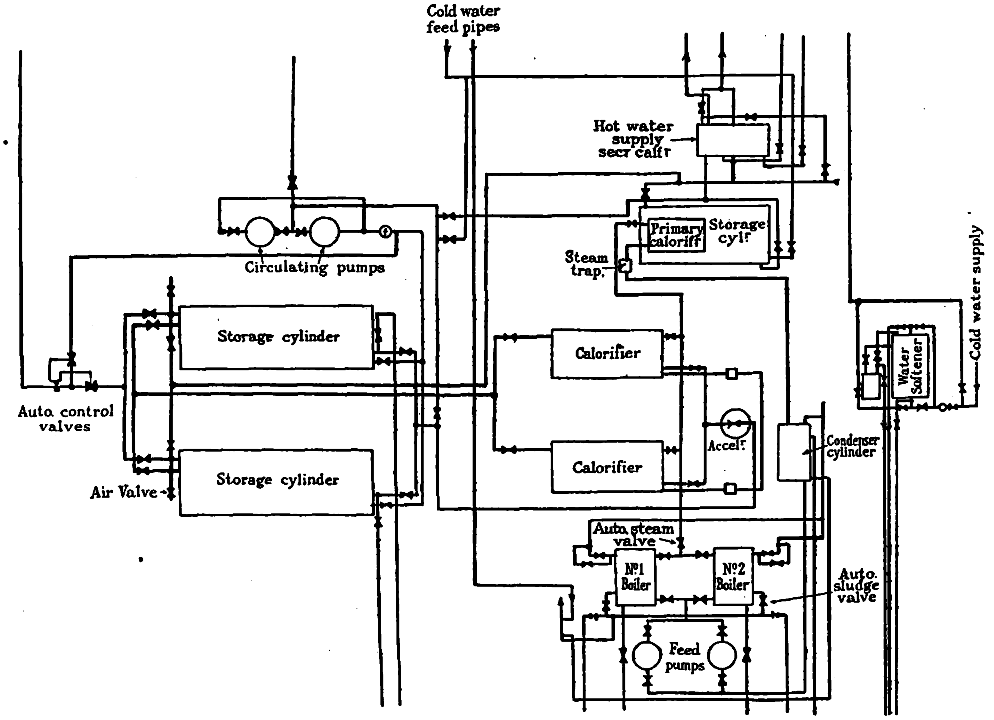

FIG. 4.—Skeleton pipework diagram of Carliol House installation.

The calorifiers, of which there are two, so arranged that either or both can be used in conjunction with each of the boilers, are each capable of handling an average steam output equivalent to 650 kW dissipation and, as already described, are somewhat similar to surface condensers in arrangement. The steam passes over a series of tubes, the water from the storage cylinders being pumped through these tubes and so warmed by contact with them, the steam and condensate being passed through traps to the feed tank and returned to the boilers.

All the water in the boiler-calorifier-feedtank circuit is initially passed through a softener and reduced in hardness from about 16 degrees to approximately 8 degrees, thus enabling the water-level in the boilers to be adjusted to about one-half or three-quarters water gauge at full load.

It has been found that there is a tendency for the hardness of the water in the boiler system to fluctuate, but this condition is satisfactorily compensated by the provision of a trickling draw-off valve which takes water from a predetermined level. Thus if the water tends to become harder, water is drawn from near the boiler bottom, while a tendency to soften is corrected by drawing off from a higher level. The heat loss involved in this process is so small as to be almost negligible. Even this small loss is further reduced, as the hot water is passed through a simple form of tubular feed-heater on its way to the drains—a precaution which also meets any local by-law that may be opposed to the passing of hot water into the town's drains. The cost of the water thus run off is negligible.

The two storage cylinders each measure 34 ft. in length and 9 ft. 6 in. in diameter, and enclose a total water volume of approximately 4 800 cub. ft. or 30 000 gallons under a pressure of 48 lb. per sq. in. Hence at storage temperature (i.e. 230° F.) there are contained in this volume of water approximately 60 million B.Th.U., of which about 50 million are available for ordinary use, the balance representing the heat first expended in raising the temperature of the town main water from 50° F. to 100° F.

Panel Heating System.—The system of radiators installed in the building is of the panel type. Each panel consists of a grid of $\frac{1}{2}$ in. internal diameter mild steel tubing sunk into the concrete ceilings and covered with a thin layer of high-grade plaster supported on scrim cloth. The normal dissipation of each panel is

FIG. 5.—Skeleton diagram of electrical connections of Carliol House installation.

about 8 000 B.Th.U. per hour, those on the north side of the building having a slightly greater pipe length and panel surface than those on the south.

Temperature Regulation.—The temperature of the water supplying the central heating system is regulated automatically by means of a relay valve system hydraulically operated and controlled by means of a thermostat in the main hot-water flow pipe, so adjusted as to maintain a normal circulating temperature of 110° F. to 120° F., which corresponds to a temperature of 63° F. at all points throughout the building, under all weather conditions. The arrangements are such that the temperature of the circulating water can be raised to 130° F. for quick heating or emergency conditions.

Consumption.—The building as so far erected is incomplete, but that portion which is in use and has been occupied for two heating seasons has an approximate content of 1¾ million cub. ft., and is therefore of such a size that any data so far obtained may be taken as being representative of the figures that will apply when the building is complete.

During the last complete heating period, which was of great severity, the building required an average daily input of 5 300 kWh, i.e. 18 million B.Th.U. The average outside temperature during this period was 44·3° F., and the air in the building was maintained at a temperature of 63° F.

The electrical consumption per office of 2 000 cub. ft. capacity (i.e. suitable for accommodating three or four persons, including its proportion of corridors, entrance hall, staircases, landings, lavatories, etc.) was 46 kWh per week, which at 0·3d. per kWh represents a weekly cost of about 1s. 1d.

The consumption of current in all cases was confined to the period 7 p.m. to 7 a.m.

On the question of maintenance charges there is little to be said. Beyond opening out the boilers for annual inspection, which occupies two days, the only expenditure that has been incurred has been the provision of one set of electrodes at a cost of £5. Fig. 4 shows a skeleton lay-out diagram of the system, while Fig. 5 shows the electrical connections.

Hot-water Service System.—In addition to the central heating system there is a separate storage cylinder of 1 000 cub. ft. capacity, working under a pressure of 48 lb. per sq. in., to supply the domestic hot-water requirements of the building.

This cylinder has a total heat-storage capacity of 15 million B.Th.U., of which approximately 11 million are available for use. This cylinder derives its heat from the boiler main steam-range, but it differs from the other storage cylinders in that it is fitted with a calorifier forming an integral part of it, the calorifier nevertheless being so designed as to be interchangeable with the two calorifiers of the main heating system.

The water in the storage cylinder is connected by means of a closed system to a secondary calorifier through which town main water is drawn and heated to a constant temperature before being passed to the building. There is, therefore, no draw-off from the storage system.

OTHER INSTALLATIONS.

A Newcastle-upon-Tyne Block of Offices and Showrooms.—This consists of a new building comprising a block of offices and showrooms, the cubical contents being 300 000 cub. ft.

The storage installation is arranged as a single unit and consists of a combined storage cylinder and water-heating equipment. The cylinder is 20 ft. long and 8 ft. diameter, and contains 6 600 gallons of water under a pressure of 30 lb. per sq. in., thus storing 7 million B.Th.U. of useful heat.

The electrical heating elements are of sufficient capacity to heat the whole volume of storage water under conditions of heaviest load, in addition to heating the building direct during the storage cylinder heating-period, and are of the wound resistance type formed into a bank of four heaters, each with a full-load rating of 50 kW. Thus the maximum electrical load is 200 kW. The resistor units are so connected as to be suitable for 500-volt working and are controlled in banks by means of a time switch and thermostat, the former switching on and the latter switching off.

The temperature of the water circulated through the building is regulated automatically in much the same way as in the Carliol House plant.

London Underground Railways Offices.—In some respects this installation, which has to heat a building of 2¼ million cub. ft., requiring 8 000 kWh per day (average) heating, is different from those so far described, the principal difference being that the plant is required to work on short charging cycles instead of continuously throughout the usual nightly off-peak period. The supply in this instance is available for use at any time other than the 4-hour morning peak and the 4-hour evening peak of the traction load of the Underground system, hence a smaller storage system than usual is installed.

There are four storage cylinders each 10 ft. high and 9 ft. in diameter. Each cylinder is fitted with three 100-kW 3-phase immersion heaters operating at 380 volts, being fed through transformers from the 11 000-volt distribution system. The cylinders are arranged to work under a pressure of 50 lb. per sq. in. and are capable together of storing some 20 million B.Th.U. of useful heat.

CAPITAL COST.

Capital cost has an important bearing upon the extent to which electricity will be used for central heating systems in the future, for it is evident that if a comparison on a heat basis shows electricity at a disadvantage, the electrical scheme must be able to claim credit on other counts if its use is to be extended.

The saving in the cost of building by the avoidance of flues, stacks, etc., is clearly in its favour, just in the same way as the saving in labour and maintenance charges may be set against the actual extra cost of electrical heat production; but although these items of cost are to be placed on the credit side of the balance sheet there are instances where the balance remains in favour of the scheme making use of solid fuel.

The saving effected by the avoidance of flues and chimney stack, and the value of the extra space that becomes available, are appreciable in the case of larger buildings, an interesting example of this being a building where the owners allowed £2 000 as the value of the stack and flues and calculated the value of their increased rent roll to be £300 to £400.

Carliol House Plant.

	Coke	Electric
Capital charges.		
	£	
Cost of whole scheme, including domestic hot-water apparatus	3 600	5 600
Estimated annual charges (normal winter).		
Energy—1 100 000 kWh at 0·3d.	—	1 375
Fuel—500 tons coke at 26s...	650	—
Interest on plant at 6 per cent	216	330
Depreciation fund on boiler-house plant:		
Coke—10 years at 7·95 per cent per annum ..	286	—
Electric—20 years at 3·02 per cent per annum ..	—	169
Maintenance and renewals ..	150	30
Attendance	550	—
Ash removal	30	—
Total ..	£1 882	£1 904

Notes: (*a*) These figures do not include the saving on flues and chimneys, which would have cost approximately £2 000.

(*b*) The capital cost of the electrical installation is high, for the reason that in this case duplication of plant is complete.

(*c*) At the present time, certain labour charges are incurred with the electrical equipment. These will shortly be eliminated when the complete automatic apparatus has been installed.

[The discussion on this paper will be found on page 676.]

THE HEAT PUMP—AN ECONOMICAL METHOD OF PRODUCING LOW-GRADE HEAT FROM ELECTRICITY.

By T. G. N. HALDANE, M.A., Associate Member.

(*Paper first received* 12*th October*, 1928, *and in final form* 25*th March*, 1930; *read before* THE INSTITUTION 19*th December*, 1929, *and before the* HAMPSHIRE SUB-CENTRE 16*th January, and the* SOUTH MIDLAND CENTRE 3*rd March*, 1930.)

SUMMARY.

The paper deals with a method—which so far has not received the attention of engineers—of converting electrical energy into heat energy. The method is based on the general principle that the efficiency of the heat engine working in the normal cycle is given by $(T_1 - T_2)/T_1$, where T_1 is the high temperature and T_2 the low, and that the heating efficiency of a reversed-cycle heat engine is given by $T_1/(T_1 - T_2)$. The reversed-cycle heat engine (or heat pump) is described, and it is shown both from theoretical considerations and from practical tests on refrigerating plant that where heat at a comparatively low temperature is required, heating efficiencies of the order of from 300 to 500 per cent or even more may be obtained, the heating efficiency being defined as the ratio of the heat produced by the heat pump to the heat equivalent of the electrical energy consumed.

The application of this principle to the heating of buildings and for such purposes as the heating of public baths is discussed, and estimated figures for a public-bath installation are given. The paper concludes with a description of experiments which the author has been carrying out during the past 2 years, and which have demonstrated the soundness of the general principles on which the heat pump is based.

ELECTRICITY AS A HEATING AGENT.

Electrical energy and mechanical energy are readily interchangeable, and it is due to the ease, simplicity and efficiency of this convertibility, combined with the high efficiency of transmission, that the great developments in the electrical supply industry have taken place. Like mechanical energy, electrical energy can also be converted very easily into heat energy, and wherever there is a flow of electrical energy this process is always present to a greater or lesser extent. With properly designed plant, such, for instance, as the electrode boiler, the conversion of electricity into stored heat energy can be carried out with an efficiency closely approaching 100 per cent. Although the processes of conversion of electrical and mechanical energy into heat energy are simple and efficient, the reverse processes can only be carried out with a much lower efficiency; i.e. we cannot utilize the stored heat energy to drive a steam engine and dynamo so as to produce as much electrical energy as was originally put into the boiler. Such a process always involves the rejection of a large proportion of the heat energy in the form of warm condensing water or exhaust steam. Even in the most efficient power stations where the similar process of conversion of the heat energy of coal into electrical energy is effected under the best possible conditions, the highest thermal efficiencies at present attained do not exceed about 25 per cent, and are generally lower. It is necessary, therefore, to burn at least 4 lb. of coal in the power station in order to produce the thermal equivalent of 1 lb. of coal in the form of electrical energy. The consequence of this elementary fact is that the cost per British thermal unit (B.Th.U.) of electrical energy produced from fuel is generally high compared with that of coal and, in most cases, of gas. For many purposes this high cost does not prevent the direct use of electricity as a heating agent, particularly where simplicity of operation, exactitude of control and cleanliness are of primary importance. The same is true where radiant heat or very high temperatures are essential, and in all these fields the electrical industry has already to a large and increasing extent captured the market.

Where heat has to be supplied at ordinary temperatures and in large quantities, and where extreme exactitude of regulation or ease of operation is not essential, it is a much more difficult matter to justify the use of electricity. To a large extent this difficulty has been met by the cheap supply of electricity during the off-peak periods when power can be supplied at the bare operating costs, but even so this cost necessarily includes the cost of burning at least 4 lb. of coal for every 1 lb. equivalent in the form of electrical energy, and unless coal can be obtained at a much cheaper price by the power station than by the consumer, e.g. where low-grade coal can be used by the power station but not by the consumer, the economic difficulties are apt to be considerable. When coal is consumed in hot-water boilers, between 50 and 80 per cent of the total thermal content of the coal can, under favourable conditions, be extracted, the exact percentage depending on the size of the boiler. In actual operation under practical conditions the percentage is generally much lower but would exceed the figure of 25 per cent applying to electrical energy. In the case of gas the process of manufacture involves the loss of some 20 per cent of the calorific value of the coal and when, for instance, gas is consumed for the production of hot water the efficiency of conversion is probably of the order of from 60 to 80 per cent. Thus the overall efficiency of heat supplied through the medium of gas is about 50 to 65 per cent.

ECONOMY OF INDIRECT CONVERSION OF ELECTRICAL ENERGY INTO HEAT ENERGY.

Because of these facts many people, including some electrical engineers, are of the opinion that electrical energy can never be used economically for producing large quantities of heat under ordinary conditions. Such opinions are, of course, based on the assumption that the consumption of 1 kWh can at the best produce about 3 400 B.Th.U. It may therefore come as a surprise to many electrical engineers to learn that this assumption is by no means justified. It is, in fact, possible to produce a very much larger number of B.Th.U. by the consumption of this amount of electrical energy, provided it is converted first into mechanical energy and then used on the Carnot principle to pump heat from a low to a higher temperature. The theoretical justification of this statement follows directly from the principles embodied in the Carnot cycle. Carnot showed in 1824, and Kelvin and others made more explicit at a later date, that if we imagine a perfect reversible heat engine operating by taking heat from a source at a high temperature T_1 and rejecting it at a lower temperature T_2, so producing mechanical energy, the efficiency, i.e. the ratio of the mechanical work produced to the mechanical equivalent of the heat taken in, is $(T_1 - T_2)/T_1$. Carnot showed also that this is the greatest possible efficiency for any type of heat engine working between these temperature-limits. It is, of course, on this fundamental principle that the design of power stations is based, though no power station yet built has ever attained the efficiency which Carnot showed to be theoretically possible. However, he was not concerned with the practical difficulties of designing a perfect heat engine, but rightly argued that because such a machine was conceivable the theoretical consequences which he deduced must necessarily be true.

If we imagine the Carnot engine reversed—that is to say, supplied with mechanical energy and made to pump heat from a low to a higher temperature—the heating efficiency [*] is $T_1/(T_1 - T_2)$. It can therefore be seen that if $(T_1 - T_2)$ be small compared with T_1, a small amount of mechanical work supplied will allow a very much larger amount of heat to be pumped from the one source to the other. In practice the source of the low-temperature heat T_2 would normally be the unlimited heat of the surroundings.

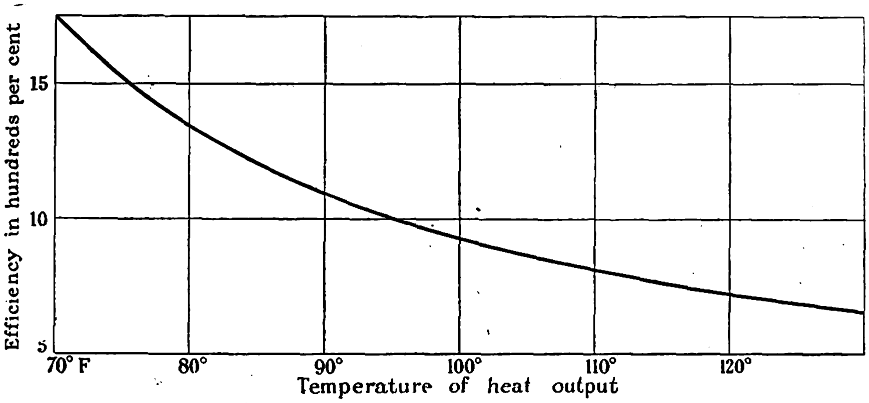

Fig. 1.—Theoretical heating efficiency of heat pump, taking in heat at 40° F.

Fig. 1 shows the heating efficiency theoretically obtainable from the perfect reversed heat engine for such ranges of temperature as might normally be required. It will be seen from the curve that if heat is delivered at 100° F. (560° abs.) and taken in from the atmosphere at 40° F. (500° abs.) the efficiency is 9·33, i.e. 560/(560 — 500). That is to say, for every B.Th.U. of electrical energy put into the heat pump 9·33 B.Th.U. will be delivered at a temperature of 100° F., and as each B.Th.U. of electrical energy may have required the consumption of some 5 B.Th.U. at the power station, the remarkable fact is revealed that it is at least theoretically possible for the consumer of the electrical energy produced at the generating station to obtain very considerably more heat than was required to produce the electrical energy which he consumes. In other words there is an economy in fuel consumption as compared with direct conversion if the fuel is first consumed in a power station, converted into electrical energy and then used to produce heat by means of a heat pump.

In the above example the economy is $(9 \cdot 33 - 5)/9 \cdot 33 = 46 \cdot 5$ per cent, but it must be noted that this economy only exists if the heat required is comparatively low-grade, i.e. low-temperature heat. The economy becomes greater as the temperature range is decreased, and reaches a very high value indeed when the range of temperature through which the heat is to be pumped is only a few degrees. The general principle of the above process was first pointed out by Lord Kelvin in 1852, and a description will be found in his "Collected Papers," vol. 1, p. 515.

OPERATION OF HEAT PUMP.

The reversible heat engine has so far been treated simply as a heat pump, and it is now desirable to describe its operation in more detail. The most familiar type of heat pump is the refrigerator. In the design of refrigerating plant the primary object is the production of cold rather than heat, but the two operations are, of course, complementary. The process of producing cold is simply that of pumping heat from a relatively cold to a relatively hot source, but in this process particular attention is paid to the prevention of the leakage of heat into the cold source, whereas no attempt is made to prevent the escape of heat from the hot source; in fact it is of assistance to the refrigerating process that the heat removed from the cold source should be allowed to escape in every possible way. If a refrigerating plant were to be treated as a heat pump in which the primary product is the heat rejected to the hot source, the order of importance would be reversed and every opportunity would be given for the leakage of heat into the cold source and every precaution taken to prevent leakage of heat from the hot source. Apart from this and minor differences in the temperature ranges over which the plant would work, a refrigerator is precisely the type of heat pump which, for the purposes of this paper, it is desired to consider.

---

[*] In what follows the term "heating efficiency" as applied to the heat pump denotes the ratio, measured in hundreds per cent, of the heat produced to the heat equivalent of the electrical energy supplied. Although this is not the true efficiency from a thermodynamic point of view it is the efficiency from the standpoint of this paper, i.e. the production of heat by the consumption of electrical energy.

REFRIGERATING PLANT.

Refrigerating plant is divided broadly into two classes. The first of these is the absorption type of refrigerator, in which the refrigerating process takes place generally without the application of mechanical work. The simplest form of absorption machine is that in which a volatile liquid is allowed to evaporate, so cooling its surroundings, and is then removed by passing into solution in some suitable liquid. This process can only be made continuous either by a continuous supply of the volatile liquid or by some process whereby the solvent in the solution is driven off and the volatile liquid so returned to its original state. It is not proposed to consider this type of refrigerator at any length because it is necessarily a comparatively inefficient process owing to the fact that, in general, as much heat has to be supplied to evaporate the solvent as is absorbed by the volatile liquid during the process of evaporation.

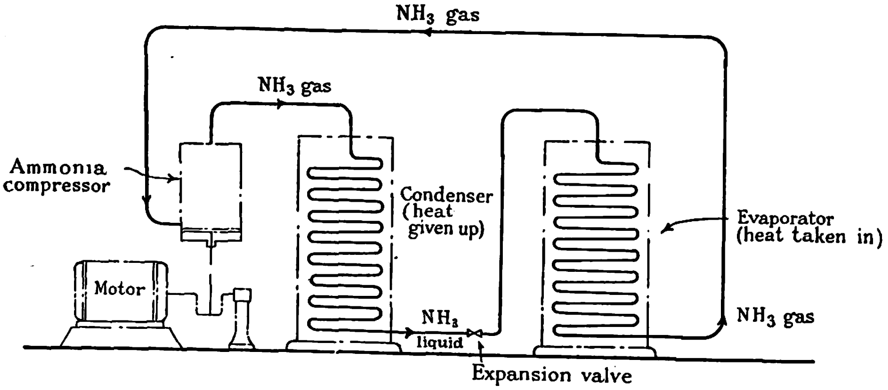

FIG. 2.

The second type of refrigerator is that in which a gas is subjected to a continuous cycle of compression and expansion by means of a compressor. During the process of expansion, heat is taken in from the cold source, and during the process of compression heat is given up to the hot source. This type of refrigerator corresponds to the perfect reversible heat engine of the Carnot cycle. The compression type of refrigerator can be made much less bulky, and consequently more efficient, if a condensable gas is employed so as to absorb heat during the process of evaporation and to deliver heat during the process of condensation. Such a gas is used in all modern types of compression machine; those most commonly employed are ammonia, carbon dioxide and sulphur dioxide, and of these three ammonia is generally recognized as being on the whole most suitable for large installations on land. Carbon dioxide is frequently used for marine plant, but owing to its low critical temperature it would not be suitable for use with a heat pump working at comparatively high condensing temperatures.

Fig. 2 shows the general arrangement of a compression type of heat pump. It will be seen that the plant consists of four essential parts:—

(1) The electric motor,
(2) The compressor,
(3) The evaporator, and
(4) The condenser.

The cycle of operations is as follows. The compressor sucks in gas from the evaporator and compresses it to a pressure corresponding to a saturation temperature slightly higher than that of the required heat. From the compressor the compressed gas passes to the condenser where it is cooled and condensed, so giving up a large quantity of heat to the water or other substance which it is desired to heat. The condensed gas then passes through the expansion valve, where a sudden reduction of pressure takes place. This reduction of pressure lowers the boiling point of the liquid, which therefore vaporizes and takes in heat from the medium surrounding the evaporator. After evaporation the gas passes on to the compressor and the cycle is completed.

It will be noted that the above process differs from that of the ideal heat engine of the Carnot cycle because there is no expansion cylinder, and therefore no use is made of the work available during the expansion from the condenser pressure to the evaporator pressure. The loss due to this cause is, however, comparatively small, and the prevention of this loss would not compensate for the complication of an expansion cylinder.

COMPARISON OF THEORETICAL AND ACTUAL HEAT-PUMP EFFICIENCIES.

It is now necessary to consider the effect of the losses which must inevitably occur in practice in plant of this type. These losses are due mainly to two causes, the first being the inefficiency of the electric motor and the second the inefficiency of the compressor. In addition to these and various other minor sources of loss, there is a loss of efficiency due to the differences of temperature which must necessarily exist between the hot condensing gas and the water being heated, and between the cold evaporating liquid and the source from which heat is being drawn. This temperature difference involves operating the plant for a range of temperature somewhat greater than that through which the heat is actually pumped, but the difference can be kept comparatively small by using an evaporator and condenser with as large a surface area as possible.

In large installations of, say, 100 kW it is quite possible to obtain an efficiency of at least 90 per cent in the electric motor and about 80 per cent in the compressor, so giving an overall efficiency of over 70 per cent. Other losses, such as absence of expansion cylinder, gas friction, heat leakage, etc., may be assumed in a large installation to amount to an additional loss of not more than 15 per cent. Thus the heating efficiencies which could actually be obtained would be at least 55 per cent of the ideal heating efficiencies shown in Fig. 1. Assuming that in cold weather the evaporation temperature is 20° F., the curve of reduced efficiencies which may be expected in such circumstances is shown by the dotted curve in Fig 3.

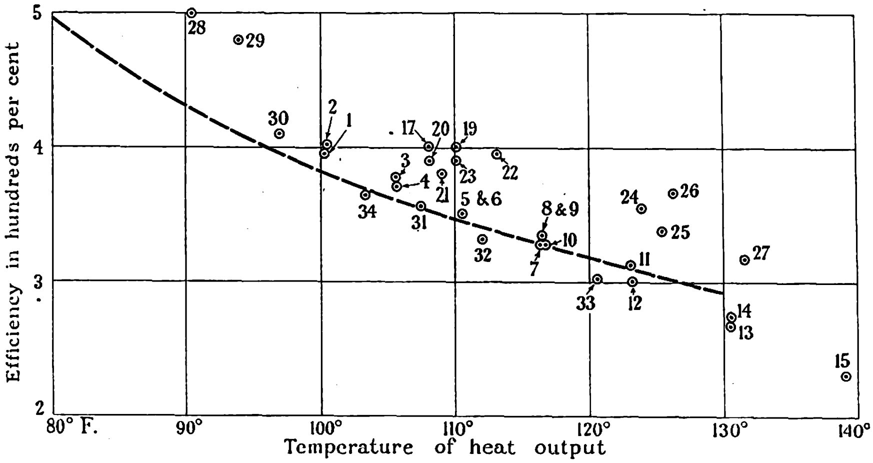

Fig. 3.—Heating efficiencies obtainable in practice, assuming 20° F. evaporation temperature.

Numbered points refer to the actual test results given in Table 1. Dotted curve shows estimated efficiency obtainable in practice.

Efficiencies Obtained in Actual Test.

To the best of the author's knowledge no detailed experiments other than those carried out by him, which will be described later, have ever been made on a refrigerator used primarily as a heat pump. There have, however, been many detailed tests carried out on refrigerating plant from which the desired heating efficiency can be obtained. With this object in view the author has analysed some such detailed experiments carried out on refrigerating plant. Owing to the fact that in refrigerating plant no attempt is made to lag either the hot pipe coming from the compressor or the shell of the condenser, the heating efficiencies tend to be slightly lower than those which would be obtained in practice with a machine designed primarily as a heat pump. Table 1 shows the results of an analysis of a number of accurate and detailed tests on refrigerating plant. The results are also expressed in this table as a percentage of the ideal heating efficiency. It will be seen that the evaporating temperatures are considerably lower than those which would normally occur in a heat pump extracting heat from the atmosphere, and in order to reduce the results to a comparable basis they have been plotted in Fig. 3 according to the range of temperature shown in Table 1, and for an assumed evaporation temperature of 20° F. Although this method of interpolating the results is not strictly accurate, the error involved is very slight, and has the effect of slightly reducing the true heating efficiencies. All the test results are plotted in Fig. 3 except No. 16, which lies outside the range of temperature shown. It will be seen both from Table 1 and Fig. 3 that the estimated efficiencies shown by the dotted curve in Fig. 3 are conservative, particularly when it is remembered that the machines tested were designed to produce cold rather than heat.

The evaporation temperature of 20° F. has been chosen because, assuming that heat is taken in from external sources, this temperature represents what would normally be the lowest evaporation temperature required during the winter months in this country. For the greater part of the winter the evaporation temperature could be considerably higher and the heating efficiency correspondingly greater.

Application of Heat Pump to Central Heating of Buildings.

The circumstances under which the heat-pump system can be applied most favourably to the central heating of buildings are:—

(*a*) Where the heating system in the building is designed to operate at a comparatively low temperature (e.g. panel heating);

(*b*) Where there is available a large supply of water for the evaporator (e.g. a building near a river or canal).

As regards condition (*a*) the temperature of the hot water supplied from the heat-pump system would, with a suitable size of condenser, be equal to, or only a few degrees lower than, the condensing temperature of the gas, particularly as the latter is normally superheated after compression and is therefore at a temperature considerably above the condensing temperature. Where condition (*b*) obtains, the evaporation temperature would normally be considerably higher than the assumed 20° F. and the heating efficiency therefore much greater than that shown in Fig. 3. When condition (*b*) does not hold it is possible to use an air-heated evaporator, but the size and cost of the evaporator would, in general, be considerably increased.

Fig. 4 shows an arrangement which might be adopted for heating a large building by means of a heat pump. In this arrangement the evaporator would be supplied with cold water which would be further cooled before being discharged. The hot water for the radiator system would be circulated through the condenser, where heat would be received from the condensing ammonia.

An alternative method of using the heat pump for heating large buildings, and one very well adapted to the characteristics of the heat pump, would be to supply heat directly to air blown into the building through a series of ducts. This air would be heated by passing over the hot condenser coils and the exhaust air would be sucked out by a fan and passed over the evaporator coils, where it would give up its heat before being passed out of the building. With this system it would probably be possible to work at lower temperatures than those assumed for the panel-heating hot-water system, with a corresponding gain in heating efficiency.

COOLING OF BUILDINGS IN SUMMER.

In Fig. 4 an arrangement of cross-over connections is shown which would enable the system to be reversed and the building cooled in hot weather. Such cooling could, however, be effected more easily with the air-duct system suggested in the last paragraph. Although in this country the periods during which it might be desirable to cool a building are comparatively short, there is no doubt that the possibility of such cooling would be a valuable asset. Any refrigeration which might be required if, for instance, the building were a large hotel could be supplied very simply.

FIG. 4.

PANEL-HEATING SYSTEM.

In applying the heat pump to the central heating of buildings it is desirable to operate with as low a temperature as possible in the radiator system, and therefore the modern panel-heating system is peculiarly adapted for this purpose because it can be operated at a considerably lower temperature than that of the ordinary radiator system. The panel-heating system can, in fact, be operated with water supplied at temperatures between 110 and 120° F. or possibly, with an increased amount of panel pipe, at temperatures even lower than this.

COMPARISON OF HEAT-PUMP AND THERMAL-STORAGE SYSTEMS.

In connection with the suggested use of the heat pump for heating installations it is interesting to note that Carliol House, the new headquarters of the Newcastle-upon-Tyne Electric Supply Co. and one of the largest buildings in the North of England, is being heated by means of an electric thermal-storage system. In this case the water for the central heating system is heated electrically during the off-peak hours when electricity can be supplied at very low cost. Although a similar heat-pump installation would not obtain power entirely during off-peak hours, it would not be difficult to avoid running the plant during the worst hour of peak load, so obtaining a supply of power at a comparatively low cost for this reason. With heating efficiencies of between 3 and 4, which might be obtained in practice with the heat pump, the cost per 3 400 B.Th.U. would be considerably less than the cost of a unit of electricity taken during off-peak hours. If, for instance, the cost of electricity taken during off-peak hours for the thermal-storage system were 0·25d. per unit, and the corresponding cost of the heat-pump plant 0·5d. per unit, the cost of 3 412 B.Th.U. supplied by the heat pump would be between 0·167d. and 0·125d., a reduction of from 30 to 50 per cent.

PRODUCTION OF ICE.

In comparing the heat-pump plant with other methods of central heating, allowance should be made for the possibility in certain cases of combining the heating function of the heat pump with the production of ice on a commercial scale. The demand for ice in summer is rapidly growing, and therefore the introduction of a freezing tank into the lay-out would admit of very profitable use being made of the plant during the summer months when the more usual forms of heating apparatus are lying idle. In this way a large proportion of the capital charges of the installation might be paid.

SWIMMING-BATH HEATING.

The heating of large buildings is not, of course, the only purpose for which the heat pump can be used, nor is it the purpose for which it can be employed with the greatest advantage. As has already been pointed out, the heating efficiency increases rapidly as the temperature difference between the heat taken in and the heat given out decreases. An ideal application is therefore to be found either where water at comparatively low temperatures is required or where it is necessary to transfer heat through a small range of temperature from waste water to clean water. The most obvious case of this sort is the heating of swimming baths. Water for swimming baths is required normally at a temperature of between 70 and 80° F., and this range of temperature is easily within that of the condensing water of the ordinary refrigerator. Consequently, not only would an extremely high heating efficiency be obtained in the heating of swimming baths, but an ordinary type of refrigerating plant could be used for this purpose with practically no modifications. It will be seen from Fig. 3 that a heating efficiency of over 5 can be obtained, assuming that heat is taken in from air at 20° F. The efficiency can, however, be increased very considerably if, instead of absorbing heat from the air, heat is taken in from the water discharged from the swimming bath. Under such conditions the heat pump is simply transferring heat from the outgoing water to the incoming clean water, and after making the necessary allowance for the thermal heads in both evaporator and condenser it is probable that a heating efficiency of about 7 could be obtained.

In many swimming-bath installations it is, however, usual to install a comparatively elaborate system of filters so as to avoid the cost of heating up the fresh cold water from the supply mains. A heat-pump installation could be run either with or without the filter system. In the latter case the capital and operating

TABLE 2.

Comparison of Costs of Coal-fired and Heat-Pump Installations for Public Baths.

Coal-fired		Electric	
	(a) Particulars of installation.		
Number of boilers	3	Number of machines	1
Average efficiency	30 per cent	Size of motor	100 kW
Consumption of coal for swimming bath	2 tons per week	Stand-by immersion heaters	150 kW*
		Size of hot-water storage tank	2 000 gals.
Consumption of coal for slipper baths	8 tons per week	Size of waste-water storage tank	2 000 gals.
Total coal consumption	10 tons per week	Heat supplied to swimming bath	2 300 000 B.Th.U. per day
Heat supplied to swimming bath	2 300 000 B.Th.U. per day	Average heating efficiency	5
Heat supplied to slipper baths and laundry	9 220 000 B.Th.U. per day	Energy consumed	135 kWh
		Heat supplied to slipper baths and laundry	9 220 000 B.Th.U. per day
Calorific value of coal	12 000 B.Th.U. per lb.	Average heating efficiency	4·5
Cost of coal	£1·75 per ton	Energy consumed	600 kWh
Temperature of swimming bath	74° F.	Energy consumed for steam and scalding water, say	100 kWh
Temperature of slipper baths	100° F.		
Staff employed:		Total energy per day	835 kWh
Mechanic	1	Cost of energy	0·5d. per kWh
Stokers	3	Staff employed:	
		Mechanic	1
		Assistant	1
	(b) Capital cost.		
Cost of boilers (3 at £300)	£900	Cost of heat-pump installation	£2 000
Cost of flues, brickwork and chimney	£750	Cost of piping	£250
Cost of piping, etc.	£250	Cost of storage tanks	£200
		Cost of stand-by immersion heaters*	£250
Total capital cost	£1 900	Total capital cost	£2 700
	(c) Annual charges.		
10 tons of coal per week at £1·75 per ton	£910 per annum	835 kWh per day at 0·5d. per kWh	£635 per annum
Wages (1 skilled mechanic, 3 stokers)	£716 per annum	Wages (1 skilled mechanic, 1 assistant)	£387 per annum
Total operating charges	£1 626	Total operating charges	£1 022
Capital charges on £1 900 at 9 per cent	£171	Capital charges on £2 700 at 9 per cent	£243
Repairs and maintenance	£25	Repairs and maintenance	£25
Total annual charges	£1 822	Total annual charges	£1 290

Saving with heat-pump installation: £532 per annum, or 30 per cent.

---

* This figure assumes that the stand-by heaters could, if necessary, operate throughout the whole 24 hours, whereas the heat pump would normally run for some 7 hours per day.

costs of the filter system would be avoided and absolutely clean water, instead of partially clean filtered water, supplied to the swimming bath. It is probable, however, that in general it would remain cheaper, as in the case of coal-fired installations, to use a filter. Most swimming baths are run in conjunction with slipper baths and it is therefore possible, by means of the heat pump, to utilize the waste warm water coming from the slipper baths for supplying the heat required to maintain the swimming bath at its proper temperature. Under such circumstances the heating efficiencies obtainable would be high.

In order to examine the economics of the electrical heating of public baths, a balance sheet has been prepared, based as far as possible on particulars obtained of the annual cost of one of the large London public baths. This is shown in Table 2.

The scheme on which Table 2 is based is shown diagrammatically in Fig. 5. In order to provide a stand-by to the heat-pump installation, allowance is made for the installation of 150 kW of immersion heaters. The comparison assumes that a filtration system is used both with the coal-fired and with the electrical systems, and the heat supplied to the swimming bath is therefore only that required to balance the losses due to radiation and conduction. In the electrical system the waste water from the slipper baths is passed through the evaporator of the heat pump, and thus the bulk of the heat in this water, which would otherwise be lost, is saved. The net annual saving (after allowing for capital charges) amounts to £532 per annum, or approximately 30 per cent of the total annual cost with a coal-fired system.

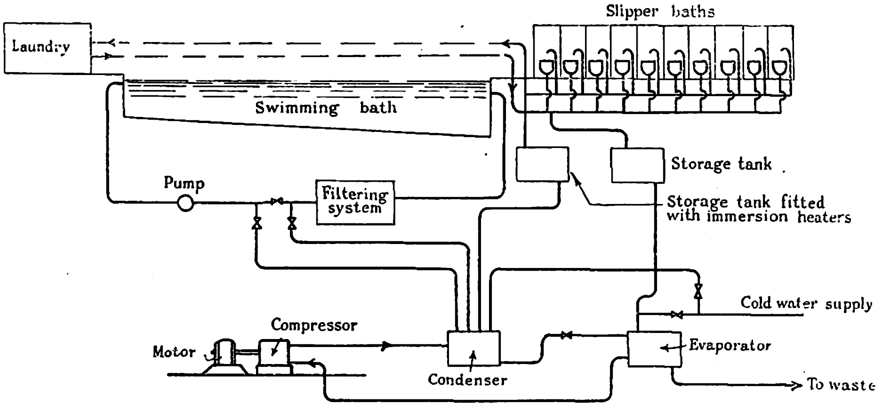

FIG. 5.—Electrical heating of public baths by means of heat-pump system.

EXPERIMENTAL HEAT-PUMP INSTALLATION.

Reference has already been made to experiments which the author has made on a heat-pump installation. After some preliminary experiments had been carried out in London, a small heat pump was installed in the author's home in Scotland and was used for operating the central heating system and for the production of a supply of hot water for domestic purposes. The arrangement of the apparatus is shown in Fig. 6, and it will be noticed that heat can be drawn either from the outside air or from a supply of cold water from the mains, or from both sources together. The compressor employed is a small ammonia machine manufactured for ordinary refrigerating purposes, and the supply of electric power (unfortunately somewhat limited in amount) is obtained from a hydro-electric installation which also supplies the cooking and lighting requirements of the house and the power and lighting on two neighbouring farms. The water from the central heating system is circulated, by means of a small centrifugal pump, through the tank forming the condenser and hence through the house. A simple and reliable automatic device is fitted whereby the motor driving the compressor is switched off if the pressure rises above a certain figure, and with this precaution there is no difficulty in allowing the compressor to run unattended for prolonged periods. Connected to the central heating system is a large storage tank which can act as a by-pass to the central heating system and so allow the hot water to be stored for domestic purposes without operating the central heating system. During the winter the plant has been used both to supply the domestic hot water and for the central heating system; during the summer it has been run only at night and used to give a supply of hot water for domestic purposes and also a supply of ice. The latter is formed in the evaporator tank, on the surface of the coils immersed therein.

In warm weather it is unnecessary to run water through the evaporator tank because sufficient heat can be taken in by the coils exposed to the air, but in cold weather the supply of heat taken from the air is augmented by heat taken in from cold water flowing through the evaporator tank. Difficulty has occasionally been experienced owing to the formation of so much ice round the coils in the evaporator tank that the flow of heat from the water to the coils is impeded. This difficulty has not been sufficiently serious to necessitate any alteration in the arrangement, but it could no doubt be overcome by forcing the water to circulate more vigorously in the evaporator tank.

As has already been mentioned, the compressor used is a small one intended for ordinary refrigeration work and is not suited for operation at high pressures and temperatures, and it has therefore been desirable to operate the central heating system at the lowest possible temperature. The minimum temperature depends, of course, on the amount of radiator surface in the house, and as in this case the available surface is fairly considerable it is possible to dispose of the heat inside the house without raising the temperature of the radiators to more than about 100° F. The supply of water for domestic purposes requires to be at a temperature somewhat higher than this, and the extra 20 or 30 degrees of temperature required is given by "topping up" the domestic supply by means of an immersion heater. The water in the main during the winter is normally at a temperature of about 40° F. and, since the heat pump raises it to about 100° F. and the immersion heaters a further 30 deg. F., two-thirds of the heating is done by the heat pump and one-third by the immersion heaters.

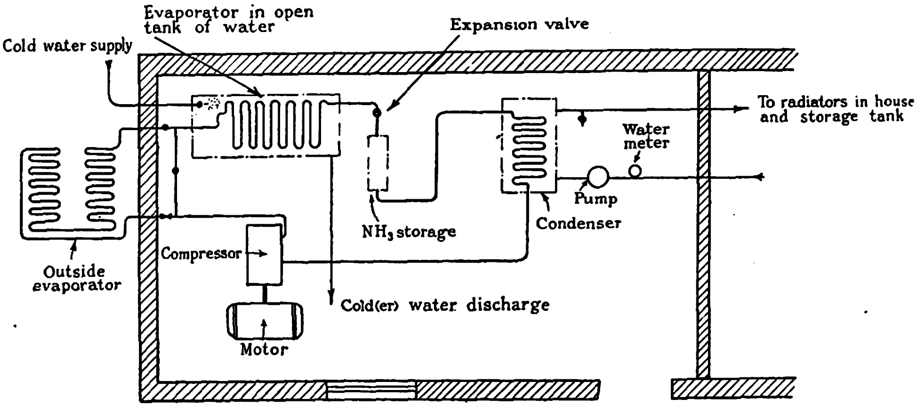

FIG. 6.—Experimental plant installed in author's home.

Repeated measurements of the heating efficiency of the plant have been taken over a prolonged period, and the efficiency curve is shown in Fig. 7. As might be expected with a small machine of this sort, the heating efficiencies obtained are considerably lower than those which have been obtained on large refrigerating plant such as those referred to in Table 1; and, as might also be expected with a small machine which is not intended to work at high pressures, the efficiency falls off considerably as the condensing temperature increases. The greater part of the reduction in heating efficiency is due to the comparatively low mechanical efficiency of the compressor and the comparatively low electrical efficiency of the motor. The maximum load of the motor is about 5 kW, and the input to the motor when the compressor is running light (i.e. not pumping) is slightly over 2 kW, thus giving an overall mechanical efficiency of rather less than 60 per cent. This compares with the overall mechanical efficiency of about 80 per cent which is obtained on larger machines, and consequently, quite apart from other sources of increased loss in so small a machine, such as valve leakage, increased radiation losses and gas friction losses, etc., the heating efficiencies for this small type of machine are about 25 per cent less than those which would be obtained on large machines.

The measurement of these heating efficiencies was carried out in two ways. In the earlier experiments the water coming from the condenser, instead of passing into the central heating system, was run to waste. Simultaneous readings were taken of the electrical input to the motor, the quantity of water run to waste, and the temperatures. Although the heating efficiency can be measured in this way with reasonable accuracy if careful readings are taken over a prolonged period, the method is somewhat laborious, and it has been found much easier to measure the quantity of water passing from the condenser by means of an accurate water meter fitted on the central heating system. The incoming and outgoing temperatures of the water from the condenser are measured by thermometers fitted in thermometer pockets on the inlet and outlet pipes, and the quantity of water flowing is recorded over a prolonged period; this gives, accurately, the average rate at which heat is being supplied to the circulating water.

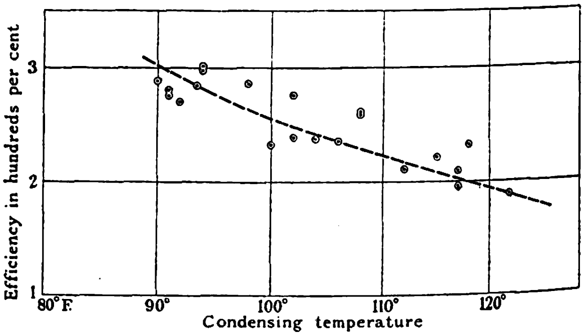

FIG. 7.—Test results on experimental heat-pump installation. Evaporating temperature 20° F.

One of the main objects in installing this experimental plant was to obtain information as to the general convenience of operation of such apparatus, and in many respects the information obtained on these points has been of more interest than the data relating to the operating efficiency. Generally speaking, the author's experience is that the plant is extremely simple to operate and requires very little attention. Compared with any coal-fired central heating apparatus, the heat pump has the very great advantage that it can be started up in a few seconds and can be shut down by the operation of an ordinary electric light switch. The adjustment of the expansion valve was found to be the only operation involving some care. This, however, has been obviated by means of an automatic expansion valve which keeps the pressure in the evaporator constant at any required value. A little difficulty has been experienced with regard to noise, but the running of the machine is audible only in the two rooms immediately adjacent: these rooms are separated by only a single brick partition. The noise has not been sufficient to necessitate any alterations to the partition walls.

CONCLUSION.

In conclusion it is advisable to point out that the author does not suggest that the heat pump is always the most economical method of heating buildings. The object of this paper is to draw attention to its possibilities in order that where conditions are favourable this method of utilizing electrical energy for heating may be used. It is probable that the heating of swimming baths is the most suitable field for the immediate application of the system.

The author's most grateful thanks are due to all those who have assisted him in the experimental work and in the collection of data for this paper. In particular he would like to acknowledge his indebtedness to Mr. L. Chew, of Messrs. L. Sterne and Co., who has taken an active part in the whole of the work, and without whose co-operation the experimental work could not have been carried out.

[The discussion on this paper will be found on page 676.]

DISCUSSION ON THE PAPERS BY MESSRS. MONKHOUSE AND GRANT (SEE PAGE 657) AND MR. HALDANE (SEE PAGE 666).*

DISCUSSION BEFORE THE INSTITUTION, 19TH DECEMBER, 1929.

Dr. S. Z. de Ferranti: All the more obvious uses of electricity have been applied on a very large scale. Lighting was naturally the first thing that brought big-power electricity into prominence. The various applications of power were obvious and have been adopted to a very great extent. Chemical processes provided another direction in which the use of electricity was advantageous; heat at high temperatures again was obviously to be obtained by electrical means. The use of electricity for providing low-grade heat was, however, quite a different matter, and for long was not considered at all, or regarded as quite out of the question. I think that, notwithstanding its present enormous applications, the opportunities for electricity in the production of comparatively low-grade heat are very great. To produce one heat unit, by electricity, at the very best nearly 4 heat units have to be used in the way of combustible at present. As time goes on, no doubt there will be revolutionary improvements in the economical conversion of electricity to heat. Everything that is done in that direction will make what has been described to-day all the more practical and all the more economical. The transmission of electricity, an expensive item, will undoubtedly be more economically effected as the amount of electric power and the length of time for which it is in use, increase. Capital charges in the production of electricity, which form a big item of expense, will undoubtedly decrease as time goes on. Now, all these things tend to show that the arguments which have been used to-day for the electrical production of low-grade heat are sound, and that such production will be more advantageous and more economical in the future. I consider that we are very indebted, as an Institution and as an industry, to the three authors for the papers which they have presented, because they give us a great deal of information and food for thought on this very vital question of the use of electricity for low-grade heating.

Messrs. Monkhouse and Grant's paper, which really deals with the use of electricity at off-peak times for heating purposes, is of the greatest importance. Some time ago, Prof. Parker Smith read a paper on his all-electric house in Glasgow. At the meeting in London I spent some time in endeavouring to stress the importance of storage. I said I felt that the immediate future of the development of electricity depended enormously upon storage, and that I could not say enough to impress the general importance of this on members. One of the electrical journals took me very severely to task for speaking at far too great a length on the subject. They said I spoke too long in proportion to the importance of the subject. Now, if I talked for the rest of my life I should feel I had not talked enough to emphasize the importance to the electrical industry of this question of storing the electricity produced. In electrical work we have not the advantage of the gasholder, which the gas industry has. We cannot store the article itself commercially. In accumulators we store the chemical product of the electrical energy. This is costly and has many limitations. Fortunately, however, in hot water we have perhaps the easiest and most economical means of storing a large amount of electrical energy, and it will be, I feel, by the use of this or some similar method that the very great electrical developments of the near future will be possible. I have had personal experience of this question of the storage of the product of electricity for household purposes, because at the beginning of 1924 I planned an installation for my home in Derbyshire, in which a 6-ton water tank, very well insulated, was installed in the basement; the heating was effected by means of ceiling panels in all the principal rooms, and there was a separate general supply of hot water for baths and washing throughout the house. At the same time a considerable amount of constructional work was done in the house to make the scheme possible. The panel-heating system is much more suitable to a new building than to one which has been already completed; the house, during the process of installing the panel heating, was considerably damaged, but the final result was excellent. The panel system of heating lends itself particularly to the use of low-grade heat. The house was not at that time connected to a public electricity supply, and we therefore had to use an oil engine to generate the electrical energy. A portion of the heating of the water in the storage boilers was done by means of the surplus current, because we had arrangements always to run the plant at full load. Advantage was taken of the presence of the oil engine to do the remainder of the heating from the exhaust of the engine and the jacket water of the cylinder. Since that time we have had the great advantage of being connected to a public supply. The engine and dynamo have disappeared, and the whole of the heating is done direct by the current from the mains. Incidentally, though it does not have a very great bearing on the subject under discussion, I may state that the principal reason for changing over from the oil engine to the public supply from the mains was to save dirtying the house and gardens by the exhaust from the oil engine. It is apparently impossible to burn oil in any form without having some greasy soot as a result. Undoubtedly this is the case where it is burned under boilers, but even with a semi-Diesel engine working under the most advantageous conditions, and where every care is taken, there is still the greasy smoke to contend with, and I have heard of installations in towns which could not be continued because of this trouble. Certainly we found the exhaust from the engine a most serious handicap and were very pleased to change over to the completely electric system. We installed a very simple automatic valve made in a single unit and controlled by a thermostat for regulating the amount of water drawn from the hot store and passed into the circulating system. This, of course, took into the heat store at the bottom of the cylinder a corresponding amount of cooler water out of the storage system. The valve, with the rest of the installation, was put to work in the autumn of 1924, and we have never known since then that we had an apparatus regulating the heat supply; it has been uniformly satisfactory during the whole period, as in fact has been the whole installation.

---

* Messrs. MONKHOUSE and GRANT's paper was read before The Institution, the North-Eastern Centre, the North-Western Centre, the Mersey and North Wales (Liverpool) Centre, the North Midland Centre, the Scottish Centre, the Irish Centre (Dublin), and the South Midland Centre, and Mr. HALDANE's paper before The Institution, the Hampshire Sub-Centre, and the South Midland Centre.

Mr. Haldane's paper starts off by stating that so far the heat pump has not received the attention of engineers. I think that the heat pump, or the reversed heat engine, has received a great deal of attention from engineers. It has not been worked out in practice because it has not been found to be sufficiently attractive or, as in my case, because there usually seemed to be a more attractive alternative. More than 20 years ago I was keenly interested in the reversed heat engine and did a great deal of work in connection with it. From time to time at short intervals since then I have reconsidered it to see whether it could be taken up commercially. I think the very greatest credit is due to Mr. Haldane for having been bold enough and persistent enough to take up such a subject as this and to work on it as he has done. If it has been so apparently unattractive to many engineers from the commercial point of view, it means that whoever steps in, at whatever period, and does useful work on the subject has conferred a very great benefit on the community. I knew Lord Kelvin rather intimately a great many years ago owing to my connection with him over early alternator patents, and discussed many problems with him. The reversed heat engine happened to be one of the subjects about which we talked. Later on, but more than 20 years ago, the late Prof. Perry was very keen on the question of the reversed heat engine. I am sure that, had circumstances permitted, he would have liked to have taken it up and would have worked on it with his usual energy. An assistant of his, who later became an assistant of mine, frequently discussed this matter with me and we made various plans for carrying it out, but, as I have said, it did not seem to me quite as attractive as other things in which we were very deeply immersed and over which we were working so hard that there did not seem to be a margin of time for anything else, and this is my excuse for not having worked on the problem more thoroughly in those bygone days. Mr. Haldane, who has not been put off by anything, has gone straight to the point and has made a trial installation, which though small is exceedingly interesting. He has given us and the world the result of his experience on this most important and interesting subject.

Mr. D. Betts : The first point to which I propose to refer in the paper by Messrs. Monkhouse and Grant is in connection with the use of the electrode boiler on high-tension circuits. When I first investigated this proposal on the Continent I was very surprised to find that the Swiss and others had no hesitation in connecting these electrode-type heaters or boilers, whether for steam-raising or merely for water-heating, to 15 000-V, or 10 000-V, or 6 000-V, 3-phase networks, without considering the question of the earthing of the neutral point. When the proposal to use this system for a rather large installation was made in London some four years ago, the first difficulty which confronted us was that the supply authority would not agree to have a boiler connected direct to its high-tension network. They insisted that we must use a 1 : 1 transformer with high voltages, so as to avoid earthing the neutral point of their system. The objection to the use of these boilers in such cases has in certain instances been removed because the supply, though of high voltage (6 000 V), is not direct from the generating station busbars. There are, however, a number of instances in which several of these high-voltage boilers are connected to a network supplied directly from generating station busbars. That is a practice which years ago would not have been countenanced, and I should like the authors to give a little further information as to what is the general opinion amongst station engineers as to the wisdom of the course. The other point to which I shall refer is this. The authors exhibited a lantern slide on which the relative heat values of coke, gas, oil and electricity were shown, and the ratio between coke (taking its efficiency as 50 per cent) and electricity (taking its efficiency as 100 per cent) was, I think, 35 to 13½. That is a ratio which is calculated on the assumption that the same quantity of heat will be required to warm a building, whether the heat is supplied by burning coke or other fuel under a boiler, or whether the heat is supplied by using electricity and thermal storage. The experience of heating engineers, however, shows that the great flexibility of control which is obtainable by the use of electricity enables a very considerable economy to be effected in the actual amount of heat required to maintain comfortable conditions in a building. A stoker, however skilful, who is firing a coke or coal-fired boiler finds it quite impossible to follow, and in fact is probably not aware of, the variations in the demand for heat which take place from time to time during the day. They may be due, for example, to variations in weather conditions, to the individual preferences of the occupants of the various rooms, or to the loss of heat resulting from the opening and shutting of doors and windows. His efforts, if he makes any, to keep his boilers at a steady temperature merely result in averaging out these variations and in the loss of considerable heat up the chimney. But with the thermostatic plant heated electrically, the amount of electricity which has to be supplied during the off-peak period is exactly proportional to the amount of heat withdrawn from storage during the day; and if, as a result of carefully designed control-apparatus, the amount of heat which is taken from that storage is reduced, there will be a corresponding reduction in the electricity consumption. Thermostatic control of the temperature in the storages and of the temperature of the water supplied to the circulating system is quite easy and is applied in practically every installation, but a very great economy can be obtained by applying thermostatic control to the rooms themselves. A recent experiment on a quite extensive panel-heating installation, with thermostatically controlled valves on the panels themselves, shows that this has resulted in extraordinary economy in the amount of heat used in the system. It is not an electrically-heated system; it is fired from a large anthracite boiler, but the economy which has resulted can be ascribed only to the fact that variations in the heat requirements of each of the rooms are promptly reflected in the amount of heat which is actually supplied to those rooms. Now, if a calculation is made of the price at which electricity must be supplied in order to compete, on the basis of heat-supply, with coke, it will be found that the figure works out at about 0·1d. That is to say, in the case of an installation where it is assumed that the same quantity of heat will be required whether coke or electricity is used, electricity would have to be supplied at 0·1d. if the electricity bill were to be equal to the coke bill, with coke at about 40s. 0·1d. is a figure which nobody has even thought of asking for a supply, but 0·25d. is a figure at which a number of authorities are prepared to supply at off-peak times. It is not difficult to show that by the saving in labour costs the figure of 0·1d. can be increased to 0·15d. and still the comparison will hold. But 0·15d. is not good enough. The further increase in the price which may be justified and which results from close thermostatic control appears to be something like 0·05d. Therefore, in the case of an installation of from 1 million B.Th.U. per hour upwards, the figure of 0·2d. is the one at which electricity would have to be purchased if the electricity bill were to be equal to the coke bill, taking into account the saving in labour. That leaves a margin of 0·05d. between the figure at which electricity can be purchased, namely 0·25d., and the figure of 0·2d. I have just quoted, and it remains for prospective users of this system to assess the money value of the amenity which results from its use. No nuisance from smoke or soot is caused, there is no ash to be handled, and, what is quite important, the boiler-house plant can be installed in a portion of the building which would otherwise not be available for this purpose. Whether the value of these amenities is equal to the outstanding 0·05d. is a matter which will depend on individual circumstances, but I think that the great economy in the actual heat requirements resulting from the use of carefully designed control-apparatus is one of the most important aspects to which attention should be devoted in dealing with the question.

Mr. P. Kemp: I shall confine my remarks to Messrs. Monkhouse and Grant's paper. It seems to me that before this method of heating can come into general use, it must be an economical proposition. Mr. Betts has mentioned the fact that electricity must be sold at the rate of 0·2d. per kWh before it can be considered as an economical proposition, viewed from the point of view of the heat basis alone. Bearing in mind the fact that the majority of the large power stations consume coal at about 2 lb. per kWh, and taking coal at about 18s. per ton, the cost is found to be about 0·2d. per kWh. Allowing the allocation of 25 per cent of the fuel costs to the standing charge (which percentage is considered to be quite normal), the price would be reduced to 0·15d. This is the absolute minimum at which electrical energy can be supplied at the present time. Of course, no undertaking would supply at that figure. It does not, however, seem to me to be beyond the bounds of possibility that that 0·15d. might be a practical proposition when increased to 0·2d., and if an undertaking can supply at 0·2d., Mr. Betts's objections will have been met. In my own case we are being supplied at 0·27d. Purely from the point of view of the heat supply, it is not an economic proposition. The amenities, the absence of smoke stacks and, in a busy London quarter, the floor space which is set free by employing thermal storage have an appreciable value. Further, in the case of the installation in which I am interested, that of the Regent Street Polytechnic, when the first tentative plans for the new building were brought forward it was decided to go down to a certain level. When the question of thermal storage was mooted, the original plans were revised, and it was found possible to go down one story deeper into the earth. From that point of view it is seen that the storage vessels and electrode boilers occupy no floor space whatever. That is a point worth considering. I notice at the end of the paper a statement that at the present time certain labour charges are incurred with the electrical equipment. These will shortly be eliminated, it is said, when the complete automatic apparatus is installed. Regarding maintenance and upkeep I cannot speak with any authority, as the plant has been running for only a very few months; but I have found that it is not so far completely automatic. I have found that in certain cases rooms may not be required for, perhaps, three or four hours at a time. By shutting off the supply of heat to those rooms quite appreciable savings have been effected, but we have had to employ labour. However, it is hoped that this labour charge will shortly be eliminated.

Mr. L. Chew: In their first lantern slide, Messrs. Monkhouse and Grant gave a table showing the available heat units from coke as 35 000 for 1d. and from electricity as 13 500 for 1d. That, of course, does not seem very favourable or hopeful from the point of view of the the development of electric heating, and I gather from the remarks of Mr. Betts that the cost per unit will have to be considerably reduced to enable electricity to compete. Mr. Haldane has told us, however, that by first converting electricity into mechanical energy by means of a heat pump, we shall get an efficiency not of the 100 per cent that we get with this direct method, but of from 300 to 400 per cent. Taking the mean of those two figures and working out Mr. Betts's calculation, I find that 46 500 B.Th.U. could be obtained for 1d. by the heat-pump process, as compared with the 35 000 units for 1d. with coke. This appears to have some bearing on Mr. Betts's remarks. The test results which are tabulated in Mr. Haldane's paper have all been taken from plants used as refrigerating machines. Unfortunately, there are no large plants—in fact, no plants at all except that of 4 kW, which Mr. Haldane illustrated—available, and none on a sufficiently large scale to enable them to be tested for commercial efficiencies. Consequently the efficiencies shown in Mr. Haldane's table are very low indeed; they are of the order of 300 per cent. The reason for this is that in a refrigerating machine every available expedient is used to dissipate the heat from the ammonia after compression. The cylinders are water-jacketed; the discharge pipes are left bare, and sometimes there is a liquid ammonia injection into the cylinders during the compression stroke to provide isothermal compression. These factors increase the efficiency of a refrigerating plant;. but all the precautions which are taken when the machine is used as a refrigerating plant are just the reverse of those which must be taken when we use the same plant as a heat pump. The object in the latter case is to conserve the heat which is given to the gas during compression, and therefore everything beyond the discharge line should be thoroughly insulated. That, of course, has a very great bearing on the tabulated efficiencies given in Table 1 of the paper; it would improve them very greatly. The mechanical efficiency of the reversed heat engine, amounting to some 10 or 15 per cent, is a dead loss in the case of refrigerating machinery. When the same machine is used as a heat pump, a good deal of that loss which is included in the mechanical efficiency really becomes a gain. For example, the friction produced by the piston rings is given to the gas as heat which should be credited to the efficiency of the machine when used as a heat pump, and would again improve the figures given. In some of these tests I observe that the machinery is driven by a steam engine, and the power input to the machine is taken as the indicated horsepower of the steam engine, probably because that was the only means of ascertaining power input. But direct-coupled steam engine sets run at a very low speed, about 60 r.p.m., and are necessarily inefficient combinations. Thus the 10 or 15 per cent loss which is debited to these efficiencies would be very greatly improved if direct-coupled motors were used; moreover, modern refrigerating plant, or heat pumps, are essentially machines which can be direct-coupled to electric motors, since the speeds are of the right order. Perhaps the average installation would be of about 100 h.p., running at 350 r.p.m. A 100-h.p. electric motor at that speed can have an efficiency of the order of 89 to 91 per cent. In Table 2 of Mr. Haldane's paper I notice labour charges amounting to £387—one skilled mechanic, one assistant, and so on—and these are debited to the heat-pump system, the comparison being between that and a coke-fired boiler. It is the general practice to-day, however, to make refrigerating machinery fully automatic. In all butchers' shops, for instance, it runs without any attention at all, starting and stopping itself and being thermostatically controlled. The same automatic features could, of course, be applied to the heat pump, and this will no doubt be done when that machine comes into use. The figure of £387 could thus be reduced very considerably, and it would make the comparison even more favourable to the heat pump. Reliability and safety are very important points. The refrigerating machine, at present the only known form of heat pump, is essentially reliable. It has had to be designed on those lines, because the produce for which it is responsible is of such very great value.

Mr. D. J. Bolton : I should like to make one or two remarks on Mr. Haldane's paper. The great ease with which mechanical power can be obtained from electricity as compared with its competitors, and the comparative difficulty and expense of getting heat from electricity, are well known. Therefore any method which uses mechanical power to get heat is to be welcomed, if only because of the high efficiency of the electric motor as compared with that of the gas engine. That is why the subject of Mr. Haldane's paper appears to be so attractive. The author speaks only of the use of condensable gas, such as the ammonia which is used in refrigerating machines. That naturally makes the apparatus small in size; but there is another gas, not easily condensable, which has several advantages, of which cheapness is only one: I refer to the atmosphere. But air presents serious difficulties; very much larger apparatus, larger surfaces, and of course a very much bigger volume, have to be dealt with. One suggestion, however, which has been made is to combine the heating of a building with its ventilation. This removes one of the disadvantages I have mentioned, that of having to deal with a large volume of gas. A large volume is necessary for ventilation and it is no disadvantage for the heat pump. The other disadvantages still remain. The use of air necessitates a large area of pipe exposed to the cooling element, making the apparatus very bulky. The arrangement would have an inlet from the atmosphere, a long pipe, containing air at a pressure less than atmospheric, and then the condenser (or blower as it would be in such a case), which would deliver at atmospheric pressure. Thus we get both ventilation and heating, while the objection of having to deal with a large volume of gas no longer arises, because that volume is necessary for ventilation purposes. The objection arising out of the large area of pipe remains; it is not desirable for the building to be adorned by a large pipe, going round it two or three times; presumably it would have to be put in the roof. I do not know if the author has investigated that, or the difficulty of the moisture in the atmosphere. I do not think the idea has ever been tried in practice. Now for another point which applies to any of these heat pumps, and which may sound somewhat fantastic. Naturally, heat can only be pumped from one place to another. If all the buildings in London were heated in this way, would the temperature become even more Arctic than it is at the moment? If every building in Oxford Street were heated thus, the heat would be pumped from Oxford Street into the buildings, and Oxford Street itself would be slightly cooler. From the point of view of someone who was selling fires or overcoats, it might improve business to make it not only warmer indoors but slightly colder outside, but for London as a whole what would be the effect? Coming up to London from the provinces, one notices that Lond on is several degrees warmer than the surrounding country, due to the fuel and kWh consumed. By this method, however, London might be made several degrees cooler!

Mr. P. M. Baker (*communicated*):—A feature of the paper by Messrs. Monkhouse and Grant is their frank recognition of the fact that electrical heating by resistance methods cannot have a thermal efficiency as high as that obtainable by other, more direct, means. Electrical heating gains nothing but rather loses by claims which cannot be substantiated. It is better to take the line adopted by the authors and to emphasize the collateral advantages of ease of control, economies arising from increased cleanliness of buildings and savings due to the elimination of chimney stacks, etc., which are purchased at the cost of a slight loss of efficiency. The plant described in the paper can give all these advantages at an overall cost, although the charge of 0·25d. per unit seems to be very low even in these days of cheap electrical energy. The figures of 8 000 kWh per hour given on page 664 for the consumption of the heating installation at the offices of the London Underground Railways appears to be high and out of proportion to the magnitude of the other quantities given. Will the authors confirm the figure?

It is quite reasonable to predict that Mr. Haldane's paper may form the starting point for a new type of water heating free from the disabilities of ordinary resistance methods. The statements on page 667 would appear to contravene the law of the conservation of energy, but the real facts of the case are, I suggest, that the elementary theory of heat is incomplete as it takes no cognizance of the temperature at which heat units exist and, therefore, of their "availability." This can easily be seen by drawing temperature/entropy diagrams, one for the original engine which supplies the mechanical energy and another to represent the heat pump; the two should have equal "mechanical energy" areas. Such diagrams confirm the author's figures. I endeavoured, for my own satisfaction and in order to gain a better understanding of the action of the heat pump, to find an analogy which would illustrate its action. I would compare the heat pump with a battery booster. A battery contains a store of energy which it cannot discharge on to the busbars of a generating station until its voltage is raised by a booster; similarly, the water supplied to the circulating system of the author's compressor contains a supply of heat energy whose temperature is raised by the pump, thus enabling it to be transferred to surrounding objects. I consider that an analogy of this kind, which to some extent enables a clear conception of the physical happenings in a piece of apparatus to be obtained, is of value. The author's experimental application of Lord Kelvin's theory seems to have made an excellent case for the use of the heat pump in such work as the heating of water for swimming baths. The combination of a swimming bath with a skating rink appears to be of sound commercial value.

Mr. A. G. Freeborn (*communicated*): As stated in the paper by Messrs. Monkhouse and Grant, heating by thermal storage does not become feasible until electricity can be purchased at something in the neighbourhood of 0·25d. per unit, and, even when purchased at this figure, it depends on the special circumstances in each particular case as to whether it is even then an economical proposition. With regard to one of the largest jobs that has been done electrically, i.e. St. James's Park station, it must be borne in mind that it has, in effect, its own power station, viz. Lots Road. Although I have no doubt that its energy is charged for on a commercial basis, the fact remains that the station and the building have common owners. In Appendix 2 of the paper comparative figures are given for the plant at Carliol House, Newcastle. I note that 1 100 000 kWh are charged for, whilst, for comparison, 500 tons of coke are taken. This does not seem to me to be quite right, because if a coke boiler were to burn 500 tons to heat the same premises it would be working at a very low efficiency. I have actual experience of modern coke-plant working in London, the volume of the building being 2 350 000 cubic ft., or a little larger than Carliol House. Half the building is heated on the "Plenum" system, which requires much more heat than the panel system of the other half, but only 251 tons of coke per annum are used. I do not see why maintenance and renewals at Carliol House should be so much larger in proportion. An annual charge of £50 is ample for the maintenance and renewals of the plant described above, and this figure is confirmed by heating engineers. For attendance, £550 seems to me to be very high. The corresponding figure for the plant which I have mentioned is well within £200. These reductions bring the figure for the coke boiler down to a total of approximately £1 100. I am not well acquainted with the working of electrical thermal storage plant, but I cannot conceive that it would run without any attention at all. To install plant of such capacity and to have it continuously in operation without attention would not be advisable. I think that the minimum cost, including an occasional inspection by a competent engineer, would be £2 000. The comparative figures are now £2 000 for electricity against £1 100 for coke. It appears to me that consideration should be given to the engineering requirements of buildings as a whole, instead of to separate supply units. As an example, I would take a block of buildings in London the heat requirements of which during the winter are between 24 and 35 million B.Th.U. per hour and the peak requirements for light and power of which are in the neighbourhood of 4 000 kW. As solid fuel is somewhat difficult to deal with in the centre of large towns it will be assumed that oil is used as the fuel. In the first place, oil of 18 000 B.Th.U. content does not cost 90s. per ton, as stated in the paper, but it is now being purchased at a little over 60s. per ton. By installing modern high-pressure (200 to 250 lb. per sq. in.) water-tube boilers, complete with auxiliaries such as economizers and superheaters, great flexibility and a thermal efficiency of not less than 70 per cent would be obtained. This means that the boiler would provide, at a cost of 1d., about 37 000 B.Th.U. in the form of high-pressure superheated steam. As this could not easily be used in calorifiers it would be passed through a back-pressure turbine so as to reduce the pressure to approximately 25 lb. per sq. in. and extract the superheat from it. Power of the order of 0·8 kWh would be obtained from a generator coupled to this turbine. The steam would then still contain 30 000 B.Th.U. which could be used in the ordinary calorifier. The net result would thus be the generation of 0·8 kWh of electrical energy and 30 000 B.Th.U. for 1d. The labour and other charges involved would be approximately 0·3d. or 0·4d., and would certainly not approach 0·8d. There are other considerations, such as make-up, on the electrical side; for this it would be necessary either to parallel on to the outside supply or to install heavy-oil engines. Modern heavy-oil engines are working in various parts of the country now, and the all-in cost per unit is considerably less than 1d., especially when, as in this case, there are no transmission losses. This equipment, in conjunction with the back-pressure turbine, will supply all the electrical energy and will satisfy the engineering requirements of the establishment at a cost which is, at present, lower than that of any other available method. The following is a comparison between the energy charges involved by an external supply and by an independent engineering scheme, for the building mentioned above. Dealing first with the outside electrical supply, the lighting and power load will have a peak of approximately 4 000 kW. The actual requirements will be about 7 million kWh per annum for light and power, and an additional 6 million kWh are required for heating. For power and lighting a price of £5 per kW of maximum demand plus ½d. per unit will be assumed, and, for heating, a rate of ½d. per unit for energy consumed during the night. The total cost is then £33 500. For the other scheme, assuming 10 000 B.Th.U. per lb. of oil delivered to the heating plant, approximately 1 000 tons of oil are required. Through a turbine working under the conditions stated above at least 600 000 kWh are obtained, which means that 6 400 000 kWh must be generated by the oil engines. This amount of energy can be generated by oil-engine installations at the rate of 0·73d. per kWh, a figure which includes interest, depreciation, labour, fuel, etc. Taking into account the charges for oil (£3 000), for stoking and maintenance of the boilers, for attendance, interest, depreciation, etc., in connection with the turbine (£2 500), and for 6 400 000 kWh generated by the oil engine (£20 000), a total of £25 500 is obtained. This represents a considerable saving on the first scheme and it has, in addition, the advantage of independence of external sources. A point which becomes very evident after working out the above is that whilst the maximum demand for power and lighting is 4 000 kW the peak load for heating is between 7 000 and 8 000 kW, or very nearly double the day-time peak. If such systems become general, it is reasonable to suppose that the supply authorities will require a certain amount of the electricity for heating to be taken during the day so as to flatten out their load curve. This may have the effect of increasing the maximum demand during the day and, therefore, the costs of thermal storage. The buildings mentioned above consume large quantities of energy for power and lighting and relatively less for heating. No mention has been made of the very obvious economies which can be obtained by installing waste-heat boilers in connection with the exhausts of the Diesel engines. In this particular case, the whole of the summer heating-requirements could be met in this way. It will be noted that whilst 100 per cent efficiency has been allowed on the electrical scheme, only 60 per cent has been ascribed to the other system. The third method mentioned above—that of obtaining the heat from oil-fired boilers, passing the steam through a back-pressure turbine and then paralleling this turbine on to an outside source of supply—is quite worthy of consideration. It has not been very extensively adopted in London, but in other parts of the world it is by no means uncommon. It would cost £3 000 for oil, £2 500 for maintenance, etc., and the electricity supply from outside would cost approximately £24 000, assuming that the turbine output is sufficient to keep down the peak by 600 kW. This gives a total of £29 500. It seems from the above that independent generation of power as make-up on the turbo-generator is the most economical proposition. The actual space required for generating-machinery is not so great as might be imagined, and the very considerable saving shown over either of the other schemes makes it a proposition to which serious consideration must be given. I have dealt only with one particular case and must therefore point out that, although electrical thermal storage is not the most economical proposition under the conditions selected, there may be many cases in which it would present decided advantages.

Prof. E. W. Marchant (*communicated*): The use of electrically operated boilers in the present-day type of hot-water system is essentially wasteful. It must be recognized that while a coke boiler provides 35 000 B.Th.U. for 1d. the electric boiler can only produce 13 000 B.Th.U. for the same cost, assuming 100 per cent efficiency for the electrical system of heat distribution. The amount of heat, therefore, which is produced by an electrically heated boiler is not much more than one-third of that obtained for the same price from a coke-fired system. Any system of thermal storage applied to the electric boiler may equally well be associated with the coke-fired boiler; it is therefore misleading to regard the introduction of heat storage as a solution of the electrical heating problem. It is clear that the coke-fired boiler must be the more economical of the two types unless the energy for the electric boiler is supplied during off-peak periods at a figure which will not cover the cost of the coal required for its production.

Mr. Haldane's paper describes an arrangement whereby low-grade heat is obtained from an inverted refrigerator, and the experiments which the author has conducted at his house in Scotland are evidence that the scheme is practicable. It is remarkable that Lord Kelvin's suggestion of using a reversed compressor has never been adopted before: it is scientifically sound and enables the present disability of having only 24 per cent of the thermal content of the coal available for heating purposes to be avoided. A great deal of time and energy has been wasted in the past upon experiments which could never have been successful. I hope that this device will be the subject of research in the future, as it should lead to extensive economies in electrical heating.

Mr. J. C. Stobie (*communicated*): It is only during quite recent years that a satisfactory shaft seal packing has been in use, and as a consequence the small domestic refrigerator is now very common. These machines will run for years with practically no attention, and without trouble due to loss of refrigerant. Investigation of the temperature-entropy diagram of ammonia when used for heating from 32° F. to 120° F. (see Fig. A) shows that the compression line AB generally results in considerable superheating at fairly high pressures. The expansion line through the expansion valve results in the line CD, and the energy lost is represented by the area CDF. Mr. Haldane does not consider that this area is sufficiently large in comparison with the total area FABEC to warrant the installation of an expansion

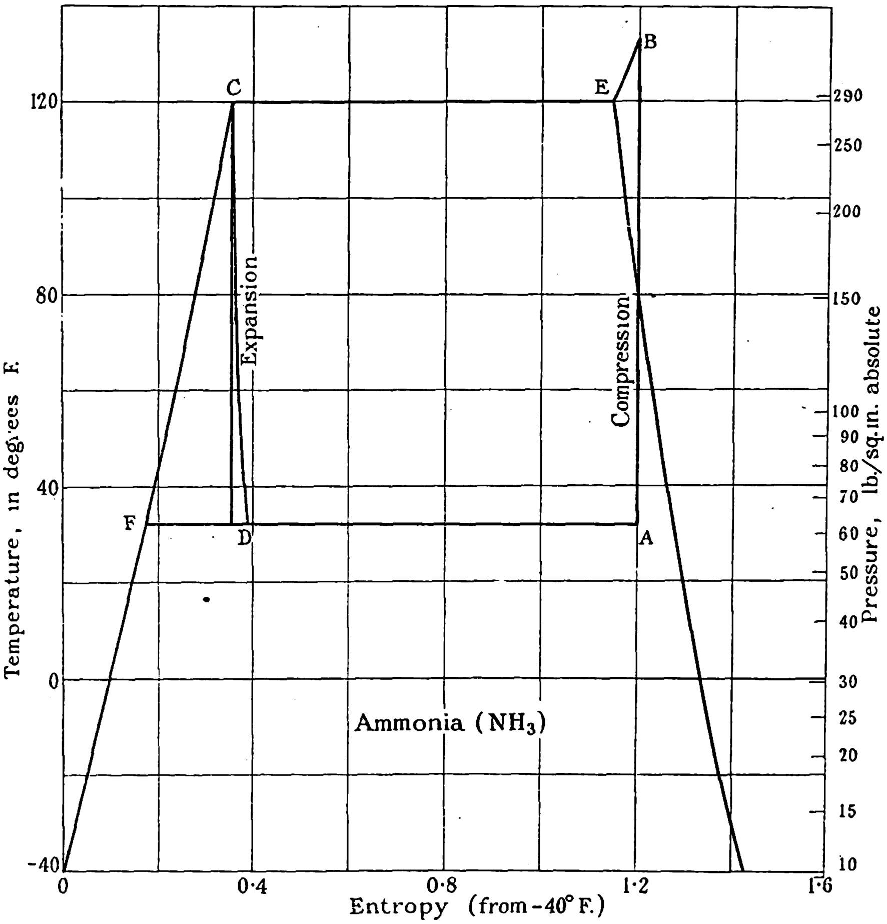

Fig. A.—Temperature/entropy diagram for ammonia.

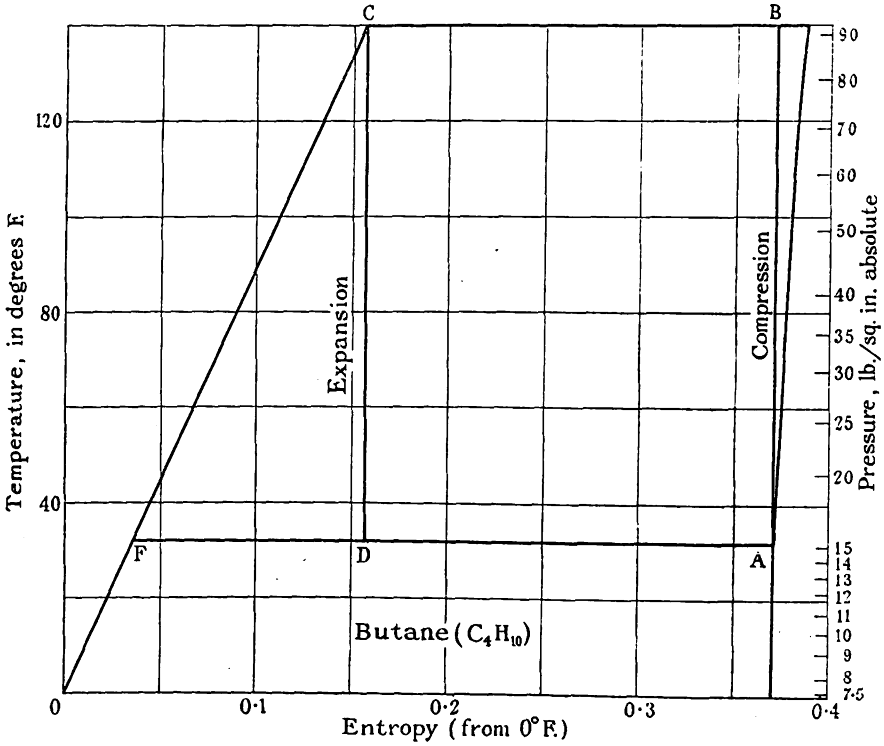

Fig. B.—Temperature/entropy diagram for butane.

cylinder. With low temperature-rises this loss is not great, but it can be seen that it increases rapidly with the temperature range. Other refrigerants in general use gave similar characteristics. They all require extremely high pressures when temperatures up to, say, 160° F. are required, so that I decided to search for other substances with the idea of boiling water. Fig. B shows the temperature-entropy diagram for butane. Here the shape of the saturation line does not cause any superheating at all on compression, from a temperature range of 32° F. to 140° F. In addition the pressure only increases to 90 lb. per sq. in. in comparison with approximately 4 times this value for ammonia, and it allows considerable energy to be returned by an expansion cylinder instead of the wasteful expansion valve. In Fig. B this saving would be about 20 per cent, but this increases with greater temperature ranges and the ideal performance is in agreement with Carnot's cycle. If the heat discharged from the pump system described above is passed through a heat exchanger to evaporate methyl-alcohol or water,

still higher temperatures are economically obtainable. The temperature-entropy diagram for methyl-alcohol is shown in Fig. C for an increase of temperature from 140° F. to 212° F. For this range an expansion valve would be quite suitable for the expansion line CD of the diagram. With this system in use in warm climates such as we have in Australia, thermal efficiencies up to 250 per cent may be possible in order to raise water to boiling temperature. In order to demonstrate the possibility of butane as a heating medium in a heat pump I was able last year to place some in the smaller sizes of Copeland refrigerator. With the assistance of the Australian Implement Co. of Adelaide we arranged a $\frac{1}{8}$-h.p. belt-driven unit to heat water as shown in Fig. D. The evaporating coils were exposed to the atmosphere, and fan arms on the motor flywheel assisted in making a draught for heating purposes. No expansion cylinder was used. With larger machines and an expansion cylinder the performance efficiency would be many times greater, but the experiment served to demonstrate the increased efficiency of the heat pump system even with this improvised equipment. The

cooled air passing the evaporating coils suggested to us that the pump would cool down our buildings as well as heat them. A further advantage brought out by these experiments was the effect of the large amount of heat which can be put into the water with a low temperature difference. As the temperature increases the performance is decreased, and only a portion of the heat is obtained at the extreme temperature difference. When we commence heating the water we have a performance efficiency of, say, 2 000 per cent which decreases to, say, 200 per cent as the water is brought up to boiling temperature. I was not aware at the time that similar experiments were being carried out elsewhere.

[The replies of Messrs. Monkhouse and Grant and Mr. Haldane to this discussion will be found on pages 699 and 702 respectively.]

North-Eastern Centre, at Newcastle, 11th November, 1929.

Mr. H. W. Clothier : Messrs. Monkhouse and Grant in their paper have demonstrated on a large scale that there is practical economy in the heating of buildings by the use of electricity compared with coke boilers; and, in addition, one has to put convenience, cleanliness and automatic regulation to the credit of electricity. As an example of the convenience of regulation it may be of interest to mention the method of control of the Reyrolle h.t. electrode boiler referred to by the authors. The electrodes are fixed inside the boiler in order that there shall be no glands for moving parts, and so the power consumption is regulated by the level of the water, which in turn is controlled by the rate of feed. Automatic control spreads the load evenly over the " off-peak " period. The required consumption for the temperature conditions of the time of the year is ascertained by experience; the control, set by a rheostat according to the required consumption, is effected by a differential wattmeter-type relay. The absence of dust and smoke is in itself a great labour-saving factor which is not always taken into proper account when comparing costs. Electricity combined with automatic control eliminates the troubles associated with laying fires and the labour occasioned by the dust and flue products, which cannot be entirely excluded from the house. The costs of electricity are so easily and accurately measured, whereas such other factors as cleanliness and health are so difficult to reduce to a monetary value, that there is a danger of paying too much attention to comparative thermal efficiency of the requisite sources of heat energy. The authors' Appendices 1 and 2 are of great importance in helping us fully to realize the problems before us. It would be useful if they would also state the efficiency allowed in compiling their balance sheet, and the effective calorific value of various forms of fuel available. The paper, though dealing only with large buildings, raises questions which apply also to small buildings. Table A comprises a comparison between electric and coke-boiler heating for a dwelling-house. The possibilities of night load in this form must, of course, depend upon the supply companies giving exceedingly low rates. A really attractive night-load tariff for dwellings would carry some profit, however limited, to the supply undertakings who wish to fill the valleys in their load curves; it would also bring a larger demand in day load for topping-up for local heat, and other uses. I have endeavoured to ascertain from the figures in the paper a basic figure for daily watt-hour consumption per unit dimensions and temperature. Presumably the figure varies with different types of buildings, the amount of ventilation, etc. What is required is the total power, in watts, used in several types of buildings, divided by the product of the total cubic capacity of the buildings, in cub. ft., the period considered, in days, and the temperature-rise, in deg. F. This figure should furnish

Table A.

Estimates from Experimental Data Obtained in a Dwelling-House, September, 1928, to September, 1929.

a useful working standard for the electrical energy required per cub. ft. per deg. F. temperature-rise per day. On page 661 the authors give a figure of 0·08 watt-hour, but this is not confirmed by the data given for Carliol House. The differences are shown in Table B.

TABLE B.

Installation	Consumption	Page
Banca Commerciale Italiana di Roma	Wh/cub. ft./deg. F. = 0·08	649
Carliol House	$\frac{5\,300 \times 1\,000}{1\,750\,000 \times 1 \times 18{\cdot}7} = 0{\cdot}162$	652
Carliol House room ..	$\frac{46 \times 1\,000}{7 \times 2\,000 \times 18{\cdot}7} = 0{\cdot}1757$	652

Having compared these figures with the results obtained from the above-mentioned dwelling-house, I would suggest that the larger figures are more correct.

Mr. S. S. Jewsbury: The authors mentioned that they believe the Carliol House plant to be the largest of its kind in use in the world. Taking the installation as a whole, that is the electrode steam-boilers, thermal storage apparatus, and the panel, or invisible radiant heating, system, as we now call it, I believe it is the first installation of its kind in the world. The adoption of a system which is a definite departure from the accepted methods of heating is a matter for congratulation. This paper will do much to stop the unfounded rumours which have been circulated regarding the heating of buildings by electrical methods. It has been suggested that if this method of heating is adopted to any considerable extent the demand will very soon exceed present peak loads. If the demand exceeds the supply the supply undertakings would, of course, only be expected to sell at the low rate that quantity of current which is represented by the valleys in their load curves, but, as the average load factor of the large power stations in this country is, I believe, at present between 20 and 25 per cent, there is at present no likelihood of using up all the available supply of current for this purpose. To have so many different rates is, no doubt, a difficult matter for the supply undertakings; and consumers will probably want to know why energy for one purpose can be supplied at a lower rate than energy for another. It is for the electrical industry to educate the public to realize that the methods adopted to maintain constant loads at the power stations will increase the efficiency of the stations as a whole, and so ultimately benefit all consumers owing to the lower rate at which it should be possible for the current to be supplied. The authors mentioned that a panel-heating installation works, normally, at a lower temperature than a radiator system, and this means that the panel system is particularly suitable for use in conjunction with thermal storage schemes. A panel system works, normally, at 120° F. and a radiator system at 160° F.; therefore, when the maximum temperature to which the water in the storage cylinder is heated is 230° F., the panel system has an operating range in its storage cylinder of 110 deg. F. as against 70 deg. F. for the radiator system. Thus the storage cylinders required for the panel system will be only a little more than one-half the size of those required for the radiator system. Incidentally, it is found that the total quantity of heat required to maintain conditions of comfort in buildings heated by the panel system is rather less than is found necessary in the case of buildings heated by radiators.

Mr. A. G. Shearer: In any scheme for using electrical energy for a thermal storage system it is essential that all losses should be reduced to an absolute minimum. When one considers that the capital cost of the lagging is spread over 20, or maybe 30 years, during which time the heat loss will be continual during an operating period of about two-thirds of each year, it can readily be proved that the first cost of applying sufficient lagging to reduce the losses to the minimum figure recommended by the authors is justifiable and essential. This subject of heat loss during storage is becoming increasingly important to electrical undertakings, particularly in view of the demand for domestic hot-water installations.* Metallic cellular heat-insulation which practically eliminates loss by radiation is now available; it consists of specially prepared bright aluminium foil. The dimensions of storage cylinders should be very carefully considered by designers, so that for a given volume the surface area is as near the minimum limit as is practicable, and where there is adequate space the volume of the storage cylinders should not be fixed at a minimum figure, as it is more economical to operate at a lower than a higher temperature. Throughout the country there must be many electrically equipped works where the consumers' transformers are not fully loaded during the off-peak supply period; this available transformer capacity can be utilized for supplying thermal-storage load to heat offices and other works buildings. If the annual payments to the depreciation fund referred to in the Appendix are invested at 6 per cent (the same rate as the interest on borrowed capital) then, in order to accumulate to a total of £5 600 in 20 years, the annual payment will only be £143 12s. 6d. instead of £169 as shown in the paper. The difference of £25 will enable the total costs against the electric scheme to balance those against the coke-fired scheme. The cost of handling and removing ashes in coke-fired installations is one which must be carefully considered, and this item is rarely fully recognized.

Mr. F. N. Linstow: Referring to large immersion-heater installations such as the one illustrated in Fig. 2B, it seems to me that it would be preferable to place the immersion heaters in a small tank by themselves, and circulate the water between the heater tank and the storage cylinder either by thermo-siphon or by force pump. With the small separate heater tank, it would be much easier to carry out cleaning operations on the heater tubes, or even replacement of a tube, if necessary, as this could be done without draining off a great deal of water; also we cannot overlook the possibility of a fault on an immersion heater being sufficiently severe in nature to burn through the tube and allow an escape of water. With the heaters in a separate chamber, stopcocks could be closed which would definitely limit the escape of water, even under the worst conditions, to that which was contained in the heater tank. In view of the possibility of electrical faults in immersion heaters causing damage to the tube, some system of sensitive earth-leakage protection is very desirable for such installations. Where the supply is taken direct from the mains, relays operating on a 2½ or 5 per cent fault current could probably be provided, but where a separate transformer is installed a much more sensitive trip-setting could be obtained and is desirable. I suggest that, under these conditions, the neutral of the transformer should be connected to earth via a relay-coil winding, and the most sensitive setting obtainable should be employed.

---

* Dr. M. FISHENDEN: "Heat Loss from Thermal Storage Tanks," *Electrical Review*, 1928, vol. 103, p. 644.

Mr. V. A. H. Clements: The authors have not stated the cost at which it is economical to supply off-peak units for thermal storage. The Appendices show that, on running costs alone (assuming 0·3d. per unit and 26s. to 27s. per ton of coke), there is little to choose between the two methods of heating, and it seems that to persuade those who are responsible for erecting new buildings or altering those in existence may be very difficult unless more favourable balance sheets can be shown. The price of 0·3d. per unit seems high where generation is carried out efficiently, and it would be of great interest to know exactly how this particular figure is arrived at, so that supply engineers in general may have guidance in furthering this excellent method of improving both their load factor and their revenue. One wonders also if the proportion of coal cost is the same as that ordinarily taken for general supplies, remembering that the coal cost itself is reduced owing to the improved load factor. In the figures shown for the first cost of the equipment, how much is allowed for the cost of the substation equipment and high- or low-voltage mains? One assumes that, in a large building such as Carliol House, a substation is almost essential, merely to cater for lighting and power, and therefore a proportion only of this should be charged against the heating plant. As the development and use of electrical thermal storage proceeds, the home market for coke, which is very considerable, will be spoilt, and the price of by-products will increase considerably, owing to decreased production. The effect of this is, of course, further losses to the colliery owners and, in coal-producing districts such as this, a decrease in revenue to the supply authorities from colliery load. We have also to consider the national point of view, whereby better use is made of our resources by burning coke than by burning raw coal, as is the present practice, in generating stations. It seems, therefore, that the development of the system of heating advocated by the authors should proceed hand in hand with that of burning coke, more especially low-temperature coke, for steam-raising in our generating stations.

Mr. W. Richardson: On page 658 the authors refer to the storage media, and a comparison between water and oil is given, in which water is shown to be the better medium. They have not made it clear that this comparison depends very largely on the effective temperature range through which water can be heated and that the circumstances may be such that oil is the better medium. There are one or two small installations working in the Midlands in which oil is used. The authors have taken for water the temperature range of 160 deg. F., i.e. from 280° to 120° F. The latter temperature is too low a circulating temperature for a central heating installation, using standard hot-water radiators, and 140° F. is a better figure; also 280° F. is rather high and I would prefer a figure of 260° F., which is the temperature which can be obtained with a suitable margin for a building providing about 70 ft. head. With these figures the storage per cub. ft. of water is 7 500 B.Th.U. Turning to the oil installation, it is not usual to circulate oil through the building, and water is used. This water is heated through a calorifier. Assuming a minimum water circulating temperature of 140° F. and 20 deg. F. drop in the calorifier, this gives a minimum oil temperature of 160° F., so that the available temperature range is 340 deg., instead of 380 deg. as given in the paper. This gives a storage capacity of 7 250 lb. per cub. ft. It will be seen from this that for any building with less than 70 ft. head, oil storage may be the better proposition; although it must be remembered that an additional calorifier is necessary to transfer the heat from the oil to the water. Can the authors give us particulars of any installations working on this system? The description of the Carliol House heating plant is full of interest, but I think that if progress is to be made with this system of heating it will be on the lines of the Newcastle-upon-Tyne block of offices and showrooms, described on page 664. This installation is very simple and can be operated with a minimum of attention. Doubts may be expressed as to the reliability of large immersion heaters, but it should be remembered that these are rather different in design from the ordinary small domestic immersion heater, as the rating and internal temperatures are very much lower. The heating installation used at the Vaudeville Theatre, London, which was the original thermal-storage heating system working in this country, and which utilizes large immersion heaters, has operated for more than 5 years without any heater breakdowns. The usual method of controlling a thermal storage installation is to circulate the water round the heating system at a predetermined temperature, and frequently this temperature is controlled automatically, but in spite of this the method of heating is not fully automatic; one has to predict the probable weather conditions outside, so as to arrange for a suitable circulating temperature. The problem in the heating of a building is to maintain a definite air temperature in the rooms, say 63° F., independent of the outside conditions, and I should like to know whether it is possible to control the installation from a thermostat registering the air temperature in a portion of the building. If this can be done, then the plant will become fully automatic, and this should be a big factor in popularizing this method of heating. I would also suggest that with thermal-storage installations it is important that the pipe arrangement should be such that the storage cylinder can be completely isolated from the circulating system, so that this can be emptied, in the event of a leak or burst radiator, without having to lose all the stored heat in the cylinder.

Mr. F. H. Williams : Thermal storage as an off-peak load should be very attractive to the supply authorities. It should be equally attractive to the owners of large buildings, but from this point of view the Appendices are not as helpful as they might be. A casual examination of Appendix 2 suggests that as regards operation the electrical installation costs about the same as the coke installation but that its capital cost is nearly 50 per cent greater. This does not sound attractive to the ordinary landlord who does not care how his building is heated; he is only interested in obtaining the maximum net return for the money invested. If the adoption of electrical thermal storage enables him to put more office accommodation on a given site and obtain a greater net revenue, he will install it. This is what electrical thermal storage enables him to do, but it is by no means self-evident from the Appendices. I think Appendix 2 should be modified, so that (i) the capital cost of the coke installation is debited with the cost of chimney and flues; (ii) the running cost of the coke installation is debited with the cost of cleaning and maintaining the chimney and flues; and (iii) the capital cost of the electrical installation is credited with the capitalized value of the extra accommodation rendered available by the omission of chimney and flues. These alterations would give a truer comparison of the costs of the two systems, and one which would attract consumers. I should like to know whether the price given for the coke installation in Appendix 2 covers duplicate plant to the same extent as the electrical installation is duplicated. Modern electric boilers should be quite as reliable as coke boilers and, if used on an " off-peak " system, there are available for maintenance 12 hours during each day which would not be available with a coke boiler. I should also like to know whether, in considering alternative schemes for Carliol House, the authors obtained prices for the ordinary hot-water radiator system and, if so, how these prices compared, both as regards capital and running costs, with the panel system. I believe that the panel system is easily the more economical in running cost, and the panel heater has no ill effects on the decorating, whereas in certain offices I occupied the ordinary radiators ruined the decorations in a single winter. I have had experience of five systems of heating for large buildings:—(i) hot air circulated through the building from a central heating chamber; (ii) coal fires; (iii) electric radiators; (iv) hot-water and low-pressure steam radiators (convectors); and (v) the panel heating of Carliol House. Although I have still to meet the ideal system of heating, I consider the panel system to be easily the best of these from the point of view of general comfort.

[Messrs. Monkhouse and Grant's reply to this discussion will be found on page 699.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 26TH NOVEMBER, 1929.

Mr. C. Howard: The recent advances in the utilization of electricity by means of thermal storage for the heating of large buildings in London has intensified the interest which was originally created by the earlier installations at Newcastle. The authors' statement that with the Sulzer boiler " movable electrodes are employed which are hydraulically raised or lowered to the required degree of immersion " is somewhat surprising, as it is to be presumed that the authors have had access to the Sulzer electrode boiler-plant installed at the Newcastle Motor Depot, of which a full description appears in the paper. The fact that the position of the electrodes is fixed has always been one of the principal claims for the Sulzer electrode system, and this seems to have been overlooked by the authors. The actual method adopted for load regulation in the Sulzer boiler depends upon the voltage of supply. With boilers arranged for low voltage, movable counter-electrodes are employed; and with high-voltage supply, movable evaporating tubes of insulating material surround the electrodes, i.e. one tube surrounds each electrode. Both these methods obviate the necessity for any form of "electric cum steam" glands to which the authors object. In the low-voltage boiler the counter-electrodes form the neutral point of the system and can therefore be electrically connected with the boiler shell. The reference to the Reyrolle electrode boiler is very interesting, as I believe that this boiler has not yet been employed commercially and few, if any, particulars have hitherto been published. It is at present, presumably, in its experimental stage. The statement that the load is regulated by " varying the rate of feed " is somewhat ambiguous, as it is not at all clear which " feed " is to be regulated. Is it the electrical feed? If so, the only means of regulation would appear to be a variation of the voltage at the electrode terminals. If, however, it is the feed water to which reference is made, then it would appear that the boiler in question is a steam boiler and that " varying the rate of feed " would be but another way of describing " alteration of the water level " as in the Oerlikon boiler. It is well known that the serious objections to this method of regulation are the arcing which occurs at the electrodes, the violent fluctuations in the electric load, and the corrosion of the electrodes themselves. These objections can only be overcome by complete submersion of the electrodes, and hence load regulation must be provided by means other than an alteration of the water-level. It will be realized that with electrode water-heaters, as opposed to steam boilers, the electrodes must of necessity be entirely submerged. The authors state that " because of the somewhat greater difficulty of applying low-voltage electrode boilers to a low-voltage earthed-neutral system the resistance heater method is frequently preferred when only a low-voltage supply is available," the reason given being that "the resistance heaters are completely insulated from earth and consequently avoid the formation of a short-circuit through earth to the network neutral." I claim that there is no difficulty whatever in applying a low-voltage electrode boiler to a low-voltage earthed-neutral system; this has actually been done in the case of one London installation in which a 750-kVA boiler operates upon a 3-phase 400-volt supply. The electrode area is provided by means of concentric cylinders into which a similar set of movable concentric cylindrical counter-electrodes move. The counter-electrodes are connected to the neutral part of the supply and thus need not be insulated from the boiler shell. Load regulation is provided by movement of the counter-electrodes. The electrodes and counter-electrodes are always completely submerged. This system of electrodes cannot be described as costly, and is certainly less so than a set of resistance heaters of similar size. The switch arrangement is also more simple, consisting of a 1 000-ampere 3-pole circuit breaker with no-volt and overload releases. A further advantage of the electrode water heater is such that arrangements can very easily be made for the time switch which terminates the supply at the end of the off-peak period first to reduce the load to the minimum before finally cutting out. The advantage of this to the supply authority is obvious, as it avoids any possibility of a large single load being suddenly thrown off the mains. A statement is made by the authors to the effect that a steam-raising boiler is more flexible than a water heater. It is surely not a question of water or steam, but rather whether the heaters—resistance or electrode—are placed in the storage vessel or are separate units. It is obvious that the separate unit is more flexible, but it is not correct to state that a separate steam-raising boiler is more flexible than a separate water-heating boiler. The water-heating boiler has the very great advantage of requiring no calorifiers for a heating installation, as the heated water can be passed directly either to the heating system or to a storage vessel. This is a special advantage where night heating of buildings is required, where the storage vessels and the heating system can be supplied with their definite quota of heat direct from the boiler. It is interesting to learn from a statement in this paper that although one new set of electrodes has been provided for the water electrode boiler at the Newcastle Motor Depot the replacement was unnecessary. As no similar reference is made in the case of the Carliol House plant, which is a more recent installation, it is to be assumed that the replacement of electrodes was a necessity. As there exists here an example of systems working under the same voltage and general conditions, but in the one case consisting of a water electrode boiler with fully immersed electrodes, and, in the other, steam boilers with partially immersed electrodes, a comparison of the state of the electrodes after 1 year's use would be interesting. The authors' comparison between oil and water for heat-storage purposes is decidedly interesting, and when the additional risks in the event of fire, and the impossibility of using other than immersion heaters, are taken into consideration it will be found that the oil storage system is only suitable for relatively small installations. The chief advantage which has been claimed for the employment of oil in thermal storage plants is the smaller volume of storage required. This paper is very interesting in exploding that theory. Although the temperature to which water may be raised in a normal heating installation for storage under the static head of the building is, I believe about 250° F., even at this temperature the comparison with oil is as 815 to 817, which small advantage is unjustified when considering cost and the difficulties of using oil for this purpose. I regret that the authors have not stressed to a greater degree the desirability of this class of load to the electrical supply authorities. From the results in the paper it would seem that the consumption of such a plant is in the neighbourhood of 1 000 units per annum for each rated kVA, and although the actual load factor is only 11·5 per cent its effect on the general load factor of the supply system is considerable. Taking the published load curves of the Manchester Corporation Electricity Department during 1928, a load of 50 000 kW could be superimposed on the existing loads between 7 p.m. and 7 a.m. without exceeding the corresponding maximum load during the day, and, assuming this load to be composed of heating plants of the nature described in the paper, the load factor would be improved from 34·64 to 38·4 per cent. Assuming the constant losses at the generating station to be as low as only 18 cwt. of coal per day per 1 000 kW of the maximum demand, such an improvement in the load factor would decrease the coal consumption per unit by 0·02 lb., equivalent to a saving of 4 200 tons per annum, or, say, £2 500 with coal at 12s. per ton. Thus each installation of 1 000 kW rating in Manchester might be regarded as additional unseen profit of £50 per annum, exclusive of the profit made on the actual consumption of current by the heating apparatus.

Mr. S. M. I. Saunders : The problem which station engineers in particular will have to face is the cost of the fuel. There are bound to be comparisons between "electrical fuel," coke fuel and oil fuel. With "electrical fuel" it appears possible to approximate to the costs obtained with oil firing, for electrical heating is much more amenable to automatic control. Automatic control can be applied to coke and oil firing, but not with the same degree of accuracy as can be obtained with electrical heating. In making the comparison between the cubic capacity required with water storage and oil storage, the authors give an absolute figure for the specific heat of the oil, viz. 0·4. Elsewhere it is given as 0·5 or 0·56. Taking the higher figure, if the lower limit of the temperature-range for the circulating water is not quite so low as quoted in the paper, the cubic capacity for the storage of equal amounts of heat in water and oil will be in favour of the latter, unless the water is at a very high temperature. A decided change is taking place in the method of heating buildings. At the beginning of the War the usual method was by ordinary pipes and radiators, but now panel heating of various types is being adopted. It appears to be a very good opportunity to combine thermal storage with panel heating, as against the pipe and radiator with oil or coke firing, because with panel heating equal comfort can be obtained with considerably less heat input than is the case with pipes and radiators, with relatively cheaper fuel cost.

Mr. W. E. Swale : The authors describe plant which has long passed the drawing-board stage, which is essentially simple in operation, cheap to install and comparatively cheap to operate, and which offers the heating engineer the advantages of electricity in an eminently practical form. Criticism of electric thermal storage plant will come mainly from three sources; from the architect and his collaborator, the heating engineer; from the electrical mains and installation engineer; and finally from the unfortunate individual who has to offer—to quote the authors—" an appreciable reduction in the prices charged." The architect and the heating engineer can, I venture to say, have nothing but whole-hearted approval for the new systems. In effect, the authors simply propose to substitute a different central heating unit. In this country hot-water heating installations are still in the overwhelming majority. Thus, no part of the building heating plant in itself need be changed. The absence of a chimney stack and facilities for fuel storage, and the correlated fact that the heating unit can now be placed anywhere in the building, are obvious advantages which need only to be fairly assessed in money values. The design and control of the plant are so simple that operation difficulties should be non-existent. The electrical installation engineer likewise has no serious difficulties to face; the connection of a 1 000- or 1 500-kW heating load to the system presents conditions in many respects less onerous than those of connecting a motor of equivalent capacity. Referring to page 659, can the authors state definitely that no troubles have been experienced by earthing the neutral point of the 6 600-volt boilers on the premises? The mains engineer's problems need more careful consideration, because on large distribution systems the load curve of the individual e.h.t. feeders does not necessarily coincide with the load curve of the generating station. To make a low price economically justifiable extra capital expenditure must be avoided, and existing mains must be utilized during suitable hours. Again, the longer the charging period the smaller can be the rating of the thermal storage unit. It seems that a charging period of at least 12 hours is desirable. It will thus be the duty of the mains engineer to choose a period or periods in the load curve when the heating load can be taken without creating fresh peaks on the distribution system. The method of regulating the load, judging from the authors' remarks, is to switch on the full capacity by time switch and to switch off successive sections by thermostat. The whole load being switched on at once, at, say 7 p.m., may cause difficulties through coincidence with existing night loads. I suggest that a device could be included in the switching arrangements akin either to a current limiter or a clock-operated cam gear, by which, during the early hours of the evening, sections could be switched on proportional to the feeder capacity available, and the complete heat rating left on until the later limit of the charging period. The last of the three possible sources of criticism will be from those who have to sell electrical power at a suitable price. The authors, very wisely, " have refrained from making any definite statement on the subject." It is primarily the function of public supply undertakings to safeguard the interests of all consumers equally. One class of load ought not to be encouraged at the expense of other consumers. The rates which have been mentioned as economical from a heating point of view are well within the range of large supply authorities, and there need be no fear that they will not take full advantage of the facilities offered. But the economics of the question must always be kept in mind, and very cheap rates cannot be quoted where extra capital expenditure is involved. Comparatively small installations of, say, 250, 500, or even 750 kW can no doubt be connected by large undertakings at a price which will make the installations competitive. With larger-sized units the question of additional expenditure on mains may have to be faced, and such installations will need very careful and individual investigation. The load factors of thermal storage plants will probably not be much higher than 16 per cent, owing to the fact that they will generally be shut down completely for 6 months in the year. The descriptive phrases now in use seem to be unnecessarily cumbersome, and I suggest the adoption of the following terms: (i) electrode T.S. plant, (ii) resistance-water T.S. plant, and (iii) resistance-oil T.S. plant. The authors' figures regarding total connected capacity in this country alone show the very considerable progress which has already been made in this new application. It seems, as the authors point out, that electricity supply engineers can now offer an ideal means of heating large buildings, with the additional benefits of substantial improvement in the station load-factor.

Mr. J. Anderson: The paper appeals to me mainly from a thermal-storage point of view. This aspect of the subject is a most important one, as it is quite apparent from the authors' remarks that the full economic benefits from the heating of buildings electrically are only possible when some form of thermal storage is adopted. I have in mind a specific case of a building which is now in course of construction, where the combined scheme of electrical boilers and thermal storage is used on a much larger scale than in ordinary buildings. The particular scheme is for a large poultry farm where constant temperature is the most vital factor. The arrangement comprises three electric boilers and a Ruths steam accumulator. The boilers will generate steam at a constant pressure and steady output during off-peak periods prevailing in the local power station. The current so consumed will be bought at specially low rates. All surplus steam will be automatically by-passed into the steam accumulator, which has a thermal storage capacity of 12 000 lb. over a pressure range from 120 to 2 lb. per sq. in. At times the whole output from the boilers will be passed into the accumulator at a pressure of 120 lb. per sq. in. When the peak periods occur at the power station the current will be shut off, thereby closing down the electric boilers completely. All steam for heating purposes is then automatically taken from the accumulator at a pressure of 2 lb. per sq. in. The storage capacity of this accumulator is sufficient to run the plant with the boilers switched off over a period of 6 hours, at an average of 2 000 lb. per hour, or 8 hours at 1 500 lb. per hour, 12 hours at 1 000 lb. per hour, and so on. Much has been written lately on the importance of filling in the valleys in a supply undertaking's daily load curve. The paper is all the more welcome on account of showing how the various professions can assist in achieving the object of more economical production of electrical energy and at the same time receive all the advantages of a more efficient system.

Mr. O. Howarth: The authors describe an electrode boiler connected direct to a 6 600-volt 3-phase supply.

The system is, therefore, used as a 3-phase 4-wire system. Are any of these boilers installed on a high-voltage system with the neutral earthed through a limiting resistance? If so, when an earth occurs on one phase of the system the electrodes in the boilers which are connected to the other two phases of the system may have full line voltage to earth impressed on them until the fault is cleared. Have the authors had any experience of such occurrences? It would be interesting to know what the Post Office engineers have to say about the adoption of an earth-return path to the station neutral for the out-of-balance current. Can the authors tell us what type of metering is used to measure the energy consumed by the electrode boilers which have been installed? A 3-phase 3-wire meter can hardly be considered to be satisfactory for measuring the energy, as current may pass via earth to the station neutral point. A 3-phase 4-wire meter is undoubtedly called for, and there are two methods of connecting the potential system of the meters. Either a 3-phase or 3 single-phase potential transformers may be used with the primary star point earthed, or a 3-phase core-type potential transformer may be employed with the primary star point left free (there are alternatives to this arrangement giving the same result). The former arrangement will measure accurately the energy consumed by the boiler. The latter arrangement practically picks out the station neutral point and will measure not only the energy consumed by the boiler but the energy consumed by the earth connections back to the station neutral. When the system is earthed through a limiting resistance the out-of-balance current returning via the earth must traverse the resistance to get back to the machine neutral, and the energy consumed by this resistance will be registered by the meter if the primary star point of the potential transformer is not earthed. The consumer will therefore pay for the energy consumed by his electrode boiler and by the station earthing-resistance.

Mr. J. Sunlight: Can the authors state what will be the inducement to the owners of a building to venture upon an installation of this kind instead of the type to which people are now accustomed? I can understand the architects, in the case of the new London Underground Railways building, having designed a very modern type of building, being anxious to attain the height of their ambition by adopting the most modern scheme, but what is going to persuade an owner to adopt it, apart from the pioneer instinct? When this method of heating is adopted, will the atmosphere in a building be in any way different from that of a building heated by hot water, coke or oil? Consider the case of a coal fire in a room at home as compared with an electric heater in the fireplace. Is there not a distinct difference in the feeling of the air? Is there going to be any difference in an office heated by this system as compared with coal or coke heating? Can it be relied upon that the temperature will be maintained at the end of the day? Another point is the question of replacement and maintenance. At the end of 20 or 30 years, owing to the wear and tear, will the bulk of the heating chamber and the machinery require replacing? If so, the question of the cost of renewing this elaborate machinery will be a very serious problem. But above all, are we likely to get supplies at economical rates? One can buy coke anywhere, but by adopting a system like this one is placed entirely in the hands of one authority.

Mr. S. S. Jewsbury: On the Continent electrically-heated thermal-storage plants have been in use for about 20 years. I have examined several of the Continental installations, and have found the conditions existing there to be somewhat different from those existing in this country, due chiefly to the extensive use on the Continent of hydro-electric power stations. The authors have mentioned several thermal storage installations where current is supplied at about 0·3d. per unit. My experience has been that very few consumers in the provinces are willing to pay this price for restricted-hour high-voltage supplies. I believe that at present the Manchester Corporation Electricity Department supplies current to dwelling-houses at the rate of £5 per annum plus ½d. per hour per unit consumed, this being a continuous low-voltage supply. In London conditions are slightly different; but in centres like Manchester 0·2d. is apparently the highest figure at which development can be expected to take place in the case of installations such as those mentioned by the authors. There are, of course, buildings where serious financial loss would be caused by dust and dirt damaging the stock, but in the majority of cases consumers are only willing to pay slightly more for the privilege of using electricity than they would have to pay if they used solid fuel, in spite of the fact that by using electricity they will avoid the dust and dirt inseparable from the use of solid fuel. My firm have found that these conditions are also applicable to oil-fired installations. The paper shows that suitable apparatus is now available, and the question of the future development of the large installations depends upon whether the power companies can bring down their charges sufficiently to justify their clients installing apparatus of the type described to us. Some years ago, at a joint meeting between the Institution and the Institution of Heating and Ventilating Engineers, a paper was read by Mr. Haden and Mr. Whysall, advocating the use of waste heat from electric generating stations. Many engineers are of the opinion that, if such stations could be erected in positions where industries using heat are located, the cost of generating electricity could be reduced considerably, and it might even become a by-product at certain times of the day. If this happened it would then be possible to supply current to districts some distance away from the generating stations at a price which would make the adoption of thermal storage schemes a paying proposition. On page 660 the authors refer to the fact that a panel-heating installation requires a lower circulating-water temperature than a radiator system. The panel system is therefore particularly suitable for use in conjunction with thermal storage schemes. Take, for example, the Carliol House installation. The water in the storage cylinders is heated to a temperature of 230° F. The normal temperature of the water in the panel system is 120° F., giving a margin of 110 deg. F. for heat storage. If a radiator system had been installed, with a normal working temperature of 160° F., the operating range in the storage cylinders would have been only 70 deg. F., and consequently cylinders of considerably greater capacity would have been required. Incidentally, we find that the total quantity of heat required to maintain conditions of comfort in buildings heated by the panel system is less than is found necessary in buildings heated by radiators. The authors did not mention one distinct advantage possessed by thermal storage installations: that is, that the maximum heat is available in the early morning, when it is most required. In some buildings sufficient heat can be stored up in the fabric and air to maintain a satisfactory temperature during the greater part of the day, when the heating apparatus is in use during part of the night and the morning. I know of one large building where the heating apparatus is only worked from 4 a.m. to 1 p.m., even in cold weather, and this enables the proper temperature to be maintained during the ordinary working hours, which are from 8 a.m. to 5 p.m.

Mr. J. Frith: We have heard a good deal about heat insulation of the apparatus immediately concerned to enable thermal storage to be carried out, but have any efforts been made to regard the building as a whole instead of merely the heating apparatus? All the pipes, cylinders and everything else are carefully insulated until we come to the actual building, and then we get rid of the heat at a tremendous rate. When faced with a heating bill of £2 000 a year, would it not pay to attempt to insulate the building? Those who have studied bricks know how very much they differ in thermal conductivity, and one might very easily use a brick which would halve the loss of heat from the building itself. I must protest against some of the terms used; for instance, a boiler is a thing that produces steam, and we should not refer to a water heater as a "boiler."

Mr. A. B. Mallinson: Whilst the cost per unit quoted in the paper is undoubtedly very low, I have no doubt that many of our supply engineers would be very glad to undertake "off-peak" loads of this character at between 0·25 and 0·27d., which is about 4 times as much as is paid in Canada for supplies for electric steam-raising. The authors indicate that this is quite a simple system, but it is extremely difficult to follow from the diagrams. For instance, in Fig. 4 there are 20 pipes leading away from the main plant, but the use of only three of these is indicated. In the figures given for Carliol House, "attendance" is *nil*. Surely somebody has to look after the apparatus. What happens if it goes wrong? For the coke-fired system, the authors give £550 for attendance. That seems to be an exaggeration. The authors mention that the system is easy to adjust, and if the day was warm less current would be switched on. The thermostats would of course maintain, say, 63° F. in the rooms, but are there not many days in our English winter when a lower temperature, say, 60° F., would be more comfortable? Has any trouble been experienced with corrosion, not particularly in regards to the electrode but in the boiler itself, and in the pipes? Can the authors give us any idea what it will cost to produce 1 000 lb. of steam or hot water at, say, 160° F.? It is a proposition which power station engineers would welcome in districts such as Lancashire where there are many works which are bound to have a certain amount of steam for their processes. If such manufacturers could buy steam at 1s. 6d. to 2s. per 1 000 lb. generated electrically on the off-peak system, it would induce them to do away with their own coal-fired steam boilers. Much has been said about the panel system which is practically universally adopted in all the modern skyscrapers in New York, but my experience in that city is that it is not altogether satisfactory. An even temperature is ensured, but this temperature may be excessive. The question of covering is mentioned in the paper and various statistics are given, but the authors are vague in their references to the class and thickness of cover adopted in the installations described. In considering this system we must always remember that coke-fired boilers are improving. There are on the market installations for coke-firing which are greatly in advance of anything produced 3 or 4 years ago, and recently I saw a coke-fired sectional water heater, of 1 000 000 B.Th.U. capacity and fitted with the Wollaston producer boiler, operating at over 80 per cent thermal efficiency. The overall efficiency could be slightly improved by raising the steam in the electrical boiler to a pressure of, say, 160 to 200 lb. per sq. in., passing it through a prime mover and exhausting into a low-pressure calorifier in the heating circuit, the supply from the prime mover being utilized in the heating circuit by a water heater. This would reduce the demand on the supply by 7½ to 10 per cent.

[Messrs. Monkhouse and Grant's reply to this discussion will be found on page 699.]

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 9TH DECEMBER, 1929.

Prof. E. W. Marchant: The case for electric heating is nowadays much stronger than may appear at first sight. With a modern power station having a thermal efficiency in the neighbourhood of 20 per cent the heat available in radiators or tubular heaters is practically 20 per cent of that in the coal. The ordinary open fire has an efficiency of about 30 per cent and the coal which is burnt in it costs at least twice as much as that used in power stations; it is evident therefore that electrical heating should be cheaper than the ordinary coal fire. As regards the heating of buildings by the means suggested by the authors, the case is not so strong, since the efficiency of the hot-water system with coke-fired boilers is much higher than that of the open fire. The figures given in the paper, of 35 000 B.Th.U. for 1d. with coke-fired boilers, as against 13 500 with electricity at 0·4d. per unit, emphasize this fact. I am inclined to think that the type of electrical heating which will be most popular in the future is that in which heating-tubes working at a fairly low temperature, or radiators, are employed. The great advantage of electricity is that the heat produced by the radiator can be generated precisely at the place where it is required. For example, the radiator can be put in front of a window if there is a draught due to the cooling effect of the latter, and one of the advantages of the electrical method is that the energy can be conveyed so easily to the place where it is to be transformed into heat. The only point in favour of the thermal-storage system is that it consumes electricity at times when it is not being utilized for other purposes. As time goes on and load factors improve, this will become of diminishing importance. There may be cases in which electrical heating by thermal storage will provide a practical solution, but I do not think it likely that they will be very numerous.

Mr. R. G. Devey: The authors have not mentioned the manufacture and life of the materials which have been used for the electrodes. I believe that common materials such as iron have been employed, but more information on these points would be of interest. It is well known that on the Continent electric boilers and storage schemes are used more than they are in this country. I do not know why this should be; it may be due to the fact that on the Continent a good deal of surplus power is available, probably because electricity can be purchased from hydro-electric companies on a kilowatt-year basis. The efficiency of thermal storage in the case of the electric boiler seems to be taken as 100 per cent. I do not think that this can be quite correct, because the night-load input of heat has to be retained and used over a period of 24 hours. It would be interesting to know the total efficiency over 24 hours, rather than over one hour only. In connection with the tubular type of heaters, I wish to ask the authors whether it is possible to use either alternating or direct current, also what is the most suitable material for the construction of the heater. On page 664 there is a paragraph in which the consumption for 2 000 cub. ft. is given as only 46 kWh per week, or something less than 1 unit per hour on a 12-hour day. This seems to be an extremely low figure. I find great difficulty in keeping a room warm with only 1 unit per hour. If electrical heating on the thermal-storage system were to be adopted on a large scale, there is no reason why this should not take place on the basis of the figures put forward by the authors. A large building like Carliol House requires 1 000 kW to provide heat for 24 hours, so that 50 similar buildings would consume a total night load of 50 000 kW. But in a city there may be several hundred buildings each large enough to require 1 000 kW at night time, so that the limits of a large power station would soon be reached, and cheap night power would come to an end. With reference to Appendix 2, page 665, showing a consumption of 100 000 kWh or about 3 740 million B.Th.U., to be compared with 500 tons of coke costing £650, I should be interested to know the calorific value of the coke. If this is taken as 11 000 B.Th.U per lb., the total heat from 550 tons is 12 320 million B.Th.U., which indicates that the coke scheme is worked at an efficiency of 30 per cent; it seems to me that the electricity supply could be shown to greater advantage.

Mr. M. P. Concannon: I am connected with the company which installed the plant at Carliol House, and I am convinced that if that system were adopted more generally by supply authorities and architects, considerable improvements in heating methods would result. It has been found at Carliol House that the panel method for supplying the heat to the rooms is very well suited to the thermal-storage system, because the panel system works at a lower normal temperature than the ordinary radiator system, the average temperature in the panel system being 120° F. The authors have pointed out that 230° F. is the upper limit of temperature to which the storage water is heated at Carliol House. This gives a much greater temperature-range than would be obtained with an ordinary radiator system working at 160° F. average temperature, and giving a temperature range of from 230° F. to 160° F., i.e. 70 deg. F. As the amount of storage water required depends on this temperature-range, considerably less storage space is required by the panel system. It is also found that the panel system requires somewhat less heat than a radiator system, to give equal comfort conditions in a given building. This point probably explains the apparently small electrical consumption per office of 2 000 cub. ft. capacity mentioned by the author, and referred to by a previous speaker as very low at 46 kWh per week. Owing to the radiant effect and to the fact that ceilings and walls are warmed, thus reducing body radiation in those directions, comfort conditions not directly measurable by the ordinary thermometer can be obtained with the panel system. In the past years, I believe, heating engineers have been somewhat unpopular with electrical supply authorities because of the many schemes for the private generation of electricity which have been put forward and carried out by heating engineers for some large public institutions. By utilizing the exhaust steam for heating purposes the overall thermal efficiency of the plant has been increased. If the thermal-storage system were to be adopted in such institutions, or elsewhere, it would provide an opportunity for heating engineers and electrical supply engineers to work together to their mutual advantage. From the architect's point of view, the thermal storage system presents a great advantage because of the saving in cost and valuable space which results from the elimination of flues. There is also greater cleanliness and absence of smoke with electrical heating. I think that if the expenditure involved in operating coke-fired boilers were to be included in the comparison, the total running-costs would work out more favourably for the thermal-storage system than the authors have shown. If the staff were reduced by one man only, the saving should, of course, be credited to the thermal-storage system.

Mr. A. H. Langley: The authors have shown that for large buildings thermal storage electrical heating is economically a sound proposition even though the initial cost exceeds that of a coke-fired system. A decided advantage of the electrical method is that the installation can be made entirely automatic. There are a few points in connection with panel heaters which have not been stressed by the authors and which I think worthy of mention; they are:—(1) draughts are avoided; (2) quite a considerable proportion of the heating-effect is by low-temperature radiation, which is preferable to air-warming; (3) no damage is caused to the decorations by convection currents such as are set up by the ordinary hot-water radiator. I should like to know whether a system of thermal-storage heating could be successfully applied to domestic buildings. It should be feasible to install such systems in the blocks of flats which are so common in London, and to add a fixed charge to the rent. It is also possible that, in future, city councils will have all-electric housing schemes on the following lines. Groups of houses will be arranged in rectangular formation, not scattered about as in the present schemes. They will be heated by a thermal-storage electric plant installed underground in the central space. Their domestic hot-water supply will also come from the installation. Electric cookers and electric light will complete the scheme, the running costs of which will, I think, be far lower than those of the present all-electric municipal corporation houses.

Mr. J. H. Collie: I have been connected with the installation of a number of tubular electric heaters, which are proving very satisfactory. Generally speaking, however, where the tariff is in the neighbourhood of 1d. per unit this system is only suitable for moderate-sized buildings which require occasional heating, such as schools, churches, halls and domestic buildings. For large buildings requiring relatively continuous heating, the running-cost at this figure is considerably in excess of that of other direct methods of heating. Recently, however, several large buildings have been fitted with tubular heaters on a special tariff of 0·5d. per unit, subject to continuous working on thermostatic control and to being cut off during peak-load periods. It is found that this method, which is really a simple type of heat storage, works very satisfactorily, and that the running-costs compare very favourably with those of other methods of direct heating. There has recently been introduced a new type of tubular heater fitted with spiral fins, which can be loaded up to 250 watts per foot, and which has the same outside temperature as the ordinary tubular heater working at 60 watts per foot. This reduces the initial cost considerably, as it is not necessary to double-bank the tubes in order to obtain the necessary heating surface. I should like to ask the authors whether any progress has been made with small storage heaters of the domestic type. The question has been raised of the possibility of heavy peak loads in cold weather in the event of considerable extension of electric heating. In this connection it was stated recently that some of the Canadian supply companies were not encouraging the electrical heating load on account of very heavy peak loads in the winter. A cold spell might embarrass some of the supply authorities in this country if electrical heating came into common practice.

Mr. S. Lowey: The building belonging to the railway company may not offer much difficulty, but, in the case of other installations, how is the load confined to the restricted hours? Is the switching accomplished automatically, or is it left to the consumer's representative to operate the switches according to time-table? The main storage of heat is really in the mass of the building structure itself, and in my view a water thermal-storage system in combination with electric panel or tubular heaters would reduce the installation cost. All these devices would of course be used only during the off-peak hours.

Mr. A. J. Pratt: One advantage in the adoption of the system of electrical heating is its application to the elimination of the smoke nuisance. I believe that in Liverpool, according to record, we are in the position of heading the list of statistics of various towns with regard to the smoke-content of the atmosphere. It seems to me, therefore, that any scheme whereby the smoke nuisance can be mitigated is to be welcomed. An article in the *Electrical Review* of the 29th November last mentioned the amenities of Tunbridge Wells and their close connection with the system of electrical heating and the installation of thermal-storage equipment. On the other hand there is a disadvantage in the electrode system of electrical heating of buildings by means of thermal storage. The paper mentions large installations of the industrial type, and it may be that the percentage cost of water-softening apparatus in such cases is inappreciable as compared with the overall cost of the equipment. However, if the ideal of a smokeless city is to be realized, the use of electrical heating apparatus will have to become fairly general and will need to be applied to groups of offices and residences, as well as to large industrial works. In some cities and towns the water is relatively soft, but in other cases the hardness of the water supply varies from 10 to 18 degrees. The cost of a water-softening installation as applied to fairly small residences is anything between £50 and £100, and to groups of offices the costs are considerable. It seems, therefore, that before the system can become of fairly general application, the small consumer will look for some adequate compensatory advantage. This may come in the reduced cost of building construction, in the avoidance of chimney stacks, etc. If one examines the cross-section of a water pipe in a district where the water is hard the bore of the pipe will be found to have been reduced to about 25 per cent of its original diameter. This is a serious factor which needs to be considered and disposed of before the electrical heating of small buildings can become universal. Local authorities should deal with this matter themselves, but unfortunately such bodies do not usually feel disposed to incur expense on these lines, even when there is a public demand for softer water for reasons of health. Plumbing work also needs to be very carefully completed, and unless air cocks are provided the whole of the system may need reorganization. I wish to ask the authors whether the capital charges quoted on page 665 include the cost of water-softening apparatus.

Mr. A. E. Malpas: The reasons given on page 657 for allocating a smaller proportion of capital charges to supplies for heating may be expedient for the purpose of further development of the heating of buildings by means of thermal storage. They seem, however, to suggest the fostering of one class of consumer at the expense of another. Great stress is laid on the saving of capital expenditure by not providing chimneys and flues in the buildings and houses. However, Prof. Parker Smith laid equal stress, I think, on the necessity for providing efficient means for ventilating all rooms. The need for efficient ventilation is exemplified in the case of the room in which we now are. I should like to ask the authors what type of water-softener has been used, whether the lime-soda or the zoolite process. In the case of the electrode heaters it would seem necessary to adopt some means for maintaining the constancy of the conductivity of the water in the system. This method of heating is inapplicable on direct-current supplies, owing to the evolution of explosive mixtures of detonating gas. Some of us have had experience of the difficulties created in the case of long and complicated pipe-systems due to the deposition of solid matter carried, either in suspension or in solution, in the water which circulates through them. I was interested in the use of the term "lag" as applied to a building, as, having adopted coke heating in my own house, I have been impressed by the slowness of the response of the inside temperature to a change in the outside temperature. I welcome the figures put forward by the speaker as to the number of B.Th.U. available per penny under the various systems quoted, and note that coke is the most economical of these systems, to the extent of about 500 per cent. In view of the ever-rising price of coal, it may perhaps be assumed that the use of coke will continue to be justified.

Mr. L. Breach: I should like to ask the authors whether they do not think it probable that the electrode type of heater will produce undesirable earth currents. With a slight deviation of the electrode from a central position in the boiler there will be a current to the casing of the boiler; this will become a leakage current and will have to find its own way back to the power station neutral connection. If there are several heating systems in proximity, and there are different deviations from the central positions in each, there will be an interchange of leakage currents through earth between the systems. Interference with telephone systems, etc., may result. In Liverpool there are some fine office blocks, equipped on the central-heating system, with coal-fired boilers, but it is found that although the offices are carefully heated, many tenants still have electric radiators. Possibly this is only for the sake of appearance and a cheery effect. Is any provision made, in the buildings mentioned in the paper, for tenants of this description?

Mr. F. E. Spencer: Supply authorities have to be very careful when offering supplies "off peak," as the peak may be moved in consequence. In my own experience the peak has been moved from 4·45 p.m. to 6·45 p.m. owing to the offer of a low tariff for domestic uses. The only safe hours during which an "off peak" tariff may be offered are, in my opinion, between midnight and 6 a.m. The rate of 0·3d. per unit mentioned in the paper is satisfactory for an authority which does its own generating, but when purchases are made in bulk more care is necessary in fixing the figure. It is proposed to erect new public swimming-baths in Birkenhead, and on account of the possible nuisance from smoke and fumes the question has been raised as to whether the water can be heated electrically. I should like to know whether the authors have any experience of the electrical heating of swimming-baths.

[Messrs. Monkhouse and Grant's reply to this discussion will be found on page 699.]

SCOTTISH CENTRE, AT EDINBURGH, 14TH JANUARY, 1930.

Mr. E. Seddon: The value of heat storage is consequent upon a cheap rate being offered for the supply of the necessary electrical energy. The system described in the paper provides just the kind of load that supply engineers desire at a time when the general demand is low, and a cheap rate can therefore be offered with mutual advantage to both parties. Some months ago I was able to inspect the Carliol House heat-storage system; the businesslike appearance and efficient lay-out of the plant impressed me greatly, whilst the figures produced by the authors show that it has been successful. As they point out, it is most important that storage cylinders for this purpose should be efficiently lagged, although I have not yet heard of the use of any commercial lagging which will provide an efficiency equal to 5 B.Th.U. per sq. ft. per hour. I am interested in the relative values of heat-insulating materials given on page 660. I find that Prof. Adams's handbook gives the following table of relative insulation conductances:—

Poultry feathers ..	6·2	Plaster of Paris ..	36·2
Hair felt	11·4	Asbestos powder	47·9
Cork powder ..	13·6	Fossil meal ..	52·1
Sawdust	14·2	Fine sand ..	56·3

A careful investigation of the many heat-storage plants now in operation, taking current during light-load periods, must appeal to station engineers who are interested in the levelling-up of their load curves. I believe it to be only a matter of time before all supply authorities will find it to their advantage to offer a low rate for this purpose. With regard to the method of applying the heat, it seems to me that the resistance type will prove to be the most popular form of heater for average-sized buildings owing to its simplicity of operation, especially where the supply is taken from low-tension distributors. I should like to call attention to the figure of 8 000 kWh per hour given on page 664 for the consumption of the London Underground Railway plant. Does not this represent the daily consumption? The tariff rate for restricted water-heating is given on page 665 as 0·3d. per kWh, whilst the authors in their lantern slides make comparisons at 0·25d. per kWh with other forms of energy. In my opinion, a rate of 0·3d. can be justified for high-tension supply under the conditions referred to in the paper, but I consider that 0·25d. is lower than most engineers will be prepared to go, even with an economical station.

Mr. A. F. Stevenson: It is interesting to hear of large buildings being heated in this way, but the costs have apparently been rather strained in order to make the electrical method come into line with coke heating. I think that smaller domestic installations would do more to fill up the valleys in the load curve. I am disappointed that the authors have not mentioned the electric heating system recently described by Mr. Haldane in which the heating effect is obtained by "reversing" a refrigerator. A comparison of the estimated costs would have been of interest.

Mr. W. Duncan: In order that the thermal-storage system may compete successfully with other heating devices, the electrical energy has to be supplied at a very low cost, and in fixing the latter it will have to be remembered that other night supplies are already being given at ordinary power rates. These rates are low enough to compete with those of other methods and to satisfy the consumers. The night supply is taken by bakeries, colliery pumping-systems, ice factories and for the machinery which prints the early morning editions of newspapers. It is difficult to see how a very low rate can justifiably be restricted to storage heating of buildings. It might be argued that in the latter the electrical supply is restricted, while no limitations are imposed in other cases. The nature of the work of certain consumers, however, is in itself a sufficient restriction in some districts. I cannot agree that a low rate can be given in the one case and not in the other, as there is no distinction between the claims of a consumer who is restricted by the supply authority and those of one to whom the exigencies of his business apply a similar limitation. If the suggested low rates are to be associated with all conditions of night load, the supply authority will require to lower the price to consumers who are already satisfied with the present tariff. All the systems described in the paper make use of water-heating. Have the authors any experience of the electrical oil-heated storage system? In this type of plant the oil, in which the heat is absorbed, is contained in a lagged tank and is passed through a calorifier. The water to be heated also passes through the latter, where it is heated, and then passed on to the radiators or hot-water draw-off points. It is claimed that the oil lasts indefinitely and that, owing to the high temperature at which the heat can be stored, the system can dispose of a quantity of useful heat which is many times as great as that with which a water storage plant can deal, under the same conditions. In addition, it has none of the disadvantages of a pressure system. I believe that several English municipalities are at present having this type of plant installed to provide heat for their showrooms and offices. It has been stated that domestic heat-storage plant is of greater interest to the supply engineer than the large installations which have been described, and I am of the opinion that if thermostatic control were to be introduced in conjunction with plant of that type, levelling of the load curve and improvement of the load factor would be more readily obtained. It would provide an all-the-year-round load which would be almost at its maximum in the summer time when coal fires are out of commission. As hot-water supplies are most commonly in use in the forenoon and late evening it is unlikely that the usual afternoon peak would be materially affected. I should like to ask whether, in the case of the building at Newcastle, the assessment was increased because of the installation of the thermal-storage plant. I think that such would have been the case if the plant had been installed in this district. Although nothing of the kind has as yet been used in Edinburgh, it is hoped that two 3-phase 450-kW electrode boilers for heating purposes will soon be on load. They are to be used for raising steam for the heating of incubators in which the chickens will also be reared after they have been hatched. This is of interest, from the power station standpoint, as an example of the variety of supply which is demanded. The cost of the energy will not, as yet, be at the rate of 0·25d. per unit, but the consumer is quite satisfied with the present rate, in view of the advantages of electrical heating.

Mr. G. Gunn: I should like to ask the authors what means are adopted by supply engineers to ensure that these comparatively heavy demands are restricted to off-peak hours.

Mr. R. Shaw: The authors mention that water has several advantages over oil, and I should like to ask what are, in fact, those advantages.

Mr. D. M. Macleod: The passing of Dr. Ferranti must have awakened feelings of regret in all. In his Faraday Lecture, two years ago, he gave a masterly review of the place of electricity in the service of man, tracing its development from the discovery of the lodestone to the present day. In forecasting the lines of future development, he dealt at some length with the question of electrical heating by means of thermal storage. He saw in that development a probable outlet for the electrical energy of large power stations, and the introduction of a night supply which would serve to level the valleys of the load curve. The authors have described the progress made during the past six years in this direction. Comparisons made between electrical development in America and that in Great Britain have hitherto been greatly in favour of the former. The progress indicated by the figure of 15 million units per annum for the consumption of these heaters during the comparatively short period since they were first introduced is, therefore, both surprising and gratifying. I was interested in the suggestion that the use of electrical heaters made chimneys unnecessary; if it is intended to apply to the usual domestic and office chimney with which we are familiar, the suggestion seems to be rather a bold one. It is a matter of common observation that were it not for the fact that they have chimneys in their rooms, many people would tend to stifle themselves. Chimneys do, in fact, serve a useful purpose in that they allow the vitiated air to escape. It would be a mistake to do without them. The question of the cost per unit of the energy with which the heaters are supplied is important and I am interested to find that the Newcastle installation is charged at the rate of 0·3d. per unit. It is very difficult to decide at what precise point a power station ceases to supply energy at a profit. I agree with Mr. Seddon, however, that 0·3d. or even 0·25d. is not too low a figure for a night load, in view of the fact that the additional output helps to keep down the standing charges per unit.

[Messrs. Monkhouse and Grant's reply to this discussion will be found on page 699.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 3RD MARCH, 1930.

Mr. R. H. Rawll: The paper by Messrs. Monkhouse and Grant is encouraging in view of repeated statements that although electricity can compete successfully with other forms of energy for power and lighting, yet for heating on a large scale it is not worthy of consideration. To counteract this pessimistic view it has been shown that at present there are electric thermal-storage plants, totalling over 12 000 kW, operating successfully in this country, and that the capital outlay on the plants installed is about £3 per kW. The authors are also to be congratulated on a paper describing not only actual installations in use, but also capital and running costs. Supply engineers should be interested in this form of night load, because it provides an ideal method of filling up one of the valleys in the load curve. It appears to me that at the moment the biggest opening for the systems described is in connection with new buildings; here the greatest economies and efficiencies would be obtained. There is, however, a wide field of opportunity for the adaptation of existing buildings to this mode of central heating, but I am of the opinion that concealed panel heaters would be ruled out on the score of cost and inconvenience of structural alterations, and in such cases tubular radiators or surface panels would have to be installed. The authors' views on this question would be valuable to many engineers. The cleanliness, convenience and efficiency of electrical heating as compared with other fuels have rightly been stressed, and they represent a definite cash value per annum which should be put to the credit of the electrical method when comparisons with other methods are under consideration. The monetary value of cleanliness and convenience is often used in propaganda work for domestic electrification, but it is difficult to impress upon the average householder the actual saving in terms of money. This difficulty should not arise in connection with large buildings, because here the savings are more apparent. Wages for stoking, space saved, collection of ashes, etc., are all items whose value a business man will readily appreciate. It is stated in the paper that in some cases it has been found necessary when using resistance heaters to insert these at different levels, or to employ a pump to accelerate the circulation during the water-heating period. The authors are no doubt aware that an immersion heater enclosed in an outer jacket, with inlet and outlet holes in the latter, has been designed for domestic use. An actual circulation of water thus takes place at the heater itself, the cooler water flowing in at one end and the hot water out at the other. On small tanks this has met with considerable success and it would be interesting to know if this method could also be applied to the larger installations to which the authors refer. The question of lagging is important and, as the authors point out, it is in all cases a matter of balancing the cost of the lagging material against the value of the B.Th.U.'s saved. There is, however, in my opinion, considerable need for research into this matter of lagging, for the success of electric thermal storage necessitates a supply of efficient, cheap and compact lagging materials. It must be confessed that the choice of such materials is at present very limited. With reference to the installation at the Banca Commerciale Italiana di Roma, it is not stated whether this is of the electrode- or resistance-heater type. I should also like to know whether a separate calorifier is utilized and the amount of the loading. With regard to the Carliol House installation, I had the privilege of inspecting this some time ago. I was impressed by the simplicity of the electrical equipment, the only visible part of which is a small switchboard. My visit coincided with the cold snap which this country experienced in the early part of last year, and, even under those conditions, all the offices and rooms in the building were comfortably warm. A figure of 46 kWh per week is given as the consumption per office. An ordinary electric radiator, which would be switched on for about 48 hours per week in the average office, could not be of a greater capacity than 1 kW for the same consumption; such a radiator would be unable to maintain a comfortable temperature. This comparison demonstrates very forcibly the efficiency of electric heating by thermal storage. It is not definitely stated in the paper, but I understand that the whole system of panels throughout the building is continuously in operation. It appears from Fig. 5 that the electrodes arc to a common neutral point. The metal casing of the boiler is earthed, and hence there appears to be a path from this neutral point to earth through the comparatively high resistance of the water. This seems to introduce multiple earthing of the neutral points on an e.h.t. system and I should like to know whether the Post Office authorities have given a general consent to this, or whether each installation has to pass their tests before permission is given. The hot-water service at Carliol House is taken from a secondary calorifier, but since there are 6 or 7 floors in this building I should like to know whether a number of storage tanks are used at different levels. This might be necessary on account of the possibility of the hot-water supply on the top floors cooling down, in which case comparatively cool water would be run off for a considerable time before the hot appeared at the tap. The automatic on and off switching of the London Underground Railway's installation is carried out, I think, on the main e.h.t. oil switch of the transformer supplying the low-voltage resistance heaters. The tariffs quoted for night loads by supply undertakings are important as regards developing and encouraging electric thermal storage. As an indication of the importance of this factor, if, in Appendix 1, the price of current had been 0·4d. per kWh instead of 0·3d. per kWh the running costs would have been increased by £90, and, in the case of Appendix 2, by approximately £450—which would possibly have turned the balance against the electric method. The authors also have been very generous in Appendix 2. There is a note that about £2 000 had been saved in buildings by using the electric method. In fairness, therefore, interest at 6 per cent on this amount should have been added to the running costs of the coke installation when a comparison was being made.

Mr. L. G. A. Sims: We in this country are now becoming acquainted with the storage principle as applied to the heating of water for domestic purposes, and the paper shows that the same principle can be successfully carried much farther by applying it to the heating of large buildings. I think that this is one of the branches of electrical engineering which we shall see develop considerably during the next few years when its importance to supply authorities has been more fully appreciated and its adoption has been encouraged. The authors are therefore to be congratulated on having put forward practical methods and figures. It would be unfortunate if, from the general title of the paper, the inference were to be drawn that thermal storage could only be successfully accomplished with water. Yet, apart from two short paragraphs on page 659, the paper is wholly concerned with water systems. I think that the authors should either have worded the title rather differently or, preferably, they should have made it clear that storage in water is only one of several commercially successful systems which have been in use in Europe for a number of years. I wish to confine my remarks, therefore, to two alternative systems for the heating of buildings by thermal storage of which I have had experience. The first employs local heating-units, usually in the form of "accumulation stoves." The complete cycle of storage of heat and subsequent release to the atmosphere takes place at the point where the heat is to be used. This system is used fairly widely in Switzerland, France and Germany for domestic and office heating; as it is scarcely more difficult to install than an ordinary electric radiator it clearly has important advantages in many instances over the elaborate central storage systems described by the authors. The disadvantage of this type of heater has hitherto been its poor temperature-characteristic during discharge. The accumulator has generally been made of stone or special gravel and, in order to obtain the necessary storage capacity, the temperature-range during charge (and consequently during discharge) has had to be considerable. The result is, in particular, a poor heat output towards the end of the discharge period. Furthermore, the heat losses during charge have been inconveniently great. For the past three years I have been concerned with work at the University of Birmingham upon the development of an accumulation heater of this general type: a design which avoids the defects of the Continental models and which shows marked improvements upon them in respect of the discharge characteristic, reduced losses and cheap manufacture, has been evolved. A solid accumulating mass, or core, of material easily obtained in this country is used instead of the special core materials of local origin such as are used in certain of the Continental stoves. The core volume per kW of rated capacity is very small—about 0·7 cubic ft. per kW for an 8-hour charging period. Mr. Sturley, who has been associated with me in this work during the last two years and who has carried out a great deal of the practical development, will give some further figures. I will merely emphasize the fact that, in this form of accumulation or storage heater, there exists not only an alternative method to that dealt with by the authors in their paper, but one which has great advantages in the many cases of existing buildings to which the application of a large central system would not be possible. Both the central system and this local unit system have a very low maintenance cost, and both provide a balanced 3-phase load at almost unity power factor. The local-unit system obviously has its most useful application in the heating of rooms of moderate size, for which a power of, say, 5 kW is sufficient. The second system of storage heating, which has been used in large schemes abroad with success, but which is not mentioned by the authors, depends upon storage in the floor mass. Heating elements are drawn into earthenware pipes embedded in the floor material. The system has a great deal to recommend it because the necessary heat is stored at a very low temperature—a consequence of the large storage mass available. I have seen this system in use in Switzerland: the temperature of the floor is so low that the impression gained when one presses a hand upon it is only one of lukewarmness. The heat, however, is continuously rising and, passing over the whole length of the body, it gives a pleasant sensation of gentle warmth. Temperature curves taken over a period of days show extraordinary smoothness. The following operating figures are remarkable. It is claimed that the heating elements work at a temperature of about 85° C. (185° F.), that is, well below the boiling-point of water. With all the elements working, the floor temperature is about 23° C. (75° F.) and the room temperature 6 ft. above the floor is about 18° C. (64° F.), under winter conditions. As there are no hot currents of air anywhere in the building the losses to the external atmosphere must be a minimum. In general, the vertical temperature-gradient is claimed to be such as to give a decrease of about 12 per cent of the floor temperature at a height of 6 ft. from the floor, and distribution of temperature horizontally is said to be absolutely uniform. The system seems to be very successful in Switzerland but it can only be adopted in conjunction with some form of ornamental tiled flooring. Wooden parquet would not be suitable nor, presumably, would linoleum, but small carpets placed about the floor have no serious effect upon the heating system. In a scheme which I worked out for a suite of offices in this country the only disadvantage was found to lie in the high price quoted for the elements, but this objection should not be permanent. For an installation in the Swiss Popular Bank at Zürich the data are as follows: 1 000 m^2 of floor area are heated by a 500-V 3-phase supply, the total loading being 270 kVA at almost unity power factor. Each element has three alternative loadings and the maximum is about 90 watts per ft. The accumulation mass is a river gravel plentiful in Switzerland. Thermal insulation is inserted on the lower side of the mass in those cases where no diffusion from the under side of the floor is desired.

Mr. K. R. Sturley: The authors will have accomplished much if electric supply undertakings are led, as the result of the paper, to give more serious consideration to the development of an off-peak load. The different conditions under which Continental authorities work—many of the systems utilize water power with its high capital charges and comparatively small running costs—have certainly encouraged the consideration of an off-peak tariff. Unfortunately, the issue in Great Britain is complicated by the fact that coal is comparatively expensive as a source of power. This difficulty, however, is not insurmountable and I hope that competitive facilities at competitive prices will soon be given for off-peak thermal loads. Of the two methods described in the paper, the separate wire-wound resistance is the better, for any electrical breakdown can be repaired without opening the boiler. In connection with resistance heaters, it is stated in the paper that the load during the heating period is automatically controlled. Why is there any necessity for this? Temperatures in the early autumn are, for example, usually higher than those of mid-winter so that some sort of seasonal control is necessary, but load variation during the 12-hour heating period should not be necessary. Wear of the electrodes and the need for constancy of the resistance of the water are the disadvantages of the electrode boiler, and I should be interested to know how long the electrodes will last under ordinary conditions. Under the heading "Consumption," in the description of the Carliol House installation, the electrical consumption per office of 2 000 cubic ft. capacity is given as 46 kWh per week. Can the authors give any information as to the number of hours weekly for which the boilers were in circuit? When research upon heat-accumulation stoves was being carried out at the University of Birmingham, the need for further development in connection with laggings was strongly felt. Difficulties were experienced in finding any connected report upon heat-insulating materials and I agree with the authors in their remarks on this point. These stoves, which have been briefly described by Mr. Sims, are designed to work by storing heat during 8 hours and discharging during the remaining 16 hours. The maximum temperature in the Continental design was about 340° C. (646° F.) and the storage factor was 46 per cent. The storage efficiency will actually be higher than this, but the experimental difficulties involved in making an accurate determination are considerable and, in order to obtain a basis of comparison with later improvements, the expression called "the storage factor" was adopted. This storage factor is the product of the heat capacity (specific heat × weight) of the core multiplied by its mean temperature-rise. It does not take into account the heat stored in the heating elements, the case and lagging, and the bed-plate. As was to be expected, this stove gave a bad discharge-characteristic, the room temperature being far too high at the beginning of the 16-hour discharge (about 75° F.) and too low (about 55° F.) at the end of this period. In the design which has been developed, all these defects have been almost completely remedied. A different solid storage-medium and laggings of ordinary commercial thickness and material have been employed. The maximum temperature is still 340° C. (646° F.) and the storage factor is as high as 72 per cent, under suitable conditions. Marked improvements are registered in the outer-casing temperatures; a reduction of nearly 70 deg. C. (158 deg. F.) from 105° C. to 35° C. (95° F.), has been effected. The storage factor may not appear quite so high as would be expected from a water storage-system, but it must be remembered that all the heat "lost" during the charging period is given out at the point at which it is required. In this respect it is more efficient than the thermal storage water-heaters which give out heat to the boiler room, where little use can be made of it, during the whole 24 hours. No figures for the storage efficiency of the installations described in the paper are given, and, even if these figures were available, I doubt whether they would show any advantage over the solid-core type of storage heater. The authors comment on the variation of heat-flow from solid storage-media at different temperatures, and in the new design this feature has been so successfully eliminated that an even room-temperature is preserved over 13 out of the 16 hours of discharge. There is a slight fall during the remaining 3 hours, with a sharp drop at the end of the discharge period, when the supply of heat to the room is cut off. Provision is made for control of the input of heat to the stove so that at the beginning of autumn, when a comparatively small amount of heat is required, the room is not overheated. Another good feature of this method of thermal storage is the almost complete absence of maintenance costs. All the materials used in the stove are of robust construction and are almost everlasting. For office use, where a steady room-temperature is required for about 10 hours, this stove may develop into a formidable competitor of the water thermal-storage system of the central heating type.

THE AUTHORS' REPLIES TO THE DISCUSSIONS.

Lieut.-Col. S. E. Monkhouse and **Mr. L. C. Grant** (*in reply*): We must all have felt the warmth and enthusiasm of Dr. Ferranti's characteristic and far-seeing contribution to this discussion. We mourn the passing of this great engineer and kindly personality. Dr. Ferranti was a prophet in a great many things and his latest remarks on this branch of electrical engineering for which he has done so much are surely words of true prophecy which will encourage us to persist in a work which can mean so much to the electrical industry.

Several speakers seem rather surprised that electrode boilers can be operated from a single electrical power source, a practice which has been common on the Continent for many years. Before the decision was made to install electrode boilers in this country, a comparison of Continental with British conditions was made and a number of Continental installations were inspected and discussed with power suppliers and users. There seems no doubt that boilers may be so used without causing trouble to communication circuits or protective gear from diffusion of the earth currents, and the experience of the last few years in this country has shown that reasonable precautions only are required to ensure trouble-free working.

We share Mr. Betts's opinion of the effect on economy of unskilful stoking; there seems no doubt that at least 10 per cent and probably 20 per cent reduction in consumption can be obtained by the use of thermal storage with automatic regulation.

Mr. Betts and other speakers have analysed the elements of the cost of a unit of electricity and it is interesting to note Mr. Betts's experience that electricity must be supplied at 0·2d. to compete with coke. Many heating plants have, however, been installed which use handier and possibly cleaner fuels than coke and usually an increase in overall operating costs of, say, 25 per cent is regarded as a fair figure for the improved facilities and amenities, which brings us again to the zone of $\frac{1}{4}$d. a unit. When, therefore, it is considered that the flexibility, cleanliness and other attributes of the electrical method are ahead of what can be obtained with any other method of heating, the small increase in operating costs should not be an important factor. In countries where central heating is largely employed, the tendency is more toward an appreciation of factors other than the fuel cost and we have been impressed with the attitude of American engineers who are accustomed to large central heating plants and who have on several occasions voluntarily expressed the opinion that the peculiar advantages of electrical thermal storage are worth not 25 per cent but 100 per cent increase in cost.

Mr. Kemp discusses the same question, and he also shows a tendency to differ about the 0·05d. This does not seem to be the logical attitude; the actual existence of that relatively small fraction of a penny is debatable, but even should it be a reality it is a very small sum to pay for the elimination of dirt and soot.

Mr. Chew should note that in the cost data on the lantern slide, labour and other charges must be added to the coke-plant figures.

Mr. Clothier's remarks and the figures he has obtained from the electrical thermal storage plant at his residence are of great value. He shows that the figures relating to the Banca Commerciale di Roma are not in agreement with the Carliol House figures when compared on the basis of a cubic foot and degree F. rise per day: we agree that the higher figures are more suitable for British conditions. Dr. Semenza's figures for the Italian Bank were obtained at an early stage of the experience with the installation, but what is more to the point is that the Italian method of calculating building cubical content seems to be different from the British method and in the Italian bank figures there is apparently an unheated section included in the cubical contents.

Mr. Linstow refers to the possibility of earth leakage and emphasizes that sensitive protection is required. Some of the storage installations with which we have been associated have been protected by means of fuses controlling banks of immersion heaters. Fuses can be obtained to blow reliably on the occurrence of 10 per cent overcurrent. Even in quite small installations there are at least four groups of heaters, so that this method is equivalent to a fault setting of $2\frac{1}{2}$ per cent, which is obtained at a relatively low cost. A circuit breaker is better but is economically justifiable only in the larger installations.

Mr. Clements asks what proportion of the substation charges would be debited to the thermal storage in an installation such as that at Carliol House. No substation is required as the installation is operated at the transmission voltage, but the switchgear (two ironclad oil switches, one for each boiler) and cablework are charged entirely to the thermal-storage installation.

Mr. Richardson refers to oil-storage installations, but it is believed that so far there are no oil-storage central heating installations in operation. Oil storage is, of course, in use for certain types of industrial work. The figures in the paper refer to oil storage with oil circulation; if water circulation is used with oil storage the storage range will be smaller. There is more to be taken into account than the mere storage range. The capital cost of the oil is considerable; it may easily be 25 per cent to 50 per cent of the total capital cost and an annual oil leakage of over 5 per cent has to be provided for. Mr. Richardson also suggests that the immersion-heater type of installation is more likely to be the general method of the future because of its simplicity. In our opinion this type of installation is usually cheaper and, of course, simpler for installations up to about 400 kW, where usually the available transformer or mains capacity is sufficient, but in larger sizes where the cost of special transformers would influence a decision an electrode boiler system is often cheaper.

With regard to Mr. Williams's remarks, the appendices were intended to show only actual results. A note is added to Appendix (2) to show the influence which the cost of flues would have, and in another part of the paper the effect of a thermal-storage installation in releasing more space for human accommodation is disclosed. These two factors alone in a modern building are sometimes sufficient to swing the balance to the electrical method. The prices for coke plant in Appendix (2) do not cover duplicate plant.

We are obliged to Mr. Howard for pointing out the error in the description of the Sulzer boiler; this has been corrected for the *Journal*. He appears, however, to have forgotten that with a steam boiler and calorifiers a greater storage capacity can be obtained for a given amount of equipment, because a higher average temperature can be obtained in the cylinder. Electrodes have been replaced both in the motor depot and the Carliol House plants.

In reply to Mr. Swale, no troubles have been experienced with high-tension boilers connected to an earthed neutral system.

Mr. Howarth's first question has already been answered. Some of the boilers in use have been connected to systems which on several occasions have had earth faults and on which consequently the electrodes of the other two phases have risen above their normal potential difference to earth. This appears to be much a matter of design, as in the case of switchgear and transformers. The actual balancing of the boilers is very nearly complete and there is never sustained out-of-balance in any particular phase. There may be a temporary out-of-balance on one phase but it quickly disappears, and variations are fortuitous and probably due to outside influence. It should be remembered that an electrode boiler does not introduce a direct path to earth. There is the considerable resistance of the water to take into account, and the resistance to earth is much greater than the resistance between phases, so that the tendency for earth current to pass is very small.

With regard to Mr. Sunlight's remarks, the elimination of a tall chimney stack and the release of space for rent production must be of great value to an architect. With a low-temperature panel system the atmosphere should be nearly perfect as there is no burning of dust particles to cause irritation of the pulmonary system or any production of fumes or noxious gases. It is debatable whether the " complication " of the electrical system is as great as the complication of, say, an oil-burning system, and the wear and tear and replacements required in connection with an electrical system are unquestionably smaller than with any known heating system.

Mr. Jewsbury emphasizes one of the advantages peculiar to an electrical thermal-storage system, namely, that normal room temperature is available at any time, even early on Monday morning.

With regard to Mr. Frith's remarks, the term " boiler " is used in the paper with all reserve and the term " water heater " is applied to installations which do not involve the production of steam (see page 659, par. 1). Incidentally it is debatable whether a " boiler is a thing which produces steam."

It is doubtful whether current is available anywhere, as Mr. Mallinson suggests, at " a quarter of the price paid here." Even on the few unique Swiss installations where energy is supplied from the pre-State-electrification hydro-electric power stations (all capital charges being written off) we have found no example of current being supplied at such low prices as 0·06d. and 0·075d. per unit. Although the thermostats are set for 63° F. they can be altered to any temperature between that of the ambient air and 70° F. The cost of obtaining a given quantity of steam at a given temperature can be calculated from the data given in the paper.

In reply to Mr. Devey, the radiation loss from the boiler is absorbed in the building, but the efficiency referred to was actually inherent efficiency. There does not appear to be any reason why direct current and alternating current should not be almost equally suitable for immersion heaters.

Mr. Collie is no doubt aware that large numbers of small storage cylinders have been installed for hot-water service. There are also one or two domestic central-heating installations working on the thermal-storage system. Simple apparatus has been developed to equip such installations, and small boilers of suitable form have been shown on the lantern slides. Mr. Collie's remarks with regard to the Canadian companies are interesting, but is there not something more to be added to this, namely, that the rate at which the domestic load has grown recently in Canada has outgrown that provided for in the Hydro-Electric Commission's concession?

In reply to Mr. Lowey, time switches are used for switching on and thermostats for switching off.

Mr. Pratt seems to have discovered that his town heads the list of towns with regard to atmospheric pollution. At one time we understood that Newcastle-upon-Tyne held that record, but a little while later it was noted that Sheffield had the honour. It is very evident, however, that the soot and smoke content of the atmosphere in large cities is a grave danger both to health and to building structures. In reply to a further question, a water-softening plant is unnecessary in small installations; simple methods are available by which this can be avoided. The figures on page 665 include the cost of water-softening apparatus. Mr. Malpas also discusses water-softening. It should be emphasized that a water-softener is purely an economical factor and not a necessity. The temperature-lag between the structure and the inside air and the outside atmosphere are important factors in the design of a heating installation; one of the lantern slides shows not only the time required to raise the temperature but also the time required for it to fall after heat is cut off. In his remarks on the relative cost of various fuels, Mr. Malpas has forgotten the all-important question of efficiency.

Mr. Breach again raises the question of earth currents, which have already been dealt with. His remarks give the impression that the adjustment of the electrodes is a delicate matter, but this is not so. He states that in Liverpool in centrally-heated offices the tenants still have electric radiators. Perhaps the central-heating installations are designed to be used with radiators for topping up.

Data in connection with the heating of swimming baths have been sent to Mr. Spencer.

In reply to Mr. Seddon, the economic point for lagging with thermal-storage installations with current at about 0·25d. per unit appears to be about 15 B.Th.U. per hour (average storage temperature). It is encouraging to find Mr. Seddon stating that it is only a matter of time before all supply authorities will find it to their advantage to offer a low rate for thermal storage. His own far-sighted and successful tariffs are well known. The heating rate of the Underground plant should be 8 000 units per *day*, not per *hour*.

Mr. Duncan questions whether a low rate is justifiable for restricted supplies. In Switzerland, Germany, Italy and other countries this is an accepted method. His remarks with regard to oil storage are interesting; we have considered oil storage for several installations but so far have not found oil storage economically justifiable. Some of the factors which must be considered in connection with this problem have been mentioned in a reply to an earlier speaker. What *are* the disadvantages of a pressure system? The installation of thermal-storage plants in Newcastle has affected neither the rates nor assurance assessments.

In reply to Mr. Gunn, usually the method of confining supplies to off-peak hours is to use clock-switch control which defines the hours of and makes available the supply, while thermostats are used to switch the plant on and off when necessary.

In reply to Mr. Shaw, the chief advantages of water over oil are that oil costs about 15 000 times as much as water, that the fire risk is greater with oil and that leakage is more troublesome with the latter.

Replying to Mr. Macleod, when flues are not embodied in a structure a simple form of wall ventilator or the judicious use of the window usually provides inexpensive and effective ventilation. A chimney is surely an expensive form of ventilator.

In reply to Mr. Rawll, the Banca Commerciale di Roma installation utilizes electrode boilers. The rating of the boilers is about 1 000 kW. Referring to the Carliol House installation, it should be noted that there is no arcing inside these or any electrode boilers. Only one storage tank is used for the hot-water service at Carliol House, and the pressure is maintained from the high-pressure town main.

We have investigated the "accumulation" stoves mentioned by Mr. Simms. Changes in design would appear to be necessary before such equipment could be generally adopted. The accumulation stove reverts to the unit heating idea and is not truly central heating. One of the obstacles to the more extended use of the accumulation stove is their high cost and their excessive bulk. We have inspected the floor-heating method adopted at the Popular Bank at Zurich and similar installations; as Mr. Simms states, the chief objection to the extended use of this method is the cost.

Mr. Sturley asks why automatic regulation is required for resistance heater installations. Because the two 12-hour cycles differ in requirements day by day and because the water temperature throughout the cylinder varies, the control gear must be prepared to take up different amounts of energy on successive days and also to cut out heaters when one part of the cylinder becomes sufficiently warm (another part may not be up to maximum temperature). Electrodes in electrode boilers give very satisfactory service and at a conservative estimate should last, under full-load conditions, more than 1 000 hours. The Carliol House boilers normally run for the whole of the week. The remarks regarding lagging are interesting and bear out our experiences. Attention was paid to the insulation and economic value of laggings before any specification was prepared. Lately an effort has been made to use methods of heat conservation which are not truly laggings. Highly polished surfaces such as prepared aluminium foil and chromium plating have the great advantage of lightness but are somewhat handicapped by the cost of installation.

The coke-boiler efficiency referred to by Mr. Freeborn is not in any way unusual; perhaps he has not counted stand-by losses: the attendance figures have already been dealt with. Mr. Freeborn is evidently able to obtain fuel oil from a source and at a price which we have so far not discovered. There is an obvious error in his B.Th.U. figures. The proposed installation which he outlines would be expensive and elaborate when due regard is paid to modern methods of giving electrical supply and other public services. The remainder of his remarks do not come within the scope of the paper.

Mr. T. G. N. Haldane (*in reply*): I should like to record how much I appreciated the late Dr. Ferranti's comments on my paper and with what deep regret I received, a few weeks later, the news of his death. Dr. Ferranti's remarks were of the greatest interest as they described his personal discussions on the subject of reversed-cycle heat engines with Lord Kelvin, to whom the world owes the fundamental principles of the operation of all heat engines. As is noted in the paper, Lord Kelvin describes the reversed-cycle heat engine in his "Collected Papers" (vol. 1, p. 515). This description was written in 1852 before refrigerating plant had been developed technically to any appreciable extent. Consequently he deals with the air-compressor type of plant, which has of course been long since superseded by the ammonia plant and other systems using condensable gases. Refrigerating plant is now developed technically to a stage which makes the heat-pump plant a much more practical proposition than it was when Lord Kelvin first suggested the idea. Unfortunately, the fact that the proposal when first put forward was turned down as impracticable, diverted attention from the method so that at a later date when technical progress had made the idea practicable it received little or no further consideration.

I am interested to note that Mr. Betts considers that electricity at the price of 0·2d. per unit will compete on a heat basis with coke. Although this is a low figure a heat pump operating with an average efficiency of 3·5 would, on this basis, compete with coke if supplied with current at the not unreasonable cost of 0·7d. per unit. This point is also illustrated by the figures given by Mr. Chew.

I am glad to note that Mr. Chew considers the figures given in Table 1 to be conservative. His long connection with the refrigerating industry and his great experience in the testing of refrigerating plant make his opinion on this matter particularly valuable. I am also fully in agreement with him with regard to the practicability of making the heat-pump plant fully automatic, and so reducing labour charges to a minimum. As regards reliability and safety, I think it would be difficult to find any plant much safer and more reliable than refrigerating plant. The reason for this is that the two moving parts of the system, i.e. the electric motor and the compressor, have all the essentials of inherent reliability. An electric motor is of course an extraordinarily reliable machine and the compressor, which runs at a comparatively low speed and is not subject to any violent shocks, explosions or high temperatures such as occur in an internal-combustion engine, is therefore also extremely reliable. The number of antiquated refrigerating installations which are to be found in operation in various parts of the country is a tribute to this inherent reliability.

Mr. Bolton describes an air-type plant which he suggests as an alternative to the ordinary condensing-gas type of plant. The scheme he puts forward is similar to Lord Kelvin's original proposal, except for the suggestion that the expansion and compression cylinders in Lord Kelvin's scheme should be replaced by a fan and that the receiver should be replaced by a long length of pipe on the suction side of the fan. The idea is attractive in its simplicity, but unfortunately there are several difficulties which make the proposal somewhat impracticable. In the first place, as Mr. Bolton himself points out, a very considerable length of suction pipe would be necessary; this might be difficult to arrange and might involve serious air friction losses. Mr. Bolton assumes that the air drawn into the pipe on the suction side of the fan will be cooled and will therefore take in heat from the surrounding air. In point of fact, however, the air drawn into the pipe is not doing work and, as in the case of gas passing through a reducing valve, will not appreciably change in temperature.

The conditions are, in fact, quite different from those obtaining in Lord Kelvin's scheme, in which expansion is carried out in a cylinder and the air is cooled by the equivalent of the work done against the moving piston. Apart from this, the efficiency of the fan would be low compared with that of an ammonia compressor. An overall mechanical efficiency of about 80 per cent can easily be obtained on an ammonia plant, but the greatest efficiency which could be hoped for with an air fan would necessarily be very much lower than this figure. For these reasons I do not consider that Mr. Bolton's scheme, exceedingly interesting though it is, can be put into practice. If the heat-pump system were to be widely used in London I do not think there would be any risk of a serious reduction in the atmospheric temperature, such as Mr. Bolton fears. All the heat passed into the buildings must sooner or later find its way back into the atmosphere, and in addition there is a small gain due to the heat equivalent of the electrical energy used.

Mr. Baker compares the operation of the heat pump with that of a battery booster, which, by raising the voltage of the battery, makes available its energy by allowing it to discharge on to the busbars. This analogy may be of some assistance, but it can only be applied to a very limited extent. The energy of a battery can, by means of a booster, be transferred from the battery to the busbars without the need of any source of external energy, but heat cannot be transferred from a cold to a hot source without employing some external source of mechanical energy. Mr. Baker's suggestion of the combination of the swimming bath and the skating rink is quite practicable and had, in point of fact, been seriously considered. A more obvious combination is that of the heating of a building with the production of ice for commercial purposes.

I am much gratified to have Prof. Marchant's support and I share his hope that the heat-pump system will be the subject of research in the future, this being one of the principal objects of the paper.

Mr. Stobie points out that the absence of an expansion cylinder leads to increasing loss with increasing condensing temperatures. This is correct, but for any moderate range of temperature such as that considered in the paper the loss is comparatively slight, whereas the additional complication would be considerable. The suggestion that butane should be used for small machines working at high temperatures is interesting and the low-pressure characteristics of this substance might be of value for high-temperature work. As regards the effect of superheating, it is theoretically desirable to operate the plant "wet" so as to avoid superheat, but the gain in efficiency is not great as compared with "dry" operation, provided the amount of superheating is not excessive. In practice ammonia plant is found, on the whole, to operate more satisfactorily with a "dry" cycle, mainly because the "dry" cycle avoids condensation and evaporation losses to the cylinder walls. The figures given by Mr. Stobie from his tests on a $\frac{1}{6}$-h.p. belt-driven refrigerator are of the greatest interest and it is to be hoped that he will continue his experiments on larger machines. Taking into account the very considerable losses due to the small size of machine and the belt drive—which together probably amount to more than half the input to the machine—the results are remarkable. It is unfortunate that the tests were not taken with larger quantities of water over longer periods and with well-lagged tanks. Test 6 shows an average efficiency of over unity for heating water to over 130° F., which for such a very small machine is a good performance. With a reasonable-sized plant this efficiency would obviously be very much higher.

INSTRUMENT TRANSFORMERS.

By J. G. Wellings, Associate Member, and C. G. Mayo, M.A., B.Sc., Graduate.

(*Paper first received* 31*st May, and in final form* 11*th April,* 1930; *read before the* Meter and Instrument Section 3*rd January, and before the* North-Western Centre 18*th March,* 1930.)

Summary.

The paper deals in a general way with the whole field of instrument transformer work, and in a more extensive manner with certain developments and views for which the authors are more particularly responsible. Among these are the following:—

Current Transformers.—(i) Short-circuit limitations are described, the conclusion reached being that reduction of ampere-turns is the only real means of increasing the short-circuit capacity.

(ii) *Accurate transformers for metering.*—The conclusions reached are that high accuracy can and should be obtained without recourse to a large number of ampere-turns, and that single-turn or bar-primary transformers with compensating windings should be used on all heavy-duty circuits.

(iii) *The design and application of current transformers for protective-gear systems.*—The conclusions reached are that current transformers are not necessarily the limiting features in the performance of protective gear; but that transformers for protective systems can and should be designed to be "ideal transformers" as far as the requirements of the protective systems are concerned.

Voltage Transformers.—(i) General features are described, the conclusions being that voltage transformers on low-voltage circuits are a satisfactory proposition subject to suitable provision of protective fuses and resistors.

(ii) On high-voltage circuits means of eliminating voltage transformers are described, by utilizing an existing power transformer, and connecting the voltage transformer to the low-voltage side and compensating for regulation of the power transformer.

Special-purpose Instrument Transformers.—Design and application of current and voltage transformers with varying ratio characteristics are described, especially in regard to voltage- or current-change amplifiers for the more sensitive operation of relays, voltage regulators, etc.

Introduction.

General Considerations of Instrument Transformer Design and Application.—The subject of instrument transformers, in the authors' opinion, deserves more specialized attention and general publicity than it has hitherto received. It is admitted that instrument transformers are only ancilliary apparatus; nevertheless, they are of such importance in modern switchgear that, unless specially considered, they may constitute the weakest point in the gear.

The general requirement is that they shall be capable of giving the desired accuracy under normal load conditions, particularly bearing in mind the high degree of accuracy now necessary, and that they should also be able to withstand, as an ordinary occurrence, the extreme overload or short-circuit conditions to which, as part of the main circuit connections, they will repeatedly be subjected.

Hitherto, there appears to have been some tendency to consider the instrument transformer either purely from the meter or from the switchgear point of view.

Naturally, from the meter standpoint, the first consideration is that the transformers should be highly accurate; viewed from the switchgear standpoint, primary importance is attached to rendering the transformers suitable for the switchgear and for the short-circuit conditions which require to be met. The result, in the authors' opinion, is that one or other of these two somewhat conflicting requirements is generally to some extent overlooked; and hence little advance has been made in producing a transformer which meets equally the requirements of both the switchgear and metering interests. Instrument transformers for protective gear should embody certain features which are no less important than either metering accuracy or ability to withstand short-circuit conditions. The authors have, therefore, made a special study of instrument transformer design with a view to reconciling the needs of all three interests. It is with these matters that this paper deals, in addition to reviewing the subject in general and describing recent advances in design and application for which the authors have been responsible.

Before passing to the separate consideration of current and voltage transformers, it may be appropriate to touch on the fundamental difference in the performance of a current transformer as compared with that of a voltage transformer.

A voltage transformer functions in the same way as a power transformer, but special attention must be given to minimizing the losses in order that the secondary voltage may be an accurate representation of the primary voltage both in magnitude and in phase.

A current transformer, however, functions on an entirely different principle. Whereas in a voltage transformer the effect of secondary burden is to produce current through the windings without appreciably affecting the flux in the core, in a current transformer the effect of burden is to produce flux in the core without appreciably affecting the current in the windings. A further contrast is that zero burden on a current transformer corresponds to a short-circuited secondary, while on a voltage transformer this condition corresponds to an open-circuited secondary.

In a current transformer, it is the production of flux in the core that has hitherto been the source of all error; thus, in order that the secondary current might be an accurate representation of the primary current, it has been necessary to keep to a minimum the losses incurred in producing the flux. The authors have, however, developed means by which the errors of a current transformer are no longer merely a function of these losses, but may be compensated for, and the accuracy of the transformer maintained, even though the losses may be relatively high. This has naturally changed the whole outlook on current transformer design and application, and is having a far-reaching effect on switchgear in general.

CURRENT TRANSFORMERS.

Current transformers may be broadly divided into two types:—

(1) Metering transformers for the operation of meters and plain overload relays. Such current transformers are only required to give a predeterminable performance from light loads up to approximately 50 per cent overload.

(2) Protective transformers for the operation of protective gear. Such current transformers are required to give a predeterminable performance from comparatively light loads up to extreme overload corresponding to the maximum "through" short-circuit current to which the protected zone may be subjected.

Both types, however, must of necessity be capable of withstanding the maximum short-circuit current to which the circuit may be subjected in the event of a fault occurring in that part of the circuit where the transformers concerned are installed. Unless this requirement is fulfilled, the transformers are always liable to be a source of trouble; and in protective gear applications the trouble is of a more serious nature in that the protective gear itself may become inoperative, resulting in considerable damage. The subject of the short-circuit rating or capacity will, therefore, be reviewed in some detail.

(A) SHORT-CIRCUIT CAPACITY LIMITATIONS.

Current transformers, being series-connected apparatus, should at all times be able to withstand any condition of through short-circuit current or transient voltage to which the circuit may be subjected. An approximate value of the maximum through short-circuit current to be allowed for can generally be deduced from the rupturing capacity of the switchgear on that part of the circuit concerned. It is practically impossible, however, to predetermine what value of transient voltage may occur.

A current transformer subjected to either one or other or a combination of both of these conditions may fail in three ways if it is of the multi-turn primary construction. The bar-primary type of construction is to all intents and purposes proof against failure under any condition of short-circuit, and such transformers may be regarded as being as reliable as the actual circuit connections.

Reverting to the multi-turn primary transformer, the causes which may lead to failure under sufficiently extreme conditions of short-circuit are as follows:—

(1) Thermal Effects, i.e. extreme overheating of the windings due to the magnitude of the short-circuit current and the time for which it is maintained. Predetermination of thermal effects presents no great difficulty, the principal uncertain factors being the cooling effect of the surrounding material, and the degree of asymmetry in wave-form during the initial period of the short-circuit.

(2) Mechanical Effects, i.e. bursting forces in the windings due to the maximum peak value of short-circuit current. Predetermination of mechanical effects is difficult, particularly as the forces may act in such a way as to damage the insulation between turns and cause local short-circuiting and consequent breakdown.

(3) Electrical Effects, due either to transient voltages "piling up" on the end turns of the primary winding and causing short-circuits between turns, or to actual puncture of the primary insulation from the same cause. It is not feasible to predetermine the electrical stresses, but, on an average primary winding

a surge of comparatively moderate frequency can cause sufficient voltage per turn in the primary winding to puncture the average insulation between turns, especially in view of resonance between inter-turn capacity and inductance, which may have the effect of piling up the voltage on the end turn.

A transformer may fail electrically owing to voltage transients only, depending on the steepness of the wave front, without the occurrence of heavy-current conditions; i.e. a transformer suitable for withstanding the short-circuit current conditions is not necessarily able to withstand the transient voltage conditions to which it may also be subjected. The authors have attempted to deduce for multi-turn primary transformers what may be termed a "short-circuit factor" which will express as a multiple of the rated current that current which an average multi-turn current transformer will withstand under average conditions of short-circuit.

It can be shown that the primary is the limiting feature as, owing to core saturation, the secondary winding cannot be subjected to much more than about 40 times full load. Accordingly, from considerations of an average primary winding, based on thermal effects, this factor appears to be about 150; but if based on mechanical effects the factor appears to vary between 50 for long rectangular coils, and about 400 for a circular coil, and is probably in the neighbourhood of 200 for an average rectangular coil.

According to the authors' experience and investigation, however, electrical effects as defined in (3) above comprise the limiting feature in the majority of cases, and the limit which is imposed by such electrical effects, caused by extreme overload conditions, appears to be about 100 times rated current. A current exceeding this value is liable to cause sufficient piling up of voltage to puncture the insulation between turns and cause a breakdown. Currents of smaller magnitude may produce similar effects if of surge frequencies, and this limitation is, in the authors' opinion, the most serious one.

For short-circuits of long duration but of limited value and free from transient conditions the thermal effects may be the limiting feature, and increasing the copper section may enable the short-circuit factor to be raised. In practice, however, it is impossible to dissociate transients from short-circuit conditions and accordingly the electrical effects remain as the limiting feature; that is to say, merely increasing the copper section in the primary winding of a multi-turn transformer cannot be said to increase its short-circuit factor. If, however, the number of primary turns is reduced the reactance is also reduced, there is less tendency for voltage to pile up between turns, and the short-circuit factor can be raised. The authors consider this to be the only practical means by which multi-turn transformers of high short-circuit capacity can be built. Conversely, a transformer with a large number of ampere-turns is more liable to fail than one with a moderate number of ampere-turns.

Hitherto, for accurate metering, a large number of ampere-turns has been necessary, and in the authors' opinion any freedom from breakdown has been mainly due to the fact that short-circuits have been of limited value. With the increase in generating plant and the linking up of stations now taking place, this condition may no longer obtain, and it is thought that multi-turn current transformers are liable to become a source of appreciable danger, especially if a short-circuit ratio of 100/1 is exceeded.

The development of highly accurate current transformers with reduced ampere-turns and, whenever possible, bar-primary construction, is accordingly of very great importance, and means by which this has been achieved in practice are described in the following section.

(B) METERING CURRENT TRANSFORMERS.

(i) *Accuracy and Causes of Error.*—The essential characteristic of the metering current transformer is its accuracy, combined, of course, with the ability to withstand with safety the worst short-circuit condition to which it may be subjected.

Bearing in mind the fundamental principle of operation of a current transformer, i.e. that the application of secondary burden is to cause flux to flow in the core without appreciably affecting the current in the windings, the limit of useful operation occurs when the production of flux does appreciably affect the current in the windings. The production of flux depends upon the magnitude of the secondary burden, and is not a direct function of the primary current. Secondary burden should strictly be expressed as an impedance, but as the secondary current is usually of some known standard value, the term "volt-ampere burden" is more frequently employed; but it must not be overlooked that this corresponds to rated load conditions only.

A current transformer on a truly zero burden, i.e. with no external or internal resistance or reactance, would require no secondary voltage to drive the secondary current through the secondary circuit, and accordingly would require no flux; and, therefore, there would be no error in transformation between primary and secondary currents. With a definite value of secondary burden a definite secondary voltage is required, necessitating a flux, which in turn requires exciting current drawn from the primary input. This exciting current is composed of core-loss and magnetizing-current components, both of which are conveniently expressed in ampere-turns. The core-loss component will be in phase with the voltage, and the magnetizing current in quadrature. For secondary burdens consisting mainly of resistance the core-loss ampere-turns will subtract practically arithmetically from the primary ampere-turns and cause an error of magnitude in the value of the secondary current termed "ratio error," while the magnetizing ampere-turns will subtract in quadrature, causing little ratio error but introducing in the resulting secondary current a phase displacement termed "phase-angle error."

On burdens consisting mainly of reactance the opposite is the case, and for intermediate power factors of secondary burden both core-loss and magnetizing-current components respectively contribute to ratio and phase-angle error. Owing to the inherent characteristics of transformer steels the core loss and magnetizing currents are not proportional to the flux density, and accordingly the ratio and phase-angle errors do not remain constant, and in general increase appreciably on lower values of primary current.

To minimize these errors, core loss and magnetizing components have required, hitherto, to be kept as small as possible, either in an "absolute" or "relative" sense. A reduction in the former may be achieved by using large iron section, a short magnetic circuit, high-permeability material for the core, etc.; and in the latter by using a larger number of ampere-turns, which hitherto has precluded the use of the bar-primary transformer below about 1 000 ampere-turns if any pretensions to accuracy are required. Accuracy is most readily obtained by using a reasonably high value of ampere-turns, but, as already shown, the provision of a multi-turn winding is by no means satisfactory from the point of view of short-circuit safety; increasing the iron section has only limited effects, and low-loss alloys, apart from being extremely expensive, are subject to the disadvantage that saturation occurs at comparatively low flux densities, and there appears to be some difficulty in ensuring that the characteristics of such low-loss irons shall be stable under service conditions.

The authors have accordingly concentrated on a means of obtaining the highest degree of accuracy with a primary of the bar type and a core of ordinary silicon steel, full advantage of which can be taken as regards known characteristics and permanency in performance. The same means, however, can be employed with any type of high-permeability alloy cores, and a saving effected in the amount of such material required.

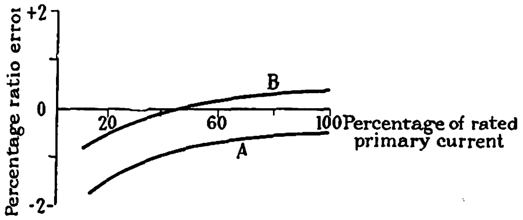

FIG. 1.

(ii) *Theory of Ratio and Phase-Angle Correction.*—In describing the development of the compensated current transformer it will be convenient first to review the elementary features in the design of the ordinary current transformer.

It has been almost a universal practice for ratio error to be corrected to some extent by adjustment in the number of secondary turns. This involves the provision in the secondary winding of slightly fewer turns than the nominal number, so that, the ampere-turns being constant, the current is slightly increased and corrects for the discrepancy due to core loss.

Fig. 1 indicates the natural ratio performance of an average current transformer, curve A representing the performance if the number of secondary turns are equal to the nominal number, and curve B showing the effect of providing "turn correction."

Hitherto, however, there has been no practical means of correction for phase-angle error, with the result that this error has always been the limiting feature in design, and has required to be kept to a minimum by the use of liberal core section and ampere-turns. Moreover, it is of greater importance to minimize phase-angle error than ratio error since, while the latter is independent of the power factor of the main circuit in its effect on metering errors, phase-angle error changes in effect with the power factor of the main circuit, being greater the lower the power factor. The reduction of phase-angle error to a minimum is, therefore, of very great importance if the highest possible metering accuracy is to be obtained.

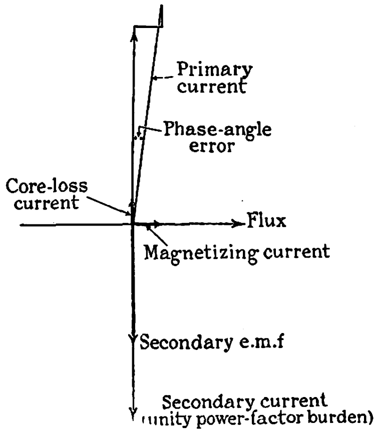

FIG. 2.

The authors are, of course, aware that it is possible to correct for some of the error of a current transformer by special adjustment of the meter when calibrating with the transformer. They have concentrated, however, on reducing the inherent errors of the transformer and rendering them as far as possible negligible, so that in the ideal case the use of the transformer introduces no errors in itself and reduces the overall errors of the combination practically to that of the meter only.

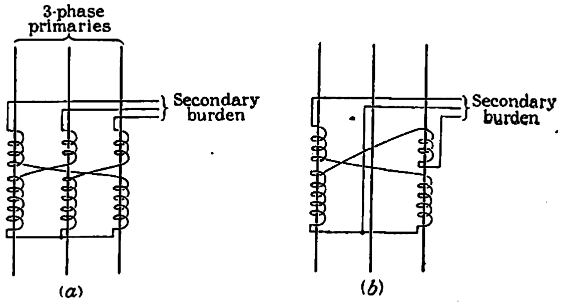

FIG. 3.

In explaining the course of development pursued by the authors it is convenient to regard the theory of ratio-error correction by conceiving that the turn adjustment is applied to the primary winding, in which case there would be a slightly greater number of primary turns than the nominal, the excess number simply providing the additional excitation necessary to allow for the discrepancy which occurs due to core loss. Once having visualized this theoretical possibility, a further step is to regard the extra primary turns as being physically separated from the main primary turns, but carrying current which in phase relationship and in ampere-turns provides exactly the same effect as when the extra turns are actually part of the primary winding.

It will now be possible to appreciate the effect produced if the extra primary turns were energized with current which had an angular displacement relative to the main primary current. In Fig. 2, which shows the elementary vector diagram for a current transformer, under unity power factor conditions of secondary burden it will be noted that the core-loss component is practically in phase with the primary current, and, therefore, can be corrected for by supplying additional excitation in phase with the primary current. If such additional excitation could be supplied with an angular displacement with respect to the primary current as mentioned above, then there would be a component available for correcting the core-loss and magnetizing-current errors.

If it were possible to excite the current transformer separately, and in such a way that the separate excitation was exactly equal to the total excitation both in magnitude and in phase, then the current transformer would operate without error between the main primary and secondary. Broadly speaking, it is along these lines that the authors have developed their type of compensated current transformer.

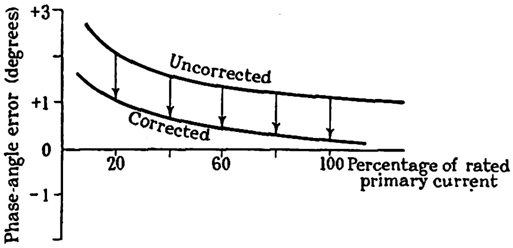

Fig. 4.

(iii) *Development of Compensated Current Transformer.*—In its simplest form the auxiliary excitation may be obtained by the provision of a small auxiliary winding associated physically with the secondary winding, and energized from the secondary winding of a current transformer in one of the other phases of a polyphase circuit. On a 3-phase circuit this automatically provides a 60-degree phase displacement, which forms a convenient value for providing components to take care of the core-loss and magnetizing-current errors. Fig. 3 (*a*) shows transformers connected in this way. If two transformers only are used, the connections are as shown in Fig. 3 (*b*).

By this arrangement phase-angle correction is made possible in the same way as ratio-error correction, and the error for a given value of ampere-turns is reduced, or, what is more important, the same accuracy is obtained with a reduction in ampere-turns; this means that the bar-primary transformer is given an extended range of application on the lower ratios. Fig. 4 shows the performance of a current transformer with its phase angle corrected in this way.

Having established this method of phase-angle correction, the next step was to develop a method by which the same effect could be obtained by using auxiliary means provided as part of the same transformer, and the method developed to accomplish this was to embody a small auxiliary core within the structure of the transformer to energize the phase-angle correction winding. In order to obtain the necessary phase relationship the auxiliary core requires to be operated at a relatively high flux density, and this, as well as accurate control of the auxiliary exciting current, is secured by inserting suitable resistance in the auxiliary exciting circuit.

Fig. 5.

Fig. 5 (*a*) shows the vector diagram for these conditions, and if this diagram is swung round so that the primary currents are coincident with the vector diagram of the main transformer, as shown in Fig. 5 (*b*), it will be seen that, although the auxiliary excitation is not quite in phase with the actual magnetizing current, as in Fig. 2, it is sufficiently nearly in phase to give the necessary components to satisfy the requirements.

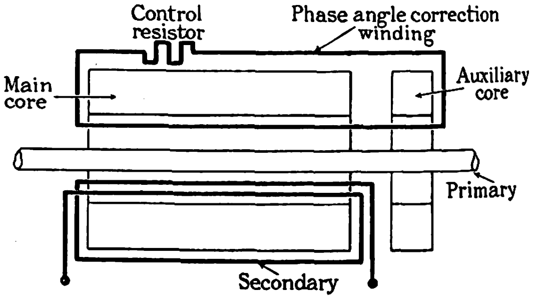

Fig. 6.

This scheme will be seen to be capable of producing phase-angle correction similar to the earlier developments, but with the advantage that the correction is obtained from the same phase, rendering feasible a self-contained transformer. The general arrangement of this auxiliary-core method of obtaining phase-angle correction is shown in Fig. 6.

Immediately the development of the auxiliary-core method of auxiliary excitation had reached this stage, further possibilities were seen by which, in addition to displacing the phase-angle curve nearer to, or even to cross, the zero line, the curve itself could be "flattened." This is achieved by arranging the design of the auxiliary core so that there is a greater relative auxiliary excitation at light loads than at full load, with the result that where the error is greatest the correction also is greatest, and a phase-angle curve of the type shown in Fig. 7 is obtained.

This constitutes a very important advantage, in that previously it had never been possible, however liberal the provision of ampere-turns or iron cross-section, to obtain a flat characteristic. Even the use of high-permeability alloys for the core material does not provide this feature, which has a very important effect on the accuracy of a meter at light loads.

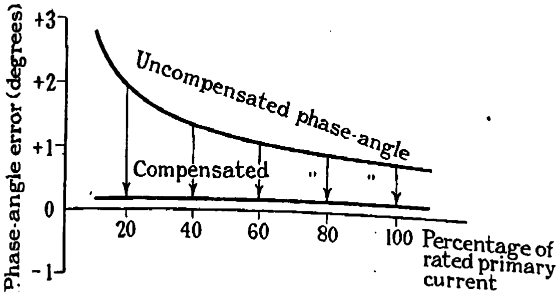

FIG. 7.

Having now developed means by which the phase-angle error was completely under control, or what may be termed "compensated" as well as "corrected," attention was turned to ratio error, with a view to eliminating this error in a similar way.

After considerable research it was found that the same auxiliary core could also be made to give correction and compensation for ratio error, and could thus be used to obtain a flat characteristic for this feature in addition to that of phase angle. Fig. 8 shows the rearrangement of windings to give this effect, where it will be noted that a few turns of the secondary winding are taken round the auxiliary core. The theory of this effect may be understood by reference to the vector diagram in Fig. 5 (*b*) in which it will be seen that the flux of the auxiliary core leads that of the main core—in practice by nearly 90 degrees—and this leading flux induces a leading e.m.f. in the secondary turns embracing the auxiliary core. By one of the first principles of current-transformer theory the voltage in the secondary circuit of a current transformer is purely a function of the secondary burden, and not of the transformer. Therefore, for a fixed burden, if a leading voltage is introduced, in order that the total secondary voltage, as determined by the secondary burden, may remain unchanged, the main secondary voltage as produced by the main core must be caused to lag sufficiently to neutralize the effect of the leading voltage. This angle of lag in the main secondary voltage causes the main flux also to lag behind its normal position, and in turn the magnetizing current for the main core lags behind its normal position.

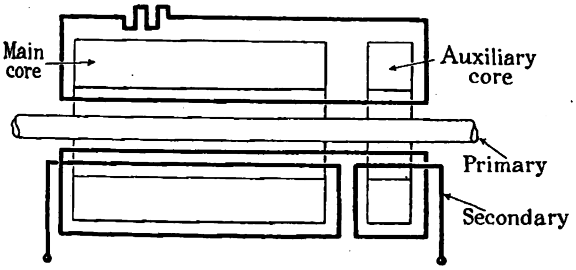

FIG. 8.

Fig. 9 shows the leading e.m.f. and its consequent effects introduced into the ordinary diagram of the current transformer, from which it will be seen the magnetizing current now takes up a position so as to call for an increase in the main secondary current, instead of the slight decrease which results from the usual vectorial position of the magnetizing current. It will be appreciated, of course, that an increase in the secondary current is equivalent to a positive ratio error, and the positive ratio error determined in this manner can be arranged to off-set the natural negative ratio error as shown in Fig. 1, curve A.

FIG. 9.

Control of the ratio correction so obtained can be effected in the same way as in the case of phase-angle compensation; i.e. a greater relative correction may be obtained at light loads than at full loads, so that the resultant ratio-error characteristic is flat.

Thus it is seen that both ratio and phase-angle errors are now capable of adjustment as required, and that for any given amount of error resulting from a given condition of secondary burden a transformer can be designed which will have both its ratio and phase-angle curves coincident with the zero line.

While this meets the requirements of any specific case in a way which has never before been possible, it is possible that a transformer compensated in this way, if sold on a commercial basis and not operated exactly at its rated burden, may have errors which are not sufficiently low at some other value of secondary burden; i.e. the transformer may be either over-compensated if the burden is less than the rated figure, or under-compensated if the burden is more. Means by which the amount of error could be reduced before compensation, therefore appeared desirable.

It is well known that the permeability of ordinary silicon steel reaches its maximum at a flux density which is considerably greater than the density at which it is possible to operate the core of the current transformer. Accordingly, by maintaining a silicon-steel core at the optimum point of the permeability curve by means of some form of auxiliary excitation, the change in flux density due to the secondary burden alternating about this optimum point can be obtained for an expenditure of magnetizing ampere-turns several times less than usual.

This scheme lends itself very readily to the compensated current transformer described above. The main core merely requires splitting into two portions, each portion being magnetized in the opposite sense by a winding energized from the auxiliary core which provides ratio and phase-angle compensation. Fig. 10 shows the core and windings arranged for this duty.

It will be understood that, the two portions of the core being magnetized in the opposite sense, there is no resultant effect on the secondary winding if the two portions are equal, as the induced e.m.f.'s in any winding which embraces both portions will cancel out. Actually, however, it is sometimes convenient to arrange for the two portions to be slightly unequal, as this then has the same effect as keeping proportions equal and retaining the ratio compensation by some of the secondary turns embracing the auxiliary core. This, however, is more a feature of mechanical arrangement than of electrical design, as the results are the same in both cases.

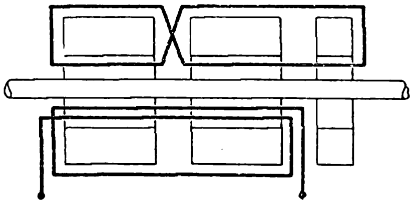

FIG. 10.

By this scheme of " cross magnetization " the ratio and phase-angle errors are reduced to roughly one-third of the figures normally obtained by the use of silicon-steel cores. Furthermore, the natural phase relationship which exists between the " cross flux " and the main flux is such that an improvement can be obtained when the secondary burden becomes reactive. This automatically compensates for the greater ratio error which otherwise exists when the burden becomes reactive.

Accordingly, in a good many instances the use of this cross magnetization is sufficient in itself to give the required accuracy for commercial application, but, as in the case of the use of special alloy cores, the errors can never be reduced to zero, and where the highest degree of accuracy is necessary a combination of cross magnetization and compensated windings is necessary. A further possibility of the compensated windings is that, if necessary, they actually permit of the ratio and phase-angle errors being reversed at light loads; i.e. the ratio error, instead of dropping to negative values as it does with an ordinary transformer (see Fig. 1) can actually be made to rise, and the phase angle to fall. This characteristic may be of advantage in compensating for any inherent error in the meter which, unless otherwise corrected, droops on light loads; thus in such instances the introduction of the compensated current transformer improves the accuracy of the meter. Summarizing the characteristics of the compensated current transformer, it will be seen that the chief points of advantage are as follows:—

(1) A degree of precision accuracy is obtainable which is not possible with any other type of transformer built hitherto, particularly with regard to the " flat " or " inverted " characteristic, and the possibility of adjusting for zero error at any specified burden.

(2) This high degree of accuracy may be combined with the use of the bar-primary construction.

(iv) *Advantages and Applications.*—In view of the absolute security of the bar-primary transformer against breakdown due to heavy overloads or surges, this constitutes a great advance in design and application; and the authors feel that in all important power-station work the use of the multi-turn primary transformer should in future be abolished, now that the compensated transformer has been developed. For small circuits of current values of about 100 amperes and less, a compensated multi-turn construction may be used, having comparatively few ampere-turns, which permits of a high short-circuit factor being obtained; such transformers may be used with much greater safety on circuits where heavy-current and short-circuit conditions are likely to be experienced.

A further advantage of bar-primary transformers is that the latter in general occupy much less space than multi-turn transformers, and this lends itself to economical layout of switchgear; for example, in high-voltage switchgear such transformers may be accommodated in oil circuit-breaker bushings or slipped over lead-covered cables, a position which is practically ideal from the point of view of reliability and safety.

In metal-clad gear their application again presents very great advantages owing to their compactness and the ease with which they can be fitted into various parts of the gear. The possibility of obtaining a high volt-ampere output from a comparatively small size of transformer is a further advantage with this type of gear. Typical accuracy characteristics of precision-type compensated current transformers are given in an Appendix. These are commercial transformers designed to satisfy the conditions of accuracy necessary in metering supplies from the " grid."

(C) RATED SECONDARY BURDEN.

From consideration of the principles of operation of the compensated current transformer, it will be appreciated that the highest accuracy can be made to occur under conditions corresponding to rated burden or load in the same way as a motor is designed to give its highest efficiency at or near to its rated load. On an ordinary current transformer this feature of design is not possible, as the highest accuracy occurs on zero burden and there is always some error under service conditions. Fig. 11 illustrates this advantage of the compensated current transformer.

It has been a common practice in the past to specify a current transformer rated at a considerably higher secondary burden than it will carry in service, with the idea of obtaining a higher accuracy when operating on the lower burden. While this practice serves its purpose with ordinary current transformers, it will be seen from the foregoing remarks that it is very advantageous that the compensated transformer should be rated according to the burden it will carry under service conditions, or some burden approximating to that value, and not an increased burden as has been customary hitherto.

It should be recognized, of course, that the rated burden may be departed from without serious detriment to accuracy, but the estimated volt-ampere burden should form the basis of the specification for the transformer required, so that the latter may operate under optimum conditions as regards accuracy.

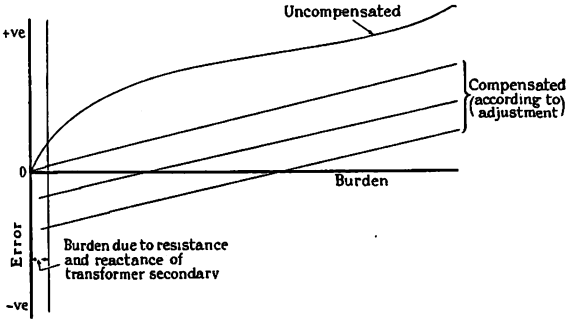

Fig. 11.

(D) Rated Secondary Current.

Hitherto this has been standardized at 5 amperes. While this value of current gives a conveniently low value of volt-ampere loss in the leads between transformer and meters, provided these leads do not exceed about 30 yards in length, above this length the loss may become excessive. This particularly applies in modern switchgear layout, where the distance between current transformers and meters may be several hundred yards. For such cases the use of a lower rated secondary current, such as 1 ampere, may be adopted with very considerable advantage. This reduces the load loss to 0·04 of the 5-ampere value, and as such is generally negligible. The only serious disadvantage in using a reduced value of rated secondary current is the resultant higher open-circuit voltage and the increased accommodation required for the larger number of secondary turns. Fortunately, however, on compensated metering current transformers with 300 amperes or more, the need to economize in lead losses is not of great importance, and it is also at primary currents in excess of this value that the open-circuit secondary volts and the number of secondary turns tend to become excessive. Accordingly the authors feel that, while on circuits of 300 amperes and above the use of 5-ampere secondaries may be retained, on circuits of lower current value, or where warranted by other considerations, a 1-ampere secondary should be standardized.

It is recognized that this involves the windings of the meters and relays, but it is thought that any difficulty in this respect is outweighed by the advantages obtained in improvement of accuracy, and the economy in cost of leads.

(E) Fractional-Turn Windings.

With the advent of the single-turn low-ratio current transformer for metering purposes, difficulties may sometimes arise in connection with the exact number of turns required in secondary windings. It will be appreciated that, for example, with a 100/5 ampere ratio one number of secondary turns may be too large and the next smaller number of turns too small.

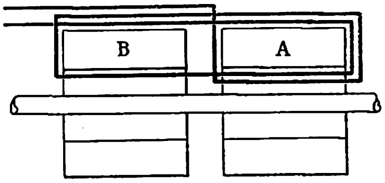

Fig. 12.

If 1-ampere secondaries are used, the difficulty is generally avoided owing to the large number of turns and the fine adjustment which one turn affords. For 5-ampere secondaries, however, the authors have developed a means of obtaining the effect of fractional turns. This is secured by making one or more secondary turns interlink only a portion of the core by passing these turns through an aperture as shown in Fig. 12. The portion of the core area embraced by the fractional turn expressed as a fraction of the total core area is an approximate measure of the degree of fractional-turn effect afforded.

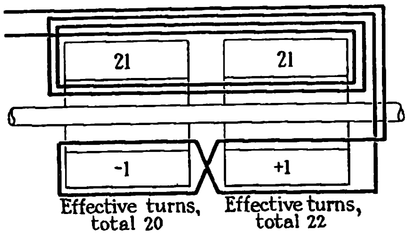

Fig. 13.

At first sight it would appear that this construction would give a high secondary reactance, but on analysis it is seen that this reactance is not large enough to be harmful and is, in fact, positively advantageous.

Referring to Fig. 13, suppose that there are 20 secondary turns over the whole core, i.e. over both sections A and B, and say 2 turns over section A only. This is equivalent to (20 + 1) turns over both A and B with, in addition, a turn over A and a turn in the inverse sense over B.

This figure-of-eight winding will, of course, constitute an inductive load on the current transformer, but the magnitude, which is readily calculated, is moderate and, owing to the fact that there is a flux due to this superposed on the normal working flux, the effective permeability of the core is increased, so that in certain cases better performance is obtained with the use of fractional turns than without. If mumetal or permalloy are used, however, the reactance due to the fractional turn may be too high, and this can be neutralized by adding a winding as shown at C in Fig. 14.

In the case of a transformer with, for example, $19\frac{1}{2}$ turns, this winding would carry $2\frac{1}{2}$ amperes at full rated primary current and this current would completely neutralize the reactance which would otherwise result from the fractional-turn construction. A further development would be to insert resistance in this winding so as to enable the transformer to operate at a more favourable part of the magnetizing curve than would otherwise be the case, since even with such alloys as mumetal the initial permeability is less than that for higher values of flux density.

An alternative means of producing a fractional-turn effect is to divide the core into two sections and wind each section for half the rated secondary current, requiring double the normal number of turns, and connecting the two windings in parallel. A 1-turn adjustment on each section then corresponds to one-quarter of that which would result from a 1-turn adjustment on a winding wound so as to embrace both sections. For a series of fractional-turn taps this scheme has advantages.

(F) PROTECTIVE TRANSFORMERS.

(i) *General Requirements.*—In the preceding sections dealing with metering current transformers, it has been pointed out how the necessary accuracy may be obtained by the provision of compensating windings, in a manner claimed to be more advantageous than has hitherto been the case.

The metering current transformer, however, has a working range limited in general from about 0·05 load to 50 per cent overload. Actually, up to about 5 times full load, the accuracy of a metering transformer tends to improve with increased load, but on higher overloads, according to the magnitude of the secondary burden, the accuracy becomes impaired. While this is of no consequence on a metering transformer, the point requires the closest attention on protective current transformers.

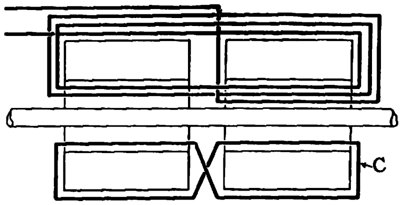

FIG. 14.

The essential requirement of a protective current transformer is that it shall enable the particular protective-gear system concerned to respond to a fault developing within the protected zone, but shall remain unaffected by any fault occurring outside the protected zone.

(ii) *Sensitivity and Stability.*—The specified value of primary current to ensure the operation of the relays when the fault is within the protected zone is termed the "sensitivity," and the specified value of primary current which the protective system must transmit, when the fault is outside the protected zone, i.e. (a "through fault") is termed the "stability." Failure to comply with the required stability may be termed "false tripping"; and the ratio of stability to sensitivity is the "figure of merit" of the protective system as a whole since, although increase of stability can always be obtained by sacrifice of sensitivity, an increase of stability without sacrificing sensitivity, or vice versa, can only be achieved by an improvement in the protective gear.

The attainment of a high value of stability ratio is the main problem in the consideration of any protective-gear system. The possibility of minimizing the sensitivity, i.e. arranging for the protective current transformer to trip the relay at the lowest possible fault current, is solely dependent upon the output available from the current transformer and the input required by the relay system. The output of the transformer is dependent upon its ampere-turns and iron cross-section; the ratio or number of turns is of secondary importance, since with any ratio the optimum condition of tripping can always be maintained by suitably adjusting the winding of the relay. The expression "optimum condition" is used advisedly, since sensitivity can be adversely affected not only by employment of too high a value of relay operating current, but to an equal extent by employment of too low an operating current. This feature is indicated in Fig. 15, which shows the primary

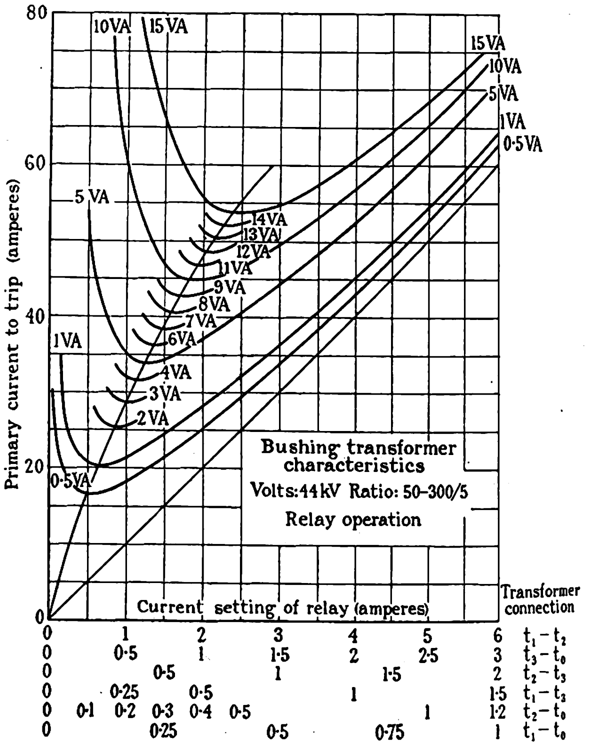

FIG. 15.

current required to operate relays of various volt-ampere consumption for variation in relay operating current. It will be seen that for every value of volt-ampere consumption there is a definite minimum primary current to operate the relay.

(iii) *Effect of Magnetizing Current.*—The losses occurring in the leads between the transformers and the relays must not be overlooked, and also those absorbed in magnetizing any other current transformers which may be in shunt. If the lead loss is comparable with the relay volt-amperes, the adoption of a lower value of secondary current, the relays being wound to suit, has a marked advantage in improving the sensitivity. As regards losses in magnetizing other current transformers in shunt, these cannot be altered for a given arrangement of transformers and must be allowed for in computing the sensitivity, especially if the transformers are of the single-turn type and of low ratio.

These considerations of sensitivity apply to any application of protective current transformers, whether of a direct-connected arrangement, such as for overload or earth leakage, or for circulating current.

The attainment of a high value of stability depends fundamentally on the performance of the protective current transformer under the extreme overload conditions to be experienced, and, indeed, if ideal current transformers were possible, there would be little difficulty in securing any desired stability and sensitivity.

In the authors' opinion, there has been a tendency to accept too readily the supposed unavoidable imperfection of protective current transformers, and much ingenuity has been expended in devising means of securing high values of stability ratio, usually by endeavouring to nullify this premised lack of perfection in the performance of the current transformers.

(iv) *Elimination of Spill Current.*—Assuming that the current transformers have been wound with the nominally correct number of turns, then any false relay or spill current will be the difference between the magnetizing currents of the transformers concerned, and, if large enough, this spill current will falsely operate the relay, causing a false trip.

It is possible that this can be prevented in three ways without rendering the apparatus less sensitive to true internal faults, viz.:—

(1) by rendering the relay less sensitive when there is heavy through current;

(2) by reducing the spill current by making the magnetizing currents of the two transformers concerned as nearly equal as possible (balancing the transformers);

(3) by reducing the magnetizing current of both transformers to an amount insufficient to trip the relay, i.e. making the transformer ideal from the standpoint of the relay tripping current.

With regard to (1), consideration of this line of attack is outside the scope of the present paper but the authors are of opinion that too much attention has been given to restraining the relay against the effects of spill current under heavy through fault conditions, instead of concentrating on eliminating the spill current at its source, or at least reducing it to a negligible value.

As a principle of general design, the authors submit that in any arrangement of apparatus each individual part should be made as perfect as possible in itself before attempting to make up for the deficiencies of the one part by an adjustment of, or special provision in, another part.

With regard to (2), balancing of the transformer means in effect that the relay will be connected across the equipotential points of the circulating pilots, extra loading resistances being employed if necessary, and the transformers adjusted to have similar performance. The disadvantages are that between transformers of different ratio there may exist no points which are equipotential at all loads, and that if the magnetizing currents are high a relatively small percentage change of magnetizing current produces a relatively large increase of spill current. This latter objection is especially cogent when account is taken of increase of magnetizing current due to transients and sudden changes of load (the so-called " doubling effect ").

With regard to (3), this would at first appear to be impossible. However, by suitable design the authors maintain that it is possible in all cases to keep the magnetizing currents as low as may be desired.

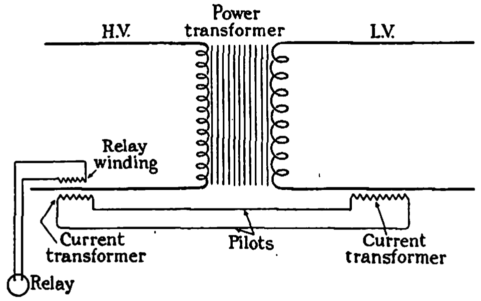

FIG. 16.

If the primary current is greater than 600 amperes at both ends, then the matter is merely one of allowing fairly generous iron and copper section in the transformers, if necessary using liberal cross-section in the pilot leads, or using a secondary rated at 1 ampere.

(v) *Position of Relay Tapping Points.*—If one of the transformers has a much lower ratio than the other and a tendency to a higher magnetizing current for equal burden, it can be relieved of part of its burden of driving current through the pilot leads by moving the relay tapping-off points nearer to it, or even attaching the relay to its terminals. In this case the only burden on the transformer is its own secondary resistance, and this can in most cases be made small enough. In this respect it is important, in the authors' opinion, to use only ring-core transformers for protective-gear purposes so that secondary reactance is avoided.

(vi) *Separate Winding for Relay Operation.*—In the extreme case, when even the resistance of the transformer secondary would lead to too high a value of magnetizing current, the relay is connected to a separate winding on the transformer, as shown in Fig. 16. In this case there is no burden whatever on this transformer, the higher-ratio transformer at the other end undertaking the entire burden of its own resistance, the pilot resistance and the resistance of the secondary winding of the low-ratio transformer. The spill current then consists merely of the magnetizing current of the higher-ratio transformer, which may be kept low by the use of ample iron section.

(vii) *Advantage of Reduced Secondary Current.*—The most difficult case, however, is that in which the primary currents at both ends are low, and in this case satisfactory performance is obtained by making the normal circulating current 1 ampere or ½ ampere. instead of the usual 5 amperes. When it is remembered that the pilot burden with a normal current of ½ ampere is 0·01 of the pilot burden with 5 amperes normal current with the same pilot section, it will be realized that this process will enable the pilot burden and secondary resistance burden, and consequently the magnetizing currents, to be reduced to any desired amount. Clearly, relays of small operating current are required with this arrangement, or alternatively relay transformers must be employed in order to reduce the current required by the relay so as to give the necessary sensitivity. In this respect the authors do not favour the use of transformers in the circulating circuit, owing to the additional burden imposed by them, and complications caused thereby.

(viii) *Avoidance of "Doubling" Effect.*—On lower-ratio current transformers the above limitation of magnetizing current automatically ensures that the maximum flux density is sufficiently low to prevent serious trouble arising from doubling of flux density due to switching, etc. With higher ratios, however, the flux density forms the limiting feature, and this should be deliberately kept within safe limits.

It should be noted that with this system there is no question of balancing transformers since, if the total magnetizing current is, say, 20 per cent of the relay operating current under the worst possible conditions, it is clear that the magnetizing current of any transformer can be several hundred per cent greater than normal without causing instability. Variations of transformer iron will be negligible when compared with the permissible variation under this system, and no great care is required in fixing the relay tapping or point. Equipotential points will not be really relevant to this system, and balancing resistances need never be used.

(G) TESTING WINDINGS.

It is considered desirable by some station engineers to be able to test the performance of current transformers, particularly when installed in position on site. This may be necessary in connection with either the operation of relays or the calibration of meters. Normally this would require the provision of testing equipment capable of giving a very wide range of current values, and if the transformer were installed in position in the switchgear it would also be necessary to disconnect the main primary leads in order to carry out the test. Accordingly, the authors have developed an arrangement whereby a testing winding is incorporated in the current transformer, the former, suitably wound, being energized with some conveniently small value of current (say 10 amperes), and at that current producing an effect on the current transformers exactly equivalent to that produced by rated current on the main primary. This obviates the necessity of removing the transformer from position and breaking circuit connections, and, further, testing equipment need only deliver 10 amperes, corresponding to rated primary load conditions, whatever the rated current of the main primary may be. This permits of considerable saving in the size and cost of testing equipment, besides facilitating portability and improving testing conveniences.

VOLTAGE TRANSFORMERS.

(A) GENERAL FEATURES COMPARED WITH CURRENT TRANSFORMERS.

Voltage transformers do not appear to be readily adaptable to the same advances in design as current transformers. This is perhaps natural in that, being a shunt-connected apparatus, the conditions of operation of a voltage transformer are less varied and there is inherently less difficulty in obtaining the necessary performance. Progress on voltage transformers has accordingly been associated more with improvements in mechanical arrangement, and with special features concerned with the accommodation of the transformer in the switchgear.

A somewhat extreme development has been the elimination of the voltage transformer altogether if particularly high-voltage ratings are concerned; one method now coming into practice in this country with this end in view is described at the end of this section of the paper.

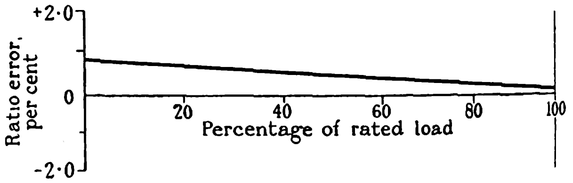

FIG. 17.

(i) *Phase-Angle Correction.*—The voltage transformer operates on the same principle as a power transformer the main difference being that the limitation of secondary burden is one of accuracy instead of heating. The normal accuracy characteristics for a voltage transformer are shown in Fig. 17. The position of the ratio curve is, of course, controllable by turn correction, the "slope" being the true criterion of ratio accuracy. The phase-angle curve is not controllable by turn correction, either as regards position or slope. Fortunately, however, the phase-angle error is not usually the limiting feature in design as in the case of a current transformer, and a design which is economic in the commercial sense gives a phase-angle error of less than 30 minutes from no load to full-load secondary burden. Moreover, the phase-angle error is practically constant and can usually be allowed for in calibration of the meter. If, however, exceedingly high accuracies are required, it is possible to correct the phase-angle error to zero by means of the connections shown in Fig. 18, which, of course, are not applicable in the case of isolated phase transformers. With 3-phase metering, however, requiring at least 2 potential elements, the scheme is generally applicable; the connections of 2 single-phase voltage transformers in open delta are as shown in Fig. 19.

By adopting this means of correcting phase angle in conjunction with suitable turn correction for correcting the ratio, a voltage transformer with practically zero error can readily be produced.

In the authors' opinion, a limiting feature in the design of a voltage transformer is the voltage stress between primary turns, which necessitates a highly sectionalized winding and reinforcement of turns. Even with these precautions the essential use of such finely-dimensioned conductors in the primary winding requires protective measures to disconnect the transformer from the circuit in case of breakdown.

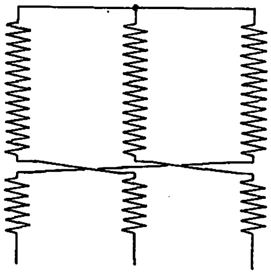

FIG. 18.

Fuses are invariably the means of protection adopted, but, being placed in the high-voltage circuit, they do not afford any protection against overload on the secondary side, and for this latter purpose low-tension fuses also are required.

In view of the magnitude of the fault current which can be fed into a voltage transformer from a modern system of supply, it has become a common practice to provide limiting resistors in series with high-voltage fuses in order to relieve the fuse of the duty otherwise thrown upon it. These resistors may be placed either on the voltage transformer side or on the line side of the fuse, but if the latter position is chosen, care must be taken to ensure that there is no possibility of breakdown on the resistor or its supports. The authors' experience has shown that the safest arrangement is to place the fuse on the line side of the resistor.

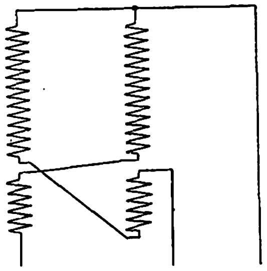

FIG. 19.

(ii) *Improvements in Use of Fuses and Resistors and Isolating Arrangements.*—A recent development is to mount the resistor as part of the voltage transformer, so that the latter, including its fuses, forms a complete unit. For voltages up to and including 11 kV a typical arrangement is to place the fuse across the cover of the voltage transformer and support it on porcelain insulators, the resistor comprising a helix of wire wound on a porcelain bobbin and placed inside one of the supporting insulators. This affords considerable economy in space and retains accessibility of both fuse and resistor, the latter being readily unscrewed from its position.

On circuits above 11 kV, unless otherwise provided against, corona may occur on the fuse wire owing to its very small diameter, and this ultimately corrodes the wire and disconnects the voltage transformer from the line. Shielding the fuse electrostatically is therefore considered essential on the higher voltages, and the authors have devised an arrangement whereby the required shielding effect is automatically provided by the helical winding of the resistor, the fuse being mounted concentrically within the resistor. It should be noted that while the fuse wire is sound the resistor and the whole of the fuse are substantially at the same potential. When the fuse wire blows, however, one end of the fuse may drop to earth potential, while the other remains at line potential. This condition necessitates a liberal spacing between resistor and fuse, and as a rule the necessary diameter of the resistor helix is such that the required spacing is obtained automatically. The same shielding effect is, of course, obtainable by means of an enclosing metallic cylinder maintained at the same potential as the fuse, but the use of the resistor to serve this purpose and to form a unit with the fuse which is readily accessible for inspection or removal, constitutes a great saving in space.

(iii) *Advances in Mechanical Design.*—Access to a fuse and resistor mounted inside the voltage-transformer tank may be afforded by an aperture in the cover of the tank, normally closed by hinged lids; but in general, if a voltage transformer fuse blows, it is necessary to remove the core and coils for overhaul, and accordingly there is actually no necessity for accessibility, although it may be of considerable convenience upon occasions.

The isolating of a voltage transformer for any required purpose may conveniently be afforded by fitting the tank with wheels in order to permit of withdrawal from the line contacts. The arcing which occurs on the relatively slow separating of the contacts while the transformer is being withdrawn is liable, however, to produce high-frequency impulses which may build up on the end turns of the voltage-transformer winding and cause breakdown. On 33 kV the arc may draw out to a length of approximately 2 in. before being extinguished, and means to avoid this are essential. The provision of a small switch inside the tank to break the magnetizing current under oil prior to withdrawal of the voltage transformer is one method, but although this is satisfactory on 22 kV the capacity leakage current of the bushings on 33 kV and above is sufficient to cause arcing on the contacts as serious as that due to magnetizing current. A means by which both magnetizing current and also the capacity leakage current of the bushings can be safely interrupted is to provide a quick-break snap-action switch at the contacts on the end of the bushing. However slowly the voltage transformer may be withdrawn, the speed of break of this switch is the same, the switch holding in until a predetermined amount of withdrawal has been effected, and then suddenly opening and instantaneously extinguishing the arc. When running the voltage transformer back into position this switch, of course, does not function, but with more rapid closing up of the contacts as compared with the opening speed the arcing in this case is so small and of such short duration as to be negligible.

(B) ELIMINATION OF VOLTAGE TRANSFORMERS IN HIGH-VOLTAGE CIRCUITS.

On voltages exceeding 33 kV a modern tendency appears to be to devise means whereby the voltage transformer is eliminated. This is mainly due to considerations of protective gear, for which purposes the majority of voltage transformers for high voltages are employed, the point being that such a transformer is no more reliable than the apparatus it is required to protect, if as reliable.

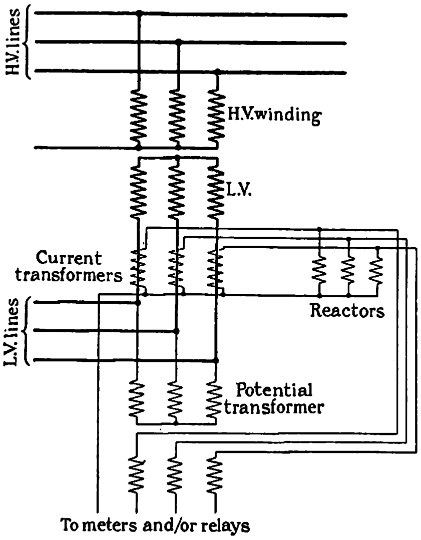

FIG. 20.

The scheme which appears to be developing is to use a power transformer which is already connected to the high-voltage circuit, and provide a voltage transformer for connecting to the low-voltage side of the power transformer, combined with a compensating device for correcting the error in the secondary voltage thus produced due to the regulation of the power transformer.

(i) *Principles of Operation of Compensating Potential Device.*—The compensating device consists of an impedance connected in each phase of the secondary side of the low-voltage transformer, having a value proportional to the impedance of the power transformer both in resistance and reactance, and energized by current proportional to the load current passing through the power transformer so that the compensating circuit is a homologue, at a reduced scale, of the power transformer circuit itself. In this way, a drop of voltage is obtained across the impedance which is proportional to the drop in the power transformer, whatever the conditions of load in the latter, and this voltage-drop across the impedance is accordingly suitable for correcting the error in secondary voltage of the low-voltage transformer due to the regulation of the power transformer, rendering available a compensated secondary voltage which is a true representation both in phase and in magnitude of the potential of the high-voltage circuit.

(ii) *Arrangements for Different Conditions.*—The elementary arrangement for a star/star-connected power transformer is shown in Fig. 20. The compensating impedances here shown are energized by current transformers in the lines of the power-transformer circuit. It is possible, however, and in the majority of cases preferable, to combine the impedances and current transformers into single units, when the connections become simplified as shown in Fig. 21. In general, however, the power transformers will have high-tension windings connected in star and low-tension in delta. In the arrangement of separate current transformers and impedances the connections then become as in Fig. 22,

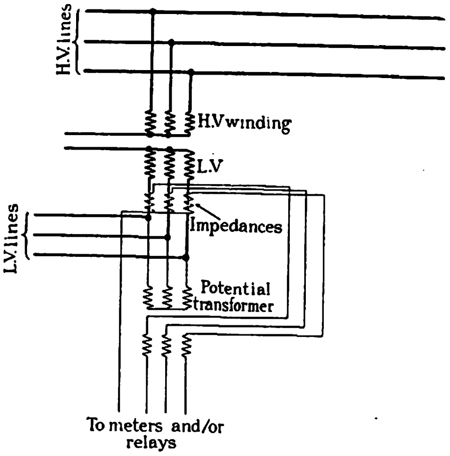

FIG. 21.

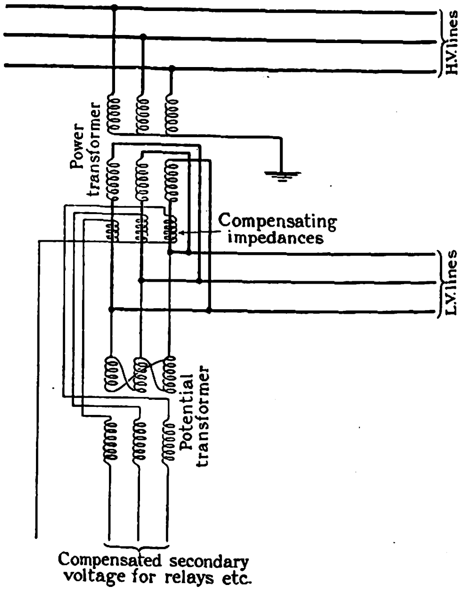

FIG. 22.

when it will be noted that the current transformers have to be inside the delta of the low-tension windings of the power transformer, and the voltage transformer requires delta-connected primary windings and its secondary in open star. The current transformer could still be maintained in the lines if installed on the high-tension side, but usually this is impracticable.

Connecting the current transformers and/or impedances inside the low-tension delta also presents difficulty, and if it is only necessary to indicate line voltage on the high-voltage side the arrangement shown in Fig. 23 can be used, the current transformers and impedances being combined as one unit and themselves delta-connected, although installed in the lines on the low-tension side of the power transformer.

(iii) *Indication of Phase Voltage.*—It will be noted, however, that there is no neutral point available on the secondary side of the low-voltage potential transformer, and hence no means of reading phase voltage. If a meter neutral point is derived from the line currents alone it will be erroneous, since a knowledge of the line currents leaves indeterminate the phase currents and hence the drops of voltage due to phase reactance. The error will be proportional to the residual current (which does not appear in the low-tension line) and since the residual current flows in the high-tension neutral it is possible, by means of a current transformer in this position, to obtain the true meter neutral point. Fig. 24 shows the connections by which this can be done.

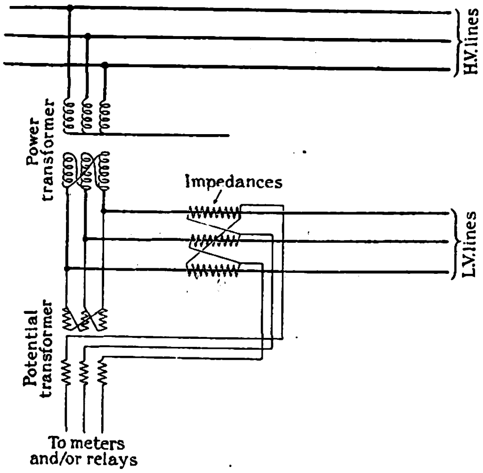

FIG. 23.

(iv) *Requirements to ensure Accuracy.*—Whatever the particular arrangement used, and whether the current transformers and impedances are separate or in single units, the effect is always to introduce a constant value of impedance into the secondary circuit of the voltage transformer, apart altogether from the compensating effect due to load current through the power transformer. This constant impedance effect produces in the secondary circuit of the voltage transformer a ratio and phase-angle change, in the same way as any other impedance connected into the secondary circuit, and accordingly the value of the impedances should be kept as low as possible; the only limit to this is the current which can be conveniently obtained for energizing the impedances, and the lower the value of the latter becomes, the higher is the current required.

In practice it is usual to compromise between these two factors so as to permit the use of a single-turn primary arrangement for the current-transformer effect in all cases. A point to be noted is that the voltage drop produced by the constant impedance effect is vectorial, i.e. there is introduced into the compensated secondary voltage a constant phase displacement, as well as a constant change in magnitude. The effect depends on the power factor of the total secondary burden and the power factor of the impedance. The latter is usually low in order to agree with the reactance and resistance components of the main power transformer impedance, and accordingly the lower the power factor of the total secondary burden becomes, the smaller is the effect due to phase displacement, and vice versa. If desired, the constant effect on magnitude can be adjusted by turn correction on the voltage transformer, and the constant effect on phase displacement may be taken into account in the adjustment of the meters or relays, according to the condition and requirements of individual cases.

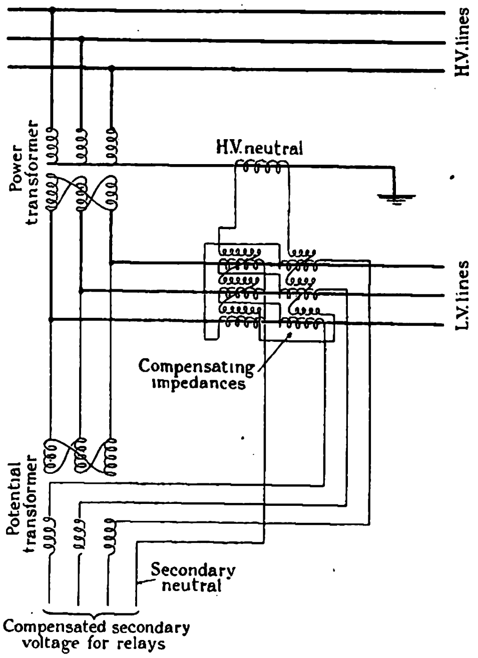

FIG. 24.

It will be seen from the foregoing that the compensated secondary voltage produced by any of the arrangements described depends upon the following:—

(1) The secondary terminal voltage of the voltage transformer.

(2) The compensating voltage as obtained from the impedances energized direct or via current transformers.

(3) The "constant drop" effect produced by the impedances.

The accuracy of the compensated voltage obtained in this way is a function of these three factors and, provided all the apparatus concerned is designed to operate as a whole so as to ensure co-ordination of the component effects, representation of the line and phase voltage system can be obtained with suitable accuracy.

SPECIAL-PURPOSE TRANSFORMERS.

Varying Ratio Features for Special Purposes.—In all the arrangements of current and voltage transformers which the authors have described in this paper the essential feature has been the maintenance of ratio under varying conditions of operation.

There are applications of instrument transformers, however, where it is desirable for the ratio to change with varying conditions of operation. In certain cases it may be required that for a given change in value of the primary current in a current transformer the secondary current shall change at a greater rate than the primary. For example, in a current transformer passing 100 amperes in the primary, the secondary current may be 5 amperes; but with 125 amperes in the primary, i.e. an increase of 25 per cent, an increase to 10 amperes, i.e. a change of 100 per cent, in the secondary current may be required. The authors have developed a current transformer having a performance of this nature which may be utilized with advantage for the operation of relays where response to small changes in primary current is required without the use of delicately set relays.

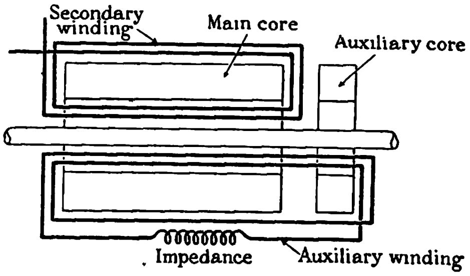

FIG. 25.

The connections are similar to those used in compensated current transformers, but since the auxiliary current is required to affect the ratio the current in the auxiliary winding is limited by an impedance of a reactive nature so that the auxiliary current is brought into phase with the secondary current and subtracts directly from it. The reactance is conveniently obtained by a winding placed circumferentially round the transformer so as to utilize the same core as part of the magnetic circuit for the reactor.

At a predetermined value of primary current the output from the auxiliary core ceases to increase appreciably with increase in the primary current, owing to saturation of the auxiliary core; and since the main-core output increases in proportion to the primary the net output, being approximately the arithmetical difference between the outputs of the two cores, increases at a greater rate than the primary output. The arrangement of this type of current transformer is shown in Fig. 32.

Similar performance is obtainable from a voltage transformer, where the voltage-change amplifying effect is particularly useful in the operation of voltage relays and regulators, since by its use a much closer regulation can be obtained with a given relay.

Alternatively to the current- and voltage-change amplifying effects described above, the opposite feature may also be readily obtained; i.e. for changes in primary voltage or current the secondary voltage or current may remain unchanged. This effect is obtainable with an arrangement of core and winding similar to that shown in Fig. 25, but with the design modified accordingly. A further possibility is that the secondary voltage or current, as the case may be, may be required to increase at a given rate up to a certain point, and then cease to increase any further. This feature also is obtainable with the same arrangement but with variation in the design.

In conclusion the authors wish to acknowledge their indebtedness to the British Thomson-Houston Co., Ltd., for permission to publish the matter contained in this paper, and to thank the company for the opportunities afforded them for research and development on instrument transformer work.

APPENDIX.

TYPICAL TEST-RESULTS ON LOW-RATIO COMPENSATED CURRENT TRANSFORMERS FOR COMMERCIAL CIRCUITS.

DISCUSSION BEFORE THE METER AND INSTRUMENT SECTION, 3RD JANUARY, 1930.

Mr. F. E. J. Ockenden: Most of the devices which have been introduced in an effort to improve current transformers have not succeeded in altering their true figure of merit. Usually such transformers fail to maintain the same high standard if the burden or the frequency is altered. The current transformer which the authors have described in their paper appears at first sight to be rather complicated. It is a little difficult to see what they have done to improve it, yet their figures undoubtedly show that they have achieved that result. Perhaps they have not explained their method of attack in the simplest way. They preface their remarks by stating that an extra primary current should be assumed in addition to the normal primary current in the busbar. Taking the device as a whole, it is obviously impossible to introduce any current other than that which is in the bar; their explanation is for this reason rather difficult to follow. However, let us consider a busbar transformer with a secondary winding connected to some specified load. The trouble with all current transformers, as the authors mention, is that they take a magnetizing current which has two components, the in-phase and the out-of-phase. The variation of the former, and with it the ratio variation of current transformers, is extremely small, but the true magnetizing component is a nuisance; it is large, and in the ordinary way it cannot be dealt with. A very well-known (though imperfect) device for solving the problem makes use of a condenser shunted across the burden. The condenser is adjusted to take a current which is precisely equal to the magnetizing component of the primary current as it would appear in the secondary circuit. Since this is in phase opposition to the current taken by the condenser the two cancel out and the main primary is no longer required to supply a magnetizing component. The phase-angle error of the current transformer therefore disappears Let us suppose that an inductance instead of a condenser is put across the burden. This may be arranged to take a magnetizing current which is precisely the same in magnitude and vector position as that of the original transformer. This current, however, is flowing in the wrong direction; instead of nullifying, it increases the former magnetizing current. The magnetizing current of the inductance must therefore be multiplied by j^2 in order to get the required result. This may be effected by feeding it through another current transformer and this is the origin of the second transformer in the authors' scheme. By thus injecting current into the secondary circuit we can achieve precisely the effect of the condenser, with the advantage that whereas the capacity of the condenser is fixed and, therefore, the compensation is only correct at one burden and frequency, compensation by means of a second transformer should apply over any reasonable variation of burden and frequency. Unfortunately, the second or compensating current transformer has to work at a fairly high density, so that the limiting values of the flux and, therefore, of the true magnetizing current are not those of the main transformer. Thus the compensation is not as perfect as would appear at first sight; it must suffer to some degree from the limitations of frequency and burden which affect the scheme involving the use of a condensive shunt. The crossed-coil device shown in Fig. 10 is very ingenious, but even with this scheme I doubt if the effective permability of a silicon steel core could be raised to the very high value obtained for the initial permeability of nickel-iron, viz. 10 000 to 15 000. My opinion is that the nickel-iron core will produce, in a much simpler way, results equal to those obtained by the authors with their form of compensation, with the additional advantage that the high figure of merit possessed by the nickel-iron core is retained under conditions in which the authors' transformer would be useless. Such a condition would occur if a number of transformers were connected in parallel for protective or summation purposes. It is of the utmost importance in such cases that the impedance of the secondary windings, when the primary is open-circuited, should be as high as possible. The impedance of the transformers described in this paper when so connected would be extremely low and possibly almost negligible. The effect of variation of burden on the phase angle of a transformer compensated by means of a condensive shunt placed across the secondary terminals may be much reduced by a modification which I have employed with considerable success in the design of current transformers of high accuracy. If the condenser is connected across the burden in the well-known manner, the voltage across its terminals varies only with the magnitude of the burden. The capacity current taken by the condenser, which serves to compensate the magnetizing component of the primary, must, therefore, also vary with the voltage across the burden, whereas the magnetizing component in the primary will vary with the flux in the core. The latter, however, will be proportional not to the magnitude of the external burden only but to the total burden of the transformer, that is, to the sum of the external burden and the burden represented by the resistance and reactance of the secondary windings. The capacity current taken by the condenser may be made to vary in a similar manner by connecting the condenser to a tertiary winding wound directly on the core. By this means not only is the compensation due to the condenser made almost independent of the magnitude of the secondary burden, but the capacity of the condenser may be reduced in value by winding the tertiary winding with a larger number of turns than the secondary. By combining this method of compensation with a nickel-iron core I have succeeded in constructing a current transformer having a phase-angle error of only 0·8 minute between full and one-tenth primary current. The ratio variation was less than 1 in 10 000 under the same conditions. The unusually small scale of Fig. 7, where the curve for phase-angle error is shown quite flat, makes it uncertain as to whether the authors intend us to consider the curve to be truly flat within a minute or two. The question of fractional turns is always rather a bugbear for current-transformer designers. The device of drilling a hole through the core and pushing one turn through is certainly quite effective, but I think it would be expensive because the position of the necessary hole would have to be fixed according to the exact fraction of a turn required, and fine adjustment would be impossible. Another scheme mentioned by the authors has the transformer in two sections wound with different numbers of turns. This was the basis of an American device, details of which were published a few months ago. For example, an e.m.f. of 1·0 volt might be induced in one coil and an e.m.f. of 1·1 volts in the other; the circulating current which flows round the transformer windings increases the apparent ratio and is used as the compensating system. The extra winding may be obviated by putting a shunt across the transformer. It is much simpler and it absorbs just that fraction of the current which is not required in the secondary circuit. This method has the defect, however, of allowing the current to vary with the resistance of the burden, but so, in fact, do all the other schemes which have been put forward either by the authors or by previous designers. There is probably no effective way of making a current transformer with fractional turns in which the secondary current is really independent of the secondary burden. In connection with the variable transformer described at the end of the paper, let us consider a normal current transformer operating the coil of a relay. As the primary current increases, so does the secondary current. Suppose the relay arm were held off by a second coil, which tended to prevent the operation of the relay. If this coil were fed from another current transformer which was almost saturated, the effect would be the same as that which the authors obtain; up to a certain point the two transformers would follow the same law and the pull on the tongue tending to operate the relay would be proportional to the current. Above that point the second transformer becomes saturated, the second coil ceases to nullify the effect of the first, and the result is apparently a greatly increased pull on the tongue, since only in the first transformer is the secondary current increasing. Let us suppose that, instead of introducing a second coil, the current from the second current transformer is merely injected into the first. Mechanical opposition is replaced by electrical opposition and we have what is, in effect, the authors' "variable ratio transformer." I think that the use of a relay with two windings, as suggested, would be more adaptable and reliable in practice than the transformer advocated by the authors, but the idea underlying their scheme is undoubtedly capable of considerable development.

Dr. C. V. Drysdale: About 25 years ago I was actively interested in this subject, and made what I believe were the first theoretical and accurate experimental investigations of the behaviour of instrument transformers; it therefore came somewhat as a shock, when I first read the authors' paper, to see that after clearly realizing the source of the errors I had missed an obvious solution. Since the vector difference between the primary and secondary ampere-turns is the no-load ampere-turns made up of the magnetizing and core-loss components, I was led to stress the reduction of the no-load ampere-turns and strongly to advocate the use of permalloy or mumetal, as soon as they became known. I have been much gratified by the remarkable accuracy which Colonel Edgcumbe and Mr. Ockenden have obtained by the use of such alloys. I still think that it is better to reduce the errors as far as possible by using these alloys, but the authors' compensation methods are extremely neat and practicable and they may still be used with advantage to compensate the residual errors in transformers of high-permeability alloys and, possibly, to effect an economy in the amount of alloy required. For switchboard use on constant secondary burden, transformers of stalloy compensated by the authors' method would probably be satisfactory; but it is obvious that the compensation must be adjusted for a particular burden, and that errors will reappear if the burden is changed. It therefore appears desirable to reduce the magnetizing and core-loss excitation to a minimum by the use of high-permeability and low-loss alloys, but this does not detract from the ingenuity of the authors' devices and the skill with which they have put them into practical form.

Mr. E. Fawssett: On page 707 of the paper there is a rather casual remark about low-loss alloys, and I am sorry to have to join with Dr. Drysdale in advocating the use of mumetal because, by doing so, I may be accused of drawing the discussion away from the design of the authors' transformers. On page 709 the authors state: "Even the use of high-permeability alloys for the core material does not provide" the features to which they refer. In my opinion, this statement is too sweeping. Mumetal is easily capable of providing a very high standard of performance. (Mr. Fawssett then exhibited three lantern slides showing the performance of mumetal.) It would be interesting to see some of the authors' test results and to find out how the theoretical conclusions work out in practice on a manufacturing basis. It may not be possible to reproduce the results with the degree of accuracy which is hinted at in the paper when (as is not unlikely) a slight change of burden occurs. Current transformers ought not to be very sensitive to burden change, for it is very difficult to forecast the burden to close limits in modern power-station lay-outs with long runs of secondary leads and where small additions to it are often made later on. The provision of testing windings [Section (G)] is a notable feature. However, if a transformer is as precise as the authors suggest, with variations of 1, 2, 3, or 4 minutes, one is bound to be critical of using anything but the real circuit. It is very doubtful whether a testing winding can really be made to reproduce exactly the main primary winding with a small variety of secondary burdens, and over the whole range of load of primary current. If, as the authors suggest, this is possible, further proof should be given. With regard to voltage transformers, the 3-phase potential transformer is not, in my opinion, ordinarily a very accurate piece of apparatus. The single-phase type is preferable, especially from the points of view of performance and safety, and it is therefore very inadvisable to mix up the phases. The single-phase transformer should not need any additional compensation and it is, in general, a much better piece of apparatus than the 3-phase transformer. On page 716 the authors suggest that voltage transformers are scarcely, if at all, more reliable than the apparatus which they are required to protect. They are definitely not as reliable, and are, in fact, nearly always the weak point in a system. The section dealing with elimination of voltage transformers in high-voltage circuits is of interest in regard to the general question of very high-accuracy metering requirements. In my opinion, if supplies are to be cheapened, it is wrong practice to insist on such extremely close limits of accuracy as those to which we are approaching. Surely the cost and complication of the gear, if very much enhanced, may not be justifiable. The statement on page 713 of the paper that "As a principle of general design, the authors submit that in any arrangement of apparatus each individual part should be made as perfect as possible," is an excellent piece of advice. (Mr. Fawssett then exhibited a lantern slide showing one way of compensating for the power transformer losses.)

Mr. R. S. J. Spilsbury: I wish that fuller experimental results had been given in the paper. For instance, no figures are quoted for the variation of the transformer characteristics with burden or with frequency; and although the compensation is specially advocated for single-turn transformers of low current rating the paper contains no results for such transformers. Another interesting point is the effect of wave-form. Since the auxiliary core must operate at quite a high magnetic density it is possible that the characteristics of the transformer might be rather seriously affected by variation of the primary wave-form. Have the authors any data on this point? On the question of the relative merits of compensation and mumetal cores, the authors state that transformers with the latter do not give a flat characteristic. Flatness is, of course, a relative term, but the ratio characteristic of a mumetal transformer can be flat within 1 part in 10 000 from full to one-tenth normal current. Probably the question will settle itself on an economic basis: other things being equal, I should prefer the mumetal transformer on the score of simplicity, but the authors' design will undoubtedly be very valuable for certain applications. The authors define the sensitivity of a relay as the current required to operate it: hence when they wish to speak of making a relay work at a very low current they refer to this operation as "minimizing the sensitivity." This seems to be rather a misleading usage and it is not supported by the B.E.S.A. "Glossary."

Mr. C. W. Marshall: This paper tends to show that the calibration of current transformers in conjunction with meters will, fortunately, soon be a thing of the past. With regard to the relative merits of mumetal and compensated current transformers, it would be interesting to hear the views of experienced engineers on the stability of the former. Its simplicity is a point in its favour, and possibly the economic side has to be considered just now, but stability is the most important factor of all. Mr. Fawssett referred to the testing winding, and I agree with him that it is undesirable to introduce that complication. It appears to me to be quite easy to ascertain whether or not a core or winding has changed, by applying a separate potential and measuring the magnetizing current in magnitude and phase at a definite point. If there has been no change, further action is unnecessary. The weak point in both the mumetal and the compensated type of current transformers is that at extremely light loads neither helps very much, and it appears that the only method of overcoming the difficulty must rely upon excitation from a parallel potential source which is independent of the current. I should be interested to hear what the authors have to say regarding the theoretical possibility of that suggestion. In actual practice the secondary circuit is just as liable to failures as the primary circuit. It should be recognized that great care must be taken in design to avoid thermal troubles. We are aiming at the greatest possible simplification of the instrument equipment, and it is my hope that a system employing one current transformer per phase and serving all purposes will eventually be achieved. With regard to potential transformers, the issue is very broad. It is generally agreed that it is difficult, if not impossible, to introduce potential transformers without considerably reducing the factor of safety. The possibilities of condenser potential measurements with or without low-voltage potential transformers, and even of the use of resistances, have been suggested as alternatives. It is, however, more hopeful to anticipate improvement on the lines which have been suggested by the authors. In the grid system we have definitely departed from the use of pilot wires in the longer sections and are thus dependent, to a great extent, on accurate reproduction of the high-voltage magnitude and phase by measurements which come through the power transformers. It is expected that a degree of accuracy sufficient for the purpose will be obtained without the introduction of 132-kV potential transformers.

Mr. W. A. Burgess: Switchgear makers are frequently requested, on the one hand, to give extremely close accuracies for metering on very small primary currents and, on the other, to provide for very heavy short-circuit conditions. The authors have shown that those two conditions are distinct, and that under normal circumstances one has to be sacrificed for the other. The extension of the range of the single-turn primary suggested by the authors is a proposition which should be very attractive to switchgear makers. The authors are inclined to investigate a number of different methods of obtaining stability in connection with protective gear. Stability is the main essential in protective gear; the setting is only incidental. The only way to attack the problem of protective gear stability is accurately to balance the current transformers, in characteristic at least. There seems to be no reference in the paper to this balancing of the characteristics in so far as it affects the attainment of a straight-line voltage relation. Whether the authors' form of current transformer compensation can be made easily, or at all, to produce a straight-line characteristic, is not clear from their paper. Such a characteristic is, in my opinion, absolutely essential for the pilot forms of feeder protection. The only form of protection to which reference is made in the paper is transformer protection; feeder protection appears to be ignored. I agree with the authors on the question of the reduction of the secondary current, but I do not think that they go far enough. Many meter engineers would agree that instruments can be provided to give on ½-ampere secondaries the accuracies required within commercial manufacturing limits, and I think that, particularly on the higher voltages, one would be better off with ½-ampere secondaries. I am rather disappointed, moreover, to find that there is no mention in the paper of the very ingenious core which, I believe, the authors' firm use for their current transformers, namely the rolled-strip core. I should like to know whether there is any appreciable difference in the phase-angle or ratio error or actual loss, between the rolled-strip core and the stamped core (for equal weight). I should also like to know how the weight of iron on a compensated current transformer with a bar primary compares with that in a multi-turn current transformer, either of the rolled-strip or stamped-type core having, say, a 100-ampere primary, a voltage of the order of 33 000 or 66 000, and a normal 15-VA output with both Class B and "precision" accuracies. The potential-transformer correction method due to the authors—for I think it is in large measure due to them in its final stage—is of great interest. I can say from first-hand experience that the accuracies obtained are very good. While accuracies with this form of potential-transformer compensation—or reproduction of e.h.t. voltage on the low-tension side—are extremely good, yet with the present tendency to use tapped transformers for voltage regulation (such as on the national "grid") considerable complication arises owing to the necessity for tapping everything. It is a nuisance, but it cannot be avoided if the method of compensation used by the authors is adopted. I suggest that the much simpler expedient of providing a low-voltage coil on the main transformer in a suitable position be adopted instead.

Lieut.-Col. K. Edgcumbe: With regard to the serious trouble which arises with an accidentally opened secondary, it seems to me that since the short-circuited winding which forms a part of the authors' current transformer is unlikely to be open-circuited at the same time as the main secondary, it may form, to some extent, a protection against undue rise of voltage. The authors state that they doubt if mumetal is truly stable. Mumetal has now been used for 4 or 5 years, and I have never heard of any instance of a definite change of characteristics. It is very susceptible to mechanical damage, so that special precautions have to be taken in making up transformers with it; but apart from that I do not know of any reason for supposing that it undergoes a change, either from age, temperature, or over-magnetization. We may expect some more figures on the subject very shortly, as a good deal of work is being done on that particular point, which is, of course, a very important one. Mr. Burgess referred to the 0·5-amp. secondary, and said that he thought that instrument engineers would agree that it was perfectly easy to construct instruments to work with such a secondary. There seems to be some idea that the secondary current affects the burden as far as the instruments are concerned. That is not so. It does not affect the burden imposed by the instruments, whether the secondary current is 5 amperes or 0·5 amp. The only advantage of 0·5 ampere (and, as the authors point out, it is a very important one) is that it reduces the losses in the connecting leads to about 1 per cent of the value at 5 amperes. The instruments behave equally well with either and are as easy to construct. A serious disadvantage of the 0·5-ampere secondary as compared with the 1-ampere is the very much higher voltage induced in the secondary in the event of an open-circuit. I hope the authors will amplify the figures of performance in their reply. At present they are very meagre and do not tell us, for example, the size of the transformers, whether their cores were small or large, or even what was the magnitude of the burden. The idea of putting on an auxiliary test winding when the transformers are first installed has, I believe, been employed before. I remember seeing a description of it some years ago. I do not see why some of the speakers have doubted whether it was a true reproduction of the primary. In a ring transformer it should reproduce the primary very accurately. Probably the same result could be obtained by subdividing the secondary into two halves and comparing them when the transformer was new. If they retained the same relative characteristics one might presume that nothing had happened to the transformer.

Mr. C. L. Lipman : In my opinion, the ½-ampere rating of the secondary current of bushing-type current transformers has rendered possible improved apparatus and instruments. The winding for ½-ampere full-load secondary current improves the performance of the "straight through" type of current transformer, as it permits a finer turn adjustment. Modern measuring instruments, including ammeters, wattmeters, reactive kVA-meters and power-factor meters consume less power when wound for 0·5-ampere than the earlier types of instrument wound for 5 amperes (other conditions such as strength of springs, etc., remaining the same). In 0·5-amp. coils it is, for example, possible to use enamelled wire with single silk covering instead of wire of large overall diameter with double cotton covering: a considerable improvement in the space and copper factors for a given winding space and hence a reduced power consumption are thus obtained. At the present time instruments are available which require a smaller electrical input, have lighter moving systems, give the same or an improved mechanical output and have a higher performance than earlier designs. One of the reasons for this improvement is the use of the 0·5-amp. secondary current.

Mr. A. J. Gibbons : Some years ago I was connected with the work of revising the metering on some 6 000-volt switchgear on high-capacity and small-current circuits. The switchgear was made by the firm with which the authors are associated, and after some demonstration tests it was decided to try some of these compensated current transformers. From the practical point of view, the results obtained in connection with meter accuracy have been all that could be desired in view of the fact that not precision accuracy, but merely first-rate commercial accuracy, was the primary consideration. The following are actual test figures taken from a watt-hour meter working on 200 : 5 current transformers:—

Load, VA	Percentage error on unity power factor	Percentage error on 0·5 (lag) power factor
full	0·8 −	0·6 −
¾	0·2 −	0·2 +
½	0·2 +	0·8 −
¼	0·3 −	1·0 −
1/10	0·5 −	
1/20	0·4 −	

I think that the figures substantiate very well the claims for enhanced accuracy on the bar-primary compensated transformers. With regard to the use of current transformers on protective gear, the authors point out that difficulty is sometimes experienced when current transformers require different ratios, presumably for protecting transformers with Merz-Price circulating-current gear. This trouble can easily be overcome by omitting the circulating-current protection and substituting core-balanced earth leakage, which is practically immune from operation on a through fault and can readily be adapted to give almost any sensitivity desired (certainly down to 20 per cent of the transformer rating). Back-up inverse time-lag overload protection will cover the exceedingly rare case of a fault between phases. I notice that the authors have in mind the provision of testing windings, and in some cases I consider that these would be a great advantage. It is frequently a matter of some difficulty to obtain a check on the performance of a current transformer. I think these testing windings will enable the check to be made very rapidly. I do not agree with the authors in regard to voltage transformers. They state (page 716) that there is no necessity for access to the high-tension fuses. On looking through some records which deal with some 90 22 000-volt potential transformers, I found that 9 fuses had blown and in no case had there been a transformer fault; the trouble was merely due to deterioration of the very fine fuse wire. So far I have yet to experience an actual transformer fault on these particular instruments.

Mr. A. E. Quenzer : The last speaker referred to testing windings. There is one point which is not in their favour and that is the danger of the terminals being short-circuited; this would obviously introduce serious errors in the main secondary winding. I am not certain as to the utility of testing windings and, from my own experience, I have found portable testing apparatus to be quite satisfactory, provided that the testing current is applied direct to the secondary terminals without disconnecting any secondary leads. This method takes into account possible errors in transformer ratios. Are the testing windings to be a feature of the general design? Referring to Tables 1 and 2 in the appendix, I should like to know the power factor of the burden and whether the tests were carried out on the rated burden of 15 VA. Some particulars of the performance of these transformers on a frequency of 25 cycles per sec. would also be welcome.

Mr. E. W. Hill: I have noticed in the paper and also in the speakers' remarks what I consider to be incorrect methods of expressing current transformer errors; they are ambiguous and unintelligible to anyone who does not know the convention upon which they are based. It so happens that the error in the ratio of a current transformer is one which has an inverse relation as regards sign to the error in the magnitude of the current delivered from the secondary windings. If the current transformer has an error and the ratio is too high, for instance, it means that the secondary current is low. All our attention is centred upon the secondary side of the current transformer. From the point of view of accuracy, we are interested in how a meter or other instrument will perform when connected up to the secondary winding of the current transformer. Therefore, any way of expressing the error of the current transformer should have some consistent relation in respect of sign to the way in which the instrument connected to the current transformer will be working. The statement that a current transformer has an error of minus 1 per cent should mean that the current delivery from the secondary winding is 1 per cent low; but it is never quite clear. I should like to appeal for an intelligible way of specifying current-transformer errors. If in one column the loadings—full, $\frac{3}{4}$, $\frac{1}{2}$, etc.—were set out, and in an adjoining column figures were set forth expressing "secondary-current magnitude percentage error," the meaning would be clear to everyone. If the error against any particular load were expressed as $+1$ per cent, it would mean that the magnitude of the secondary current was 1 per cent high. There would be no ambiguity, and no need to infer from the known characteristics of current transformers the sign of a particular set of errors. When the authors' ideas come into full effect and we find the inflection of the current-transformer characteristic curve inverted, matters will be more difficult. We shall not then be able to infer the sign of errors merely from an inspection of the curve presented to us. If under present conditions we see a current-transformer curve with positive errors at the top and negative errors at the bottom, we can, it is true, interpret what is meant, but only by inference from the shape of that curve. The method which I have indicated would, however, obviate any chance of mistake in such a case. In any event I should like to see references to current-transformers' "ratio errors" entirely suppressed, since they are bound to be misleading. As regards phase-angle errors, these could be set out against loadings so as to have, in the second column of the table, the "secondary-current phase-angle error" expressed as "degrees of lead" or "degrees of lag," thus avoiding the use of the terms "positive error" and "negative error."

Mr. W. J. Minton (*communicated*): I am sorry that Mr. Fawssett seems to have withdrawn his plea for a high degree of accuracy. I believe I have heard him say that a decrease of 0·5 per cent in the registration of the meters is sufficient to annul the profits of many concerns. I wish to draw attention to the loose way in which accuracies are stated and to express the opinion that these figures should refer back to the quantity which is to be measured. The terms "positive" and "negative" should also, in my opinion, be eliminated and accuracy should be stated in terms of registration, as a fraction or percentage. Thus, for too great a registration 1·03 or 103 per cent would be given, whereas 0·97 or 97 per cent would be obtained if the registration were inadequate. The chief advantage of this suggestion is that it enables accuracies, which are usually read off from a slide rule, to be entered up without the trouble of converting once again to the usual form. When several accuracies have to be allowed for, as, for example, when two potential transformers are used, this involves a considerable saving of labour.

Mr. H. Trencham (*communicated*): There is a good deal of evidence that the operation of instrument transformers is not as well understood as is desirable, even amongst engineers responsible for electric power distribution. Since current transformers are series-connected they form an essential part of the supply equipment in which they are used, notwithstanding that their function is ancillary; they frequently constitute part of the bus system, as in bulk-metering arrangements and on most incoming feeders. The authors' contention (page 704) that there is a tendency to regard instrument transformers purely from the meter or from the switchgear point of view is important, and its truth has been instanced on more than one occasion by specialist switchgear manufacturers who have found it necessary to undertake the design and production of their own instrument and protective transformers. A recognition of broader claims than those of metering or switchgear work alone would surely be of value. The statement on page 705 ["Current Transformers" type (1)] is open to amplification, as a range up to 50 per cent overload cannot be considered sufficient to meet requirements of relays or trip coils which may be calibrated to twice and three times normal load. The benefits to be derived from the use of current transformers of few ampere-turns (of the straight-through or bushing type) are so great and so much needed in the industry that their application to plain overload protection, which is after all by far the most usual type, should not be left in any uncertainty. The authors' statement appears to mean that at loads in excess of 150 per cent of normal there may occur a falling-off in ratio which would vitiate the correct operation of relays or trip coils calibrated in terms of secondary currents up to 10 and 15 amperes. As primary current is the true criterion, however, the case might have to be met by special calibration of such relays or trip coils with their own or representative transformers, a practice which would not be welcomed where large production is the aim. Some further thought on this subject may be found profitable. In regard to short-circuit capacity, it should be remarked that oil circuit-breakers are frequently applied in locations where they may be subjected to short-circuits well above their rated breaking capacity. It is advisable to bear this in mind if the breaker rating be used as a basis for the selection of current transformers, and this rating should definitely err on the conservative side. Concerning secondary-current rating (page 711), there is a good deal of interest attaching to the suggested 1-ampere secondary; apart from the technical issues involved, the cost of secondary wiring for large power-station equipments is considerable and it is frequently necessary to use quite large cables with 5 amperes of secondary current because of the long runs involved. The limit of a 300-ampere primary for 1-ampere secondary design would not, however, be very helpful in this problem as the majority of power-station circuits nowadays carry considerably more than 300 amperes. The special devices which have been developed by the authors to reduce and compensate for errors exhibit an interesting degree of resource and are, in the main, of a sufficiently simple character to ensure their ready application in practice. It will be of interest to note their progress in the immediate future.

[The authors' reply to this discussion will be found on page 730.]

North-Western Centre, at Manchester, 18th March, 1930.

Mr. J. Randle: On first reading the paper it appears that the ratio error correction follows logically upon the authors' ingenious method of phase-angle correction. A second reading reveals a distinct break in the method, and I wish to ask whether the ratio error correction was rendered necessary by the increase in ratio error introduced by the phase-angle correction. It is interesting to note that the correction of ratio error involves an increase in phase-angle error. The authors claim to have reduced the current in bar-primary transformers from above 1 000 amperes down to above 100 amperes. What are the considerations fixing the figure of 100 amperes? If the authors' recommendation of a 1-ampere standard burden is adopted, will this extend the range even further? An acquaintance with the manufacture of the cumbersome 2-turn primary with specially shaped copper and hand insulation, makes one welcome an extension of the range of bar-primary transformers. In the variation of the compensated current transformer employing a split main core, the increased flux density will lead to high core losses. When such transformers are used in a circulating-current system of protection a large " through " fault will cause considerable heating. I should like to know whether, in this type of transformer, thermal considerations prove to be a limiting feature in design.

Mr. W. Holmes: The paper is entitled " Instrument Transformers." I do not expect that all types of instrument transformers could be reviewed in one paper, but this paper is rather confined to the description of another compensated type of instrument transformer. I mention this particularly because the authors state that this particular type of compensated transformer has changed the whole outlook of current-transformer design. I cannot see any difference in principle between the transformer designed by the authors and the 2-stage current transformer designed by Brooks and Holtz over 10 years ago. This transformer is put on the market by the British Sangamo Meter Co. and is fully described in the *Transactions of the American I.E.E.* (1922, vol. 41, p. 382), and it is also mentioned in the *I.E.E. Journal* (1927, vol. 65, p. 576). It consists of a core divided into two parts, a compensating winding from one part to the other, but instead of using a resistance inside the transformer this method uses another winding on the meter. This makes a rather simpler transformer, and there is no difficulty in giving the meter a double winding. Another type of compensated current transformer was described by Wilson in a paper read before the American I.E.E. in January 1929. It is made by the General Electric Co. of America. In this transformer one leg of the iron core is split into two parts, and a lagging coil is placed round one part in the same way that the quadrature band is put on an induction meter. Surprising results are claimed for this transformer. Curves of phase-angle errors are shown on the zero line from full to 1/10th load current, and the errors are only 2 minutes at 1/20th load current. Compensated current transformers introduce unnecessary complications, viz. the extra windings; the two cores; the joints in the windings; and the wrapped up resistances or shunts introducing weak links which in time give trouble. The current transformer has been, and still can be, a very simple piece of apparatus. By using cores of nickel iron such as mumetal and permalloy, it is possible to get an almost perfect transformer. On page 707 the authors dismiss low-loss alloys in 6 lines, but in reply to their remarks I would say that the cost now is not extremely high—it has been reduced in a few years by two-thirds. I admit that saturation occurs at a density of about 3 000, but this is unimportant when current transformers usually work at densities below 1 000. In fact it has a definite advantage—it helps the short-circuit characteristics. Time has proved that mumetal and permalloy are now very stable under service conditions. In Tables 1 and 2 the authors give tables of phase-angle errors reaching 10 and 17 minutes. This is rather disappointing after all the complicated compensation involved. With a simple mumetal transformer having the same number of ampere-turns the errors are well within half this value. The last paragraph on page 709 reads:—" A transformer compensated in this way, if sold on a commercial basis and not operated exactly at its rated burden, may have errors, etc., at some other value of secondary burden." Is the method of further compensation for this, shown in Fig. 10, where a further third-stage transformer is used, only for laboratory use? The reason for all this compensation is to obtain a bar-primary construction, and the reason of the bar-primary construction is to make the transformer safe on short-circuits, with which I entirely agree. The information about short-circuits, given on page 706, paragraph 3, is very interesting. There is just one point, however, on which the authors might have been more precise. They mention a factor of 150, based on thermal effects. Time should, however, be coupled with this factor. When considering thermal effects, for instance, a transformer would easily withstand 150 times full load for a fraction of a second, and it would be easy to calculate how long would elapse before the copper melted.

Mr. H. C. Turner: The design of the bushing transformer with which the paper largely deals is of great importance in these days of the National Grid, and although I do not think that the methods of correction employed by the authors are final, the solution may be found along the line of thought which they have started. The correction of a current transformer by injecting into its secondary a current equal and opposite to the primary magnetizing and iron-loss current has been thought of before. It has been impossible, I have always understood, to find a suitable source of current to balance the magnetizing and iron losses, but the authors have solved this to a degree by employing the auxiliary core which, in order to do its work, must be run at a fairly high density. This core, whilst capable of providing sufficient current by its secondary winding, unfortunately does not provide it in the right direction. In Fig. 5 the current vector lags behind the main core vector, with the result that whilst the phase angle is corrected it is corrected at the expense of the ratio. The method of correcting the ratio shown in Fig. 9 cannot, I think, be employed concurrently with the above-mentioned method of power-factor correction, as the lengthening of the reversed secondary vector is caused by the magnetizing vector which lags more than 90° and which, owing to the impossibility of it being in line with the secondary current vector, must increase the phase angle. The last paragraph but one in col. 2 on page 708 should, I think, state that either phase or ratio correction can be provided but not both. The use of an auxiliary core at a higher density than the main core is rather unsatisfactory as it means that the correcting current will remain constant over a part of the range where the total magnetizing current is growing—in other words, the currents will not match. The method of correction which employs the auxiliary and crossed windings and in which the density in the main core (or rather cores, as it is now split) has a set-up zero, is not fully described and it would be interesting to know what results the authors have obtained. This is important as they have apparently discarded the previous methods in its favour. The use of other phases to provide the correcting current is not, in my opinion, to be encouraged, as the load cannot always be balanced and fault conditions may cause grave errors in reading and in the control of protective gear. The transformer figures mentioned in Tables 1 and 2 are good, but the load is reasonably low and the primary ampere-turns are higher than those in the worst cases. It would be interesting to see figures for 80/5-ampere and possibly 40/5-ampere transformers. The method of obtaining fractional turns is not simple and would perhaps be better replaced by that of winding all low-primary transformers with ½-ampere secondaries. This is another instance of the illusions of youth disappearing. We used to be told that it was just as impossible to have less than one turn as it is to make a clock strike less than once—yet instrument engineers frequently have to provide 100 or 200 ampere-turns with a current of 500 or 1 000 amperes, and have no difficulty in doing so. For protective schemes a more satisfactory practice than that of designing special balancing transformers is to use absolutely standard and cheap transformers and rely on biasing these as is done in the case of the McColl scheme in which, under normal conditions, the relays are held open by the secondary current, and in which the unbalance of current transformers does not affect the operation. Except for the most exacting conditions the present design of potential transformers gives all the accuracy demanded, and I do not think that improvements in this direction are necessary. The improvement of insulation is of greater moment. A point recently arose in connection with transformers where the frequency varies. With voice-frequency apparatus and picture telegraphy, frequencies range from 50 to 12 000 cycles per sec., and we find that iron powder solves the difficulty. Have the authors tried the use of powder instead of laminations?

Mr. M. W. Sheppard: The authors lay great stress on the advantages of bar-type current transformers over the wound type, but although I agree in general I think they overstress the point. The percentage of wound-type current transformers which break down owing to short-circuits on the line is extremely small and it should be noted that multi-turn current transformers are still extensively used in America, notwithstanding the fact that the compensated type of current transformer has been available for a number of years, and I believe large blocks of power are dealt with. In the authors' comments upon high-permeability iron they mention the disadvantage of its comparatively low magnetic saturation value, yet a few lines further on they claim that by using a compensated winding a reduction in core area may be effected. This would seem to accentuate this apparent disadvantage and hardly seems consistent. My view is that for ordinary purposes this is not a real disadvantage and, should the secondary be inadvertently open-circuited and the flux rise to an extremely high value, the iron losses under these conditions are so low when compared with those inherent to stalloy that the heating effect would not be sufficiently great to damage the core or windings. I note that in the compensated current transformer an auxiliary core is used which operates at a comparatively high flux density. I should like to have the authors' assurance that after a few years' service or a heavy short-circuit this core will maintain its magnetic characteristics. If this is not so it appears to me that its value as a compensating device is rather problematical, as it should be remembered that the inherent phase-angle of each individual current transformer may be of the order of, say, 200 minutes at low values of current. Therefore a 10 per cent variation in either current transformer represents an unbalance of 20 minutes, whereas when a current transformer with a nickel-iron core having an error of, say, 10 minutes, varies 10 per cent, this represents a difference of only 1 minute. I fail to see the relationship between Figs. 3 and 6; in one case current is taken from separate circuits and added vectorially, whilst in the other the flux in the main core is controlled by means of a current taken from the same primary circuit. It is not clear to me how the conditions contained in the text with regard to Fig. 10 are obtained. From the diagram it appears that half the main core is supplied with an additive flux, while the other half has a subtractive flux applied. Thus the respective resultant fluxes are very different, and from this I fail to see how the authors can substantiate their claims to be operating the core at its point of maximum permeability. I should like to see the tables giving actual test figures extended to cover the effect of a change of VA burden or frequency, as the necessity of calibrating for one particular burden or frequency is a distinct disadvantage, and even with a standard design the variations in different consignments of iron makes this imperative. I also note the authors' remarks regarding the losses in the leads, but from the above it seems essential either to allow for this extra burden when calibrating, or to keep it extremely low. The use of fractional turns to effect ratio compensation has been in use for many years, but I agree with the authors that a lower value of secondary current might be an advantage for the lower ranges. Turning to transformer protection, I am of the opinion that the best conditions are obtained when current transformers having similar characteristics are used. To meet this, it is necessary to have a wound type on one side at least, but the current transformers can be made to withstand a heavier overload than the transformer to be protected, and the " switching in " surge may be guarded against by the use of " kick fuse " relays. My view is that the current transformers should not balance under normal conditions, owing to the effect of the magnetizing current of the power transformer. If this is compensated for, as is often the case, a serious out-of-balance will obtain on a through fault. The authors' connections for voltage transformers show considerable ingenuity and appear to be a modification of the customary inter-star connection. With regard to the general aspect of design, apart from the minor improvements effected by shunts and turns compensation there are three definite lines of approach. The first is to compensate the errors of the main current transformer by means of an auxiliary current transformer, (*a*) by adding the secondary currents magnetically in the manner described by the authors, or (*b*) by adding both secondary currents vectorially, a method which has been in use in America for many years. The principle of the two above methods appears to be identical, but the application is slightly different. The second method is to control the shape of the magnetizing and iron-loss curve by means of a magnetic shunt, making it approximate to a square law. This practically ensures a constant-ratio error which can be adjusted by turn compensation. The phase angle is corrected by means of a lag band encircling part of the core. The above methods are very ingenious and at the time of their introduction marked a decided advance in design, but one must not lose sight of the fact that they are only palliatives and the error is still inherent in the transformer. The third method goes to the root of this error, and is to use a core of high-permeability, low-loss alloy. By the use of this metal a transformer may be built having a bar-primary and having all the advantages of a wound-type current transformer as regards reliability, simplicity and ease of manufacture and test, and yet having a greater accuracy than either the wound type or compensated bar-type current transformer. Moreover, it will have a performance which is not seriously affected by change of burden or frequency. My partiality to current transformers with nickel-iron cores is due to the fact that they are the nearest approach to a perfect transformer yet obtained—that is, a transformer having a current ratio corresponding to the turn ratio and without phase displacement under all normal conditions, yet simple to manufacture and test, which can be put to stock and used as required without the necessity of calibration or an uneasy feeling that all is not well. A transformer having a nickel-iron core is particularly applicable as a bushing-type current transformer for use on high voltages and low currents, as it should be remembered that a compensated current transformer takes a comparatively large volt-ampere load to magnetize it, and this power is not available under the above conditions. A disadvantage of this alloy is its relatively high cost, but no doubt this will be considerably reduced with greater demand. To set against this is the distinct saving in manufacture and testing due to the simplicity of design.

Mr. V. A. Brown : The use of high-permeability, low-loss core materials such as mumetal, etc., in the construction of current transformers has enabled the absolute values of error to be reduced, but the ingenious methods of compensation invented by the authors have brought the variations of error under the control of the designer. To my mind, the simultaneous use of the lower and upper bends in the magnetization curve is very unusual practice, and it is surprising that no one has previously visualized the use of the upper bend as a corrective against the lower bend. It is a pity that more detailed information concerning the special-purpose instrument transformers, dealt with at the end of the paper, is not given, and I hope that the authors will amplify this in their reply. It is with the questions of short-circuit ratings and protective transformers that my only real criticism of the paper is concerned. Under headings (i) and (iii) of the Summary the authors claim responsibility for certain views which are also held by other instrument transformer designers. For example, under heading (i) the short-circuit limitations of current transformers and the view that a reduction of ampere-turns is the only real means of increasing the short-circuit capacity, have been well appreciated for some time. With reference to heading (iii), it has long been my practice to limit the core density in protective transformers to a safe figure at the maximum " through " short-circuit current for which they are designed. Of course, at low values of rated primary current this has meant generous physical dimensions of the current transformers, combined with a reduction in the volt-ampere burden imposed by the pilot wires. I have never regarded biasing arrangements as a good method of getting stability and, so far as the reduction of spill current by the balancing of transformers is concerned, I am firmly convinced that the provision of large transformers does not cost any more when the expense of balancing smaller transformers is considered. Nevertheless, I do not advocate the abolition of a single balance test as a check against errors of design or workmanship. I agree with the authors when they say that a current transformer should be rated according to its service burden and not at an increased burden as is frequently specified. There is no point in calling for the higher value of volt-ampere rating if the required limits of error, corresponding to the service burden, be specified. I endorse the authors' view that, strictly speaking, the secondary burden of a current transformer should be expressed as an impedance, and I hope that the British Engineering Standards Association will consider this suggestion when next they revise B.S.S. No. 81. The expression of secondary burden in volt-amperes is a snare when the burden of secondary apparatus is expressed in volt-amperes at a current differing from the rated secondary current of the transformer. I have in mind the case of a user who was attempting to check the performance of a current transformer at 1/10th rated primary current with a 0·5-ampere meter having a consumption of 2 volt-amperes at full-scale deflection. He complained that the transformer was reading badly low and had failed to appreciate that this ammeter imposed a burden of 200 volt-amperes on the current transformer by virtue of its high impedance, namely 8 ohms. The above case also explains why some users fail to see that they cannot have very low leakage settings from a bar-primary current transformer with a leakage relay (or trip coil) that is capable of being set at the desired low values. There is an optimum number of turns on the relay (or trip coil) which will give a minimum value of primary tripping current, and this point is well illustrated by Fig. 15 of the paper. The methods of compensating voltage transformers, when fed from the lower-voltage side of power transformers, should eliminate the necessity for such transformers rated higher than 33 kV. Any indication of voltage for synchronizing purposes on circuits at the higher voltages can be catered for by low-voltage tappings on the terminal bushings of oil circuit-breakers.

Mr. O. Howarth : I endorse the authors' statements that the subject of instrument transformers deserves more specialized attention and more general publicity than it has hitherto received. Mr. Wellings mentioned that a poor current transformer is put into a vital position and disappears when faults occur. Well, the mistake we make is in putting a poor current transformer in a vital position; we should see that a really good current transformer is put into that vital position. I have in mind certain current transformers in this district with wound primaries, which have been subjected to very heavy short-circuit currents and to fairly severe transients, and have given good service for many years without showing any signs of distress or breakdown. The compensated current transformer is of more use for the higher ratings, so far as achievement of satisfactory performance is concerned, than for the lower ratings. A compensated current transformer rated as low as 100 amperes will probably not be satisfactory for operating a meter. Whilst it may be nominally within some class appearing in B.S.S. No. 81 I think that in practice its performance will not be good. The lowest limit for a really accurate metering transformer with a bar primary, even when compensated, is about 300 amperes. I have tested some transformers of this type rated at 3 000 amperes and the compensation certainly gave very good features. A 3 000-ampere transformer should be fairly accurate without compensation, but in these compensation was a decided advantage. I should like the authors to give some information on one point: How does the secondary impedance on a compensated current transformer compare with the secondary impedance on a straight transformer of the same ratio and primary ampere-turns? This is rather important when summating two circuits by means of current transformers in each circuit operating the same meter, because the magnetizing current of an idle transformer may be taken from the transformer supplying the current going through the meter. It has some bearing on the meter accuracy. The higher the impedance of the secondary, the better. It would be interesting to hear how the design of protective transformers which reduces the magnetizing current to a negligible value is achieved. With regard to voltage transformers, the authors justify putting the fuses inside the tank by saying that if a voltage transformer fuse blows it is necessary to remove the core and coils for overhaul, and accordingly there is actually no necessity for accessibility although it may be of considerable convenience upon occasions. I do not agree, however. I think that the voltage-transformer fuse is the most wonderful time-lag fuse ever invented. After 12 months' service it blows without any fault occurring on the potential transformer. Manufacturers can supply good, accurate transformers; the trouble is that, from the users' point of view, manufacturers usually do not. Take the case of meters. The British Standard Specification—and manufacturers have some hand in the drafting of these specifications—says that Class C current and potential transformers are for ordinary industrial purposes, and Class B is for metering equipments where close accuracy is required. Close accuracy is required on all ordinary metering equipments on which accounts are based. Meter manufacturers who also make instrument transformers will persist in supplying Class C current transformers with their meters. The authors tell us that we ought not to ask for transformers rated for a volt-ampere burden higher than that with which they are to work, but we do get a more accurate transformer if it is rated for a higher burden than is actually imposed.

Mr. T. W. Ross : There is one important point to which I should like to refer in connection with the use of current transformers in compound-filled armour-clad switchgear, and that is the desirability of such transformers being of the single-turn primary type. I have seen switchgear specifications in which 20/5-ampere current transformers with an output of 15 VA were specified. It will be obvious that to obtain such an output several primary turns would be required, and in order to accommodate these turns in the space available the cross-section of the conductor would be limited. The current transformer being covered with the compound and the normal rating of the circuit breaker being, say, 300 amperes—which rating is marked on the name plate —the current transformer would have to carry such currents if at any time the switch was loaded up to its rated capacity. This seems to me to be a real danger and should be kept in mind when considering the application of current transformers in compound-filled gear. It would surely be preferable to have a reduced accuracy from the current transformer and get a more robust equipment both from the point of view of short-circuit stress and thermal rating. Although in certain cases it is desirable and probably necessary to provide special current transformers such as those described by the authors (in order to obtain the accuracy required for watt-hour meters), I would suggest that in many cases it would be better practice to measure the energy on the low-tension side of the power transformers and so be in a position to make use of the larger currents available. It seems to me that we very often depart from the ideal, that is to employ extra-high tension for transmitting power between two points with the least possible complication, by including metering equipment when the metering could just as well be carried out on the low-tension side. The authors make a strong claim for what they consider to be the desirability of designing current transformers to suit any conditions in their application to protective apparatus. Whilst agreeing that this is one method of ensuring stability of balanced protection on " through " faults, I have always made a point of testing protective current transformers for balance before despatch from the factory. The test is made with primary currents up to 15 000 amperes, and I consider that it is justified, because it will most probably indicate any defect in the construction of the current transformers. The excellent results which have been obtained with protective gear after these tests are a practical proof of their usefulness, and because of the great importance of satisfactory protective gear it seems desirable that they should be carried out.

Mr. J. H. Buchanan: I am wholly in agreement with the claim as to the merits of transformers constructed according to the ideas put forward in the paper. I believe that, on the whole, the split core with a " figure 8 " winding will be found to be sufficient in itself for most practical purposes. It gives a remarkably flat characteristic both for ratio and phase-angle errors at any particular burden, and furthermore a transformer constructed on those lines, in contrast with many compensated transformers, is insensitive to variations in burden. It has also the merit of being insensitive to variations in the power factor on the secondary side. In some current transformers of conventional design the performance is very much affected by variations in power factor. While that is to some extent the case in these transformers with " figure 8 " windings, they are only affected in a very much slighter degree. I am glad the authors have drawn attention to the fact that instrument transformers have not in the past always received the attention they deserve, but in my opinion the users themselves are largely to blame for that. I know one case where six transformers—quite expensive ones—were delivered on site but the buyers were not ready to use them and they were, apparently, left out of doors for weeks, with the result they were rendered unusable. They were sent back to the makers for overhaul. They were put right and returned to site, when the same thing happened a second time. They had to be overhauled a second time before they could be put into service. With regard to short-circuit limitations, I think that enough distinction has not been made between primaries which have 2, 3 or 4 turns and what are admittedly weak windings having a very considerable number of turns. I consider that a good design can be made with 2 or 3 primary turns to be substantially as secure against short-circuit effects as most bar-primary designs, as regards both electrical and mechanical limitations. The advantages gained by doubling or trebling the ampere-turns, in the case of low ratios, are so great that I think that in the future more attention will be given than has been the practice in the past to 2- or 3-turn primaries designed specially to resist severe short-circuit conditions.

Mr. E. H. W. Banner (*communicated*): It is difficult for anyone not thoroughly conversant with modern facts and figures of all types of instrument transformers to appreciate fully the importance of the compensated transformer. I suggest that a summary in the form of a table or curves showing for stalloy, nickel-iron and compensated transformers the connection between costs, accuracy obtainable, ampere-turns, total weight and minimum range for a bar-primary, would be extremely valuable in order to enable engineers to realize the improvement in accuracy and how this varies with cost of each type, together with the other less important factors mentioned above.

Mr. S. Farrer (*communicated*): The amount of compensation required to correct for ratio and phase-angle errors, due to the main core of a current transformer, will be roughly inversely proportional to the size of that core. Thus the size of the auxiliary core must be greater, the less is the size of the main core. A definite optimum relationship between the sizes of the two cores might, therefore, be expected for a current transformer of any rating, from the point of view of accuracy for either given total space or given total cost. I should be very interested to know whether the authors have found any definite ratios to exist between the lengths of the two cores and whether it has ever been necessary in practice to use stampings for the auxiliary core of different size from those for the main core. In the design of a current transformer for minimum phase-angle error, it seems evident that some definite portion of the B–H curve for the material of the core would have to be chosen, i.e. that by working on some portion of the B–H curve optimum correction for all loads would be obtained; similarly some portion of the curve would be best adapted for use in obtaining a minimum range of ratio errors. It is unlikely that these two portions of the curve could be arranged to coincide and therefore, in obtaining maximum correction for one error, a suitable range of values of B would be chosen and this would greatly limit the possible compensation for the other error by means of a winding on the same auxiliary core. It seems probable, then, that in order to obtain, in a current transformer, precision accuracy from the points of view of phase angle and ratio, the use of two auxiliary cores would be indicated. I should be glad to know whether the authors have found it necessary in practice to employ separate cores for ratio and phase-angle correction. On page 710 a scheme of cross-magnetization of a divided main core for a current transformer is described. As the two equal portions of the core are magnetized in opposite senses by a winding energized by the auxiliary core, it is stated that there would be no resultant effect on the secondary winding; it seems to me that this would only be the case if the main core were being worked on a perfectly straight portion of the *B–H* curve. I should be very grateful if the authors would explain in a little more detail their scheme of cross-magnetization.

Mr. S. R. Mellonie (*communicated*): Dealing with current transformers for the operation of overload coils on page 705, the authors imply that the performance above 50 per cent overload is not important, but B.S.S. No. 116 requires a setting at 300 per cent of load. The limit of 40 times the secondary current quoted on page 707 shows how such values may vary, and is of great importance when considering protective devices. This should be compared with a figure of 14 times which was given in the *Journal* (1927, vol. 65, p. 583). Dealing with potential transformers, the authors rightly emphasize the danger of failure which exists owing to the use of very fine wires for the high-tension windings. These wires are difficult to insulate and are mechanically weak and therefore susceptible to corrosion. It is suggested that a minimum value of 0·01 in. diameter is a practical compromise. Troubles due to coronæ on fuse wires have been eliminated by coating the wire with insulating material. I have designed and tested a fuse fitted with electrostatic shields, but this gave trouble due to flashing over when the fuse blew. A very compact and sound job is made by enclosing the transformer limiting resistance and fuse in the same oil tank. The authors recommend that potential-transformer fuses should be coupled on the line side of the limiting resistance, but I should like to know their reasons for this. From theoretical considerations the resistance should be coupled to the busbar or heavy-current circuit. In this way the entire length of conductor associated with the potential transformer circuit is protected. In fact, the resistance should be regarded as protecting the fuse, and not vice versa.

Mr. A. M. Strickland (*communicated*): For some time past there has been a demand for improved performance of current transformers for use with metering equipments, and the paper gives an excellent exposition of one method of making such improvement. It would perhaps at first sight appear that their design, which entails some complication, is not now warranted owing to the more recent introduction of low-loss irons which appear to give very good results. However it is evident that, with a combination of the two, in the future the production of reasonably accurate bar-type current transformers for primary currents as low as possibly 20 amperes will not be out of the question. It is suggested that the authors have omitted one argument in favour of the simple ring current transformer, that is its convenience for use on ordinary power consumers' metering in sizes up to 50–500 primary amperes. They have great advantages for this work as they require little mounting and can be easily changed at any time with the minimum of interruption to service, inconvenience and cost. At the same time, with improved characteristics metering accuracy at low loads and low power factors should be improved. Another use to which current transformers of the authors' design have been put is in connection with meter-testing equipments. Here high accuracy is essential. The transformers are used with multi-turn primary winding ranges and with a polyphase wattmeter on the secondaries, and as the phase-angle error is practically nil the resultant simplification in routine testing is a matter to be considered. It would be of interest to know whether, in view of their statement that it is doubtful whether the new low-loss irons are stable in service, the authors anticipate any trouble with the auxiliary core iron which, they state, is run at fairly high flux density. The suggested methods of obtaining partial turn adjustments are exceedingly interesting; in view of this is it necessary to advocate 1-ampere secondary metering when it is borne in mind that the usual VA load for induction-meter series coils is about 2 VA at the most, and it is not considered good practice to load metering current transformers with other apparatus than the above. As rapid improvements are evident in current transformers it would appear questionable whether, apart from special cases, in the near future the wound primary transformer will not be used. Do the authors consider their type of transformer to be less liable to damage by accidental open-circuiting of secondaries?

THE AUTHORS' REPLY TO THE DISCUSSIONS.

Messrs. J. G. Wellings and **C. G. Mayo** (*in reply*): In replying to the many points raised by the various speakers, we should like to express our appreciation of the way in which the paper has been received, and the interest taken in the various views expressed in it.

Meter and Instrument Section.

Mr. Ockenden mentions true figure of merit, and we take it that by this he means not only performance under rated burden but also performance with any burden up to rated burden. In this connection we have added an Appendix giving test results at burdens of 5, 15 and 40 VA on a 40-VA transformer in which precision accuracy is maintained throughout. Nevertheless, it should be pointed out that still higher accuracies may be obtained with the transformer if designed to give its best performance at a stated burden. Again we would emphasize that the conventional type of current transformer can only give its highest accuracy at zero burden, which condition is not realized in practice.

The similarity which Mr. Ockenden draws to the use of a condenser in shunt is not strictly true, as the compensating effect produced in such a way does not lend itself to varying values of primary current and secondary burden as regards power factor. The way in which Mr. Ockenden describes his theory of the compensated current transformer is not, in our opinion, so clear as the way described in the paper, and is also subject to correction as described above.

Mr. Ockenden states that it is difficult to follow our explanation of the source of the separate excitation provided by the auxiliary core, and that it is impossible to introduce into the primary any current other than that which is in the bar. We would point out that it is possible to obtain any amount of additional exciting ampere-turns once the provision of separate cores is visualized. In this connection the question of flatness may conveniently be raised. Flatness is, of course, a relative term, and any degree of flatness can be secured by using sufficient ampere-turns and/or using mumetal, but to secure adequate flatness it will be found that the absolute errors must be so reduced that the transformer is unnecessarily bulky and costly. In other words, the change of error becomes the limiting feature. With compensated current transformers using stalloy the permeability is not increased to the same maximum as mumetal, but is increased to a large value which remains substantially constant at varying primary currents, a feature which, in our opinion, is superior to an extremely high permeability at one value of primary current, coupled with much lower values of permeability at other values of primary current. Furthermore, it should not be overlooked that our type of compensating windings are not restricted to silicon-steel cores, but are equally applicable and effective where used with cores of such materials as mumetal, i.e. the use of compensating windings is such as to improve the permeability and maintain it substantially constant over a wide range of primary currents.

As regards the operation of current transformers in parallel for summation metering equipments, undoubtedly the compensated current transformer has a lower shunt impedance than a transformer with equivalent accuracy, obtained either by the use of liberal ampere-turns or by the use of nickel-alloy cores. It has been our experience, however, in the majority of such metering equipments that the length of the pilot leads from all the various circuits which have to be metered brings up the total impedance very considerably, so that the mutual impedance is comparatively small, and as a matter of fact the figures given by Mr. Gibbons in his contribution to the discussion refer to an equipment of this nature. On the other hand, this same feature of the comparatively lower transformer impedance compared with the more conventional type is advantageous in giving a reduced value of open-circuit voltage should the secondary windings be disconnected.

As regards Mr. Ockenden's remarks on the fractional-turn arrangement, he appears to be under the misapprehension that a circulating current flows round the transformer windings. Actually the effect of the use of two cores in parallel may be regarded as equivalent to that obtained by using two independent current transformers, the one for 2·5 amperes, and the other to give, say, 2·525 amperes, so that the total current is 5·025, and hence giving a closer degree of correction than would otherwise be possible if there were only one core. Our preferred method, however, is the use of one or more turns linking only a portion of the total core section, and this, as described in the paper, has the added advantage of improving the permeability of the core material, and is both convenient and effective. We appreciate the interest shown by Mr. Ockenden in our paper, and for bringing to light other aspects of the matter which may not have been sufficiently described in the paper.

Dr. Drysdale appreciates the advantages of our methods of compensation, particularly that they can be applied to cores of nickel alloys as well as those of silicon steel. This is a point which it is certainly desirable to emphasize. By these means we have been able to produce bar-primary transformers with a rated current as low as 50 amperes without the cores being of other than usual proportions, and with an accuracy practically equal to that obtainable with class "A" (B.S.S. 81—1927). Dr. Drysdale mentions the same point as Mr. Ockenden, viz. that the accuracy will be changed if the burden is changed. While this is definitely so, and applies to transformers of all types, we would again stress the point made in our paper that with a compensated design the minimum errors can be made to occur at rated burden instead of only at zero burden, and, therefore, under operating conditions a higher degree of accuracy is obtainable.

Mr. Fawssett begins his remarks by advocating the use of mumetal. Towards the end of his remarks, however, he refers to the high cost of obtaining the accuracies at present being specified, and we would here point out that the compensated transformer is capable of giving those high degrees of accuracy without the use of a highly expensive metal such as mumetal, although, as mentioned in our reply to Dr. Drysdale, in extreme cases we recommend a combination of both mumetal and compensated windings. Mr. Fawssett again refers to the question of change in burden, and we would refer him to replies made to other speakers on this matter. In our experience with many switchgear developments, there is very little difficulty in forecasting approximately the burden which will occur in service, and it is our understanding that when meters are calibrated with their current transformers it is invariably metering practice to request definite information of the total impedance in the secondary circuit, and to test only under those prescribed conditions. As regards the use of testing windings, we have made exhaustive tests proving that, provided a ring core is used and the secondary winding is evenly distributed over it, the performance obtained when the testing winding is used is exactly the same as when the main primary is used. Col. Edgcumbe's remarks confirm this result.

Mr. Spilsbury's queries with regard to the variation of errors with burden are dealt with in our reply to Dr. Drysdale and in the Appendix now attached to the paper. Compensated current transformers have been built to give precision accuracy at any frequency from 25 to 100 cycles. As regards wave-form, this is a matter which has had our attention, and variations due to wave-form can be rendered negligible by proper design. The flatness of characteristic curves was dealt with in our reply to Mr. Ockenden.

Mr. Marshall's suggestion that, in order to overcome the weakness of all known types of current transformers at extremely light loads, excitation should be derived from a separate source of potential, is extremely interesting, and by this means it would be possible to make the effective permeability almost constant at all values of primary current, and this permeability would be very high. There is, however, a weakness as follows:—Suppose the flux density to be maintained by separate potential at a point corresponding to the point of inflexion of the magnetization curve for the material. If then the superposed working flux were out of phase with this flux and relatively small the effective permeability would be that corresponding to the working point. If, however, the superposed working flux were in phase with the original flux the effective permeability would be that corresponding to the slope of the inflexional tangent to the magnetization curve, and many times greater than in the above case. Thus, although the errors would be practically independent of the magnitude of the primary current they would be affected by the phase of the primary current. They would, however, be considerably less than those in a plain transformer at light loads. We do not agree that in practice the secondary is just as liable to failure as the primary, and, moreover, a failure on the primary winding has far greater consequential effect than a failure in the secondary winding of a current transformer.

We do not agree with Mr. Burgess that balancing of transformers is the only way to achieve stability in balanced protective gear. We do not even believe that it is a satisfactory way. In protective-gear transformers the critical point for accuracy is at primary currents of the order 10 to 20 times rated primary, and what is required is high permeability not so much at low flux densities as at moderately high flux densities. Compensated current transformers would, therefore, not be used for protective gear, although the same methods may be used to secure improved sensitivity without sacrifice of stability. With regard to the rolled strip core, the characteristics obtained with such cores are substantially the same, bulk for bulk, as those obtained from cores of stamped rings over the range of flux density usually employed in current-transformer design. With regard to the weight of cores for compensated current transformers compared with the conventional multi-turn types, in general the size of core is greater, but the overall dimensions of the transformer are in general less, particularly when allowance is made for clearances around the primary windings and its terminals. As regards the question of lower rated secondary currents than the usual standard of 5 amperes, it is our opinion that 1 ampere is exceedingly desirable as an alternative rating, and in some cases 0·5 ampere as well, according to pilot burden and the characteristics of the transformers concerned.

In reply to Col. Edgcumbe, an Appendix has been added giving further results on compensated current transformers of various ratios. We are interested in the remarks of Col. Edgcumbe and those of other speakers as regards the stability of mumetal and, as described in the paper and emphasized in our reply to another speaker, there is a very definite application in the use of mumetal in extremely low ratios, combined with compensating windings to reduce the quantity of material required and also to improve the performance obtained from it.

Mr. Lipman deals with the 0·5-ampere secondary winding of a current transformer. It is true that the increased number of secondary turns provides extremely fine adjustment in turn correction, but in our opinion sufficiently fine adjustment is obtained with 1-ampere secondary current, which avoids other difficulties such as high open-circuit voltage, low space factor of windings, etc.

We are indebted to Mr. Gibbons for the performance figures he gives in regard to a metering equipment employing compensated current transformers tested by him. With reference to his statement as regards certain advantages of earth protection as against circulating current, it must not be overlooked that circulating-current conditions may apply to the transformers used in certain forms of core-balance protection. We appreciate Mr. Gibbons's comments on the question of accessibility of fuses. These would appear to justify ready accessibility being provided in all cases.

Mr. Quenzer queries the necessity of testing windings, and considers it satisfactory to connect the testing leads to the secondary terminals of the current transformer. This, however, does not check the transformation performance of the current transformer. Other points raised by Mr. Quenzer are dealt with in our replies to other speakers.

We are fairly in agreement with Mr. Hill on the question of statement of current-transformer errors, and would go even further and advocate the statement of phase-angle error in radians.

The points raised by Mr. Minton have been dealt with in our replies to Mr. Fawssett and Mr. Hill.

We are glad to have the support of Mr. Trencham in advocating the proper correlation of switchgear and metering requirements. Mr. Trencham also emphasizes the need for current transformers to be as reliable as the bus connections, a point which is not necessarily taken care of in the ordinary use of multi-turn current transformers.

Manchester Discussion.

Mr. Randle surmises that the ratio-error correction was rendered necessary by the fact that phase-angle correction increases the ratio error. This is to some extent true, but it must be noted that this vitiation of ratio error is not large enough to make ratio error the limiting feature, were it not for the fact that the phase-angle error is so greatly improved. In other words, the reduction of the phase angle by our method of compensation so improves the accuracy of the transformer in this respect that ratio error becomes the limiting feature, and accordingly it appeared desirable to find some means by which ratio error could be similarly compensated so that this feature became in keeping with the reduced phase-angle error. The ratio-error correction neither necessarily nor generally causes an increase of phase angle, and it may even be arranged to reduce phase-angle error. This is because ratio-error correction is due roughly to the rotation of a vector already approximately normal to the secondary vector, i.e. phase-angle change due to ratio correction is, therefore, usually of the second order. With inductive burdens the exciting current vector is no longer approximately at right angles to the secondary vector, and in this case ratio-error correction tends to prevent the usual increase of ratio error with reduction of phase-angle error. Col. Edgcumbe has pointed out in his contribution that reduction of secondary current does not *per se* reduce the burden. It should be borne in mind that to operate any given instrument or relay the power required mechanically is independent of the current rating of its operating coil. The flux density in the auxiliary core is high only from the usual current-transformer point of view, and does not necessitate consideration of core heating.

Mr. Holmes states that he cannot see any difference in principle between our compensated transformer and the Brooks two-stage transformer. We would point out that there is a fundamental difference, both in principle and in application. The Brooks transformer, it is true, has a main core and an auxiliary core, but beyond this all similarity ceases. The Brooks transformer operates on the principle of supplying the " error current " electrically to the instrument being operated by providing the instrument with an additional winding energized from the auxiliary core, which in turn operates on the difference of the input and the output ampere-turns of the main core. Our type of compensated transformer has the " error current " supplied, in effect, magnetically to the main core by specific design of the auxiliary core, and accordingly the output of the transformer, so far as the meter is concerned, is inherently compensated, and the meter only requires the one usual winding. That is to say, our compensated transformer can be regarded as an ordinary plain transformer requiring an ordinary plain meter; and even to a non-technical man there is no difficulty in distinguishing between this and a current transformer requiring double pilots and double-element meters. With regard to the comparison of our transformer with the Wilson transformer as produced in the United States, it is more difficult to draw any fundamental difference as regards the methods of ratio and phase-angle compensation compared with our compensated transformer. However, we would point out that this transformer was developed in the United States subsequently to our work in England, the first compensated transformers of our design being supplied as far back as 1923. As regards comparison of our transformer with the transformers with mumetal cores, this point has already been referred to in our reply to other speakers. As regards the query as to whether the compensation shown in Fig. 10 is for laboratory use, we would point out that our designs of compensated transformers are primarily intended for use on commercial metering circuits where extremely high accuracy is required, such as is specified for the Central Electricity Board, etc. The form of compensation shown in Fig. 10 is used for special purposes, sometimes by itself and at other times in conjunction with the methods shown in Fig. 8, according to conditions. So far we have not attempted to produce transformers for laboratory use, but have concentrated on producing transformers to meet certain specific high grades of accuracy with the transformers as small as possible physically and with the bar-type primary down to the very minimum primary current. Large numbers of transformers have been supplied and have been operating in service under these conditions for many years where the use of the bar primary instead of the multi-turn, which would otherwise be required, has enabled the lay-out of the switchgear and likewise its reliability to be improved to a greater extent. With regard to the short-circuit factor of 150 based on thermal effects, this of course involves a time factor, and the duration of the short-circuit is assumed to be the average time which a circuit breaker takes to clear, namely, about 0·25 sec. This assumption for the duration of the short-circuit period, and also other assumptions as the average symmetrical effect, were intended to be covered by the statement of " average conditions " of short-circuit as quoted in the paper. Since the publication of the paper we have been most interested to see expressions of short-circuit capacity in technical papers published in France and America, which agree very closely with the short-circuit limitations as determined by us.

Mr. Turner's idea that phase-angle and ratio compensation cannot be used together is entirely erroneous and this point is dealt with more fully in the reply to Mr. Randle. The fact that the correcting current tends to remain substantially constant over a part of the range is a decided advantage, and intentionally so, and means that the correcting current is a greater percentage of the primary at lower values of primary current, and this is precisely what is required. As stated in the paper, the use of the crossed-winding method of Fig. 10 increases the effective permeability from 3 to 4 times, depending on the burden and primary current, the improvement being greater with smaller burdens and values of primary current. Very approximately, with a transformer of this type, halving the burden halves the phase-angle error. The previously described methods are very simply and effectively superposed on this to give even better results. An Appendix giving further test-results has been added to the paper.

We cannot agree with Mr. Sheppard that the advantages of bar-primary transformers may be over-stressed. From the experience from which we have had with large station switchgear we are convinced that the requirement for current transformers to be of the bar-primary type is of an importance practically overruling every other consideration. It should be borne in mind that every piece of apparatus in a large system has some form of protection, and the current transformers themselves have to be assumed beyond reproach, and accordingly anything in the form of a coil for the primary winding should be avoided wherever possible. As regards the point as to permanence and performance after years of service with frequent heavy short-circuit duty, we would point out that we have had this type of compensated transformer in service now for many years, and there has been no indication as to any change in performance nor would any such change be expected as the density, although high from an ordinary current transformer point of view, is not high intrinsically. As regards the arrangement shown on Fig. 10 and queried by Mr. Sheppard, we would refer Mr. Sheppard to the paragraph at the top of page 710. We can only amplify this by stating that the alternation of flux density as required by the secondary burden is so small compared with the alternation of the flux produced by the figure-of-eight winding that the permeability is very approximately a differential permeability. Roughly speaking, transformers compensated solely by the method shown in Fig. 10 may have their errors reduced to approximately one-quarter of what they would otherwise be for the same size of core operating uncompensated. Furthermore, the arrangement of

Fig. 10 is extremely effective in producing the flat characteristic, as mentioned by another speaker who is familiar with this type of transformer. We would refer Mr. Sheppard to the Appendix, now added to the paper, which gives typical performance of compensated current transformers under varying conditions of burden and ratio, etc. As regards Mr. Sheppard's statement that certain schemes of compensation are only palliatives and that the error is still inherent in the transformer, we would refer him to our reply to Mr. Ockenden in the discussion before the Institution.

We are glad to note that Mr. Brown is so fully in agreement with us on the general views expressed in the paper and particularly with regard to balanced protective gear, where we note that Mr. Brown's practice and views have for some time been those put forward in the paper.

We thank Mr. Howarth for his favourable comments on the 3 000/5 transformer which he has tested. The question of secondary impedance has been dealt with in the reply to Mr. Ockenden. The magnetizing current of protective transformers is reduced mainly (*a*) by generous iron section of the cores, and (*b*) by reduction of pilot burden by such methods as magnetic balance or using smaller rated secondary currents. On the question of potential-transformer fuses, it would appear that there is good reason for accessibility of fuses. As regards the blowing of fuses, our experience has been that, since the provision of electrostatic shields, corona on the fuse wire is avoided, so that on higher-voltage designs failures after about 12 months' service have practically been eliminated. We agree with Mr. Howarth's inference that the present British Standard Specification for Instrument Transformers is not in accordance with present-day practice, and we hope that shortly a revision will be made, when the users will no doubt have ample opportunity for specifying their requirements. In this respect we feel that the users should more definitely state their requirements. That is to say, if they require a certain grade of accuracy, that accuracy should be mentioned to the maker instead of ordering a transformer of a higher volt-ampere burden at a lower accuracy and trusting that such a transformer on a lower burden will give the higher accuracy which the user really has in mind.

We are glad to note Mr. Ross's general agreement on the question of the short-circuit capacity. Particularly do we feel that more use should be made of the installation of transformers on the low-tension side of power transformers so as to avoid the complications and comparative weakness of the high-tension transformers, unless these latter windings can, by means of compensating windings, be made to give the required accuracy with the single-turn primary construction.

Mr. Buchanan mentions that the construction shown in Fig. 10 may be found sufficient in itself for most practical purposes. We have perhaps hardly emphasized sufficiently in the paper the remarkably flat characteristic which transformers compensated in this way give in spite of variations in burden. As mentioned in the paper, however, still higher grades of accuracy can be obtained by the combination of the arrangements shown in Figs. 10 and 8. We are in agreement with Mr. Buchanan that there should be a distinction between transformers having 2, 3 or 4 turns and those having a very considerable number of primary turns. Nevertheless, a transformer even with only 2 turns is in a fundamentally different category from those which have only a straight-through primary. It must be borne in mind that the circuit frequency has only to be high enough on even a 2-turn primary to build up sufficient voltage to break down the insulation between those two turns. Provided, however, that such 2- or 3-turn primary transformers are given liberal insulation between turns, they have an exceedingly useful field of application, and we are all in favour of their use.

In reply to Mr. Banner, an Appendix showing the performance of compensated transformers with varying burdens and ampere-turns has now been added to the paper.

As Mr. Farrer suggests, there is an optimum relation between the sizes of the main and auxiliary cores, and this has been determined in a large number of cases by calculation. It has not so far been necessary to use different sizes of stampings for main and auxiliary core. So far, the need of separate cores for ratio and phase-angle compensation has not arisen, and transformers in practice are constructed in which the same auxiliary core serves: (*a*) for compensation in accordance with Fig. 10, (*b*) for phase-angle correction in accordance with Fig. 6, and (*c*) for ratio correction in accordance with Fig. 8. It should be noted that the magnetizing forces on the two halves of the main core are equal and, therefore, in the absence of magnetizing ampere-turns due to the effect of the burden on the transformer the flux densities on the two half-cores, and therefore the induced e.m.f.'s, must be equal and opposite and therefore there is no resultant e.m.f. in the secondary. This would be the case were the transformer short-circuited at its terminals and without secondary resistance. As soon as resistance is introduced in the secondary circuit the secondary ampere-turns differ from the primary ampere-turns, this difference increasing the flux density numerically on one-half core and decreasing it on the other half, the two fluxes now no longer cancelling but combining to give the required secondary e.m.f. at, however, a much reduced cost of magnetizing current or difference between secondary ampere-turns and primary ampere-turns, owing to the permeability being, in effect, differential.

We thank Mr. Mellonie for drawing our attention to an apparent error in the statement of overload capacity of metering current transformers. Our statement should have read that metering accuracy should be maintained up to, say, 25 per cent overload but that the transformers should still maintain sufficient accuracy for relay operation up to 300 per cent load. We are interested to note that Mr. Mellonie has designed and tested fuses fitted with electrostatic shields, but that his arrangement gave trouble due to flashing-over when the fuse blew. In our combined arrangement of fuse and resistor development, in which the resistor acts as an electrostatic shield to the fuse, particular care has been given to prevent arc-over when the fuse blows. We have a large number of these combined fuses and resistors operating under service conditions, but so far every satisfaction has been obtained and there has been no cases of arcing-over when the fuse blows. As to whether the fuse should be on the line side of the resistor or vice versa, it is our experience that there are advantages and disadvantages either way. A decision as to which is the better method must in our opinion, be based on the particular arrangement of the connections involved. We have known of one case where with the resistor mounted in front of the fuse of one of the supporting insulators of the resistor failed and the fuse was of course unable to clear the fault. With the fuse installed in front of the resistor the fuse could have cleared the fault.

We are glad to note that Mr. Strickland appreciates the possibilities of using nickel-iron alloy in conjunction with the methods of compensation described in the paper. The question of the flux density of the auxiliary core has been dealt with in the replies to the other speakers. We thank Mr. Strickland for drawing our attention to the possibilities in connection with meter-testing equipment. As regards the effect of accidental open-circuiting of the secondary of a compensated transformer, we would state that the presence of the compensating windings reduces the value of the open-circuit voltage which would otherwise occur.

AN INVESTIGATION OF EARTHING RESISTANCES.*

By P. J. Higgs, B.Sc.

[From the National Physical Laboratory.]

(*Paper first received 16th August, 1929, and in final form 20th February, 1930.*)

SUMMARY.

The phenomena of polarization and endosmose which accompany the flow of direct current in soil were investigated in various laboratory experiments. Polarization was an effect of gas bubbles on the measured soil resistance—bubbles which formed owing to a small electrolytic decomposition of the soil moisture by the current and which accumulated at the electrodes. Endosmose was extensive and occurred even against an appreciable hydraulic back-pressure. The earthing resistances of electrodes of inextensive area depend directly on the resistivity of the surrounding soil, and so relations were obtained showing the effect of moisture, temperature and salt on soil resistivity. The resistivities of coal, coke, ashes, chalk and dried soil were also obtained.

Various types of electrodes of inextensive area, viz. pipes, plates and strips, were installed in a plot of ground and tested over a period covering one year. The results are important as being typical of what may be obtained in practice, but not as criteria of comparative utility of the various electrode types on account of the soil resistivity being—there were reasons to presume—appreciably non-uniform. The earthing resistances of the various electrode types were, however, calculated theoretically, a soil of uniform resistivity being assumed, and the results obtained may be used as criteria. The seasonal variations in resistance were determined during the year, and the effect of moisture in this respect was greater than that of temperature.

Some electrodes of extensive area, viz. water pipes, the lead sheath of a large size cable and the steel structures of buildings, that were in the vicinity of the other electrodes, were also tested. Their earthing resistances were much smaller than those of the other types, and the smallest resistance was that of a water pipe. The possible differences between alternating-current and direct-current measurements made on electrodes in the field were investigated. The greatest difference obtained was an increase in resistance of about 20 per cent with direct current and with the positive electrode one of inextensive area.

The various types of electrodes of inextensive area are considered theoretically in an Appendix.

Appendix. A theoretical consideration of the earthing resistances of various electrodes of inextensive area.

SECTION (1). AN INVESTIGATION OF SOIL RESISTIVITY UNDER DIRECT-CURRENT AND LOW-FREQUENCY ALTERNATING-CURRENT CONDITIONS.

Earthing in electrical practice is carried out to mitigate primarily the dangers of shock to persons and of leakage currents with regard to starting fires. To make them effective, earthing resistances are generally made as small as possible. An earth connection may be made either for alternating or direct current, and its resistance may not be the same with each on account of the effects of polarization and endosmose with direct current. These effects were investigated in some preliminary experiments.

(A) DIRECT-CURRENT POLARIZATION OF SOIL.

A sample of sandy loam taken from the ground and containing about 15 per cent by weight of moisture was placed between copper disc electrodes in a glass tube 10·5 cm in diameter and 15 cm long, in order to investigate the direct-current polarization of soil. The arrangement of the apparatus is shown in Fig. 1. It includes various switches by means of which resistance measurements were made as required, either with alternating current or with direct current flowing in either direction. The electrodes were lightly pressed against the soil in order to ensure good contact. Each kind of measurement was made with 140 volts and the soil resistance was taken to be the ratio of the voltage to the current.

Polarization was investigated by making various switch operations in a considered sequence and observing the resultant changes in soil resistance. To investigate the effect of the nature of the electrode contacts on polarization, tests were also made with tinfoil placed between the copper discs and the soil, and with the tinfoil replaced by carbon powder.

---

* The Papers Committee invite written communications, with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The results of the tests and notes bearing mainly on the effects of polarization are given below.

(i) The primary effect of polarization was a decrease of direct current with time at constant voltage. The rate of the increase of apparent resistance was greatest initially and decreased gradually to zero, and the magnitude of the total change was in some cases such that the final value was about three times the initial. The actual range of resistance measured in this way was from about 2 000 ohms to 6 000 ohms. The measurements were somewhat inconsistent, as shown by repeat tests, under apparently similar conditions, giving sometimes appreciably different results. A possible explanation of the inconsistency is given below.

The soil being visible in the glass containing-vessel, it was noted that an effect of the flow of direct current was a slow electrolytic decomposition of the contained moisture, for gas bubbles were continually forming. As the gas bubbles formed they accumulated in the interstices at the electrode contacts and the direct current decreased in value. When the interstices, which were small in volume, were filled with gas the current was more or less steady, on account of the production of gas being balanced by its escape.

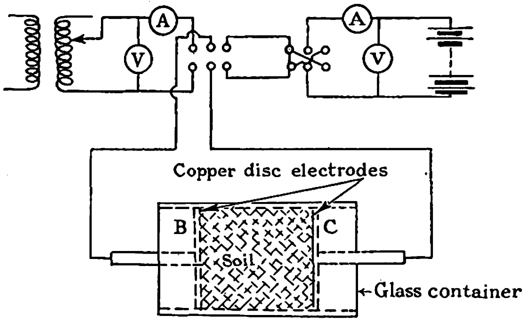

FIG. 1.—Soil resistivity tests. Direct-current polarization in soil.

The increase of soil resistance to a final steady value with the flow of direct current appeared, therefore, to be primarily owing to the accumulation of gases at the electrodes. On the current ceasing to flow, the soil resistance would slowly decrease to its former initial value as the gases became gradually dissipated, and this feature was observed in the tests.

(ii) The resistance of the soil was slightly greater with an initial direct current than with alternating current. The difference was probably due to a small back electromotive force of electrolysis with direct current as in the electrolysis of water.

(iii) The increase in the resistance of the soil owing to the polarization effect of direct current of one direction of flow was apparent in measurements made with alternating current or with direct current flowing in the reverse direction. This feature is in accordance with the supposition that the increase in resistance, or polarization effect, is mainly a pure resistance due to the accumulation of gas at the electrode contacts.

(iv) With tinfoil between the copper discs and the soil, the resistance of the soil with alternating current or with an initial direct current was about 80 per cent of its respective value measured with the plain copper electrodes. The decrease in resistance was presumably owing to improved electrode contact, but the increase in resistance on account of polarization was proportionately about the same as before.

(v) With carbon powder instead of tinfoil between the copper discs and the soil, the initial resistance of the soil was further slightly decreased, presumably owing to still better electrode contact. The increase in resistance owing to polarization was, however, comparatively small, possibly on account of the fine carbon particles preventing the accumulation of gas either by absorption or by themselves simply occupying the interstices.

(B) EXPERIMENTS IN ELECTRICAL ENDOSMOSE.

When the direct current flowed continuously for several minutes in the tests described previously, it was noted that the soil near the positive electrode was getting wetter and that near the negative electrode drier. The effect, which was one of movement of moisture in the direction of the current-flow, was investigated by the experiments described below.

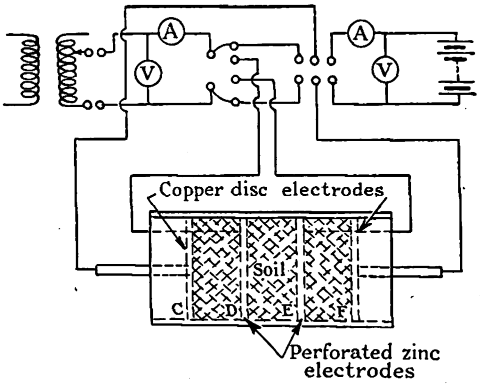

FIG. 2.—First electrical endosmose experiment.

First Electrical Endosmose Experiment.—A sample of sandy loam, containing about 12 per cent by weight of moisture, was placed in a glass tube with four metal disc electrodes, as shown in Fig. 2. The outer electrodes C and F were made of copper and the inner, D and E, of commercial perforated zinc. The soil was divided by the electrodes into three approximately equal parts. The electrical connections to D and E were rubber-insulated conductors, and to C and F brass rods. The outer electrodes were lightly pressed against the soil when the measurements were made, in order to ensure good contact.

Endosmose was produced in the soil by means of a small direct current which flowed continuously during the experiment, except for periodic short intervals of time when measurements were made with alternating current to ascertain the effect of endosmose on the various sections, and on the whole of the soil.

The results obtained are given by curves in Figs. 3 and 4. Fig. 3 shows the relations between voltage-drop and time for the individual sections. The voltage-drop across a particular section would increase or decrease with decrease or increase of moisture, and the curves may be taken to indicate approximately the movement of moisture among the sections during the experiment. There was no net loss of moisture, except possibly a little owing to electrolysis.

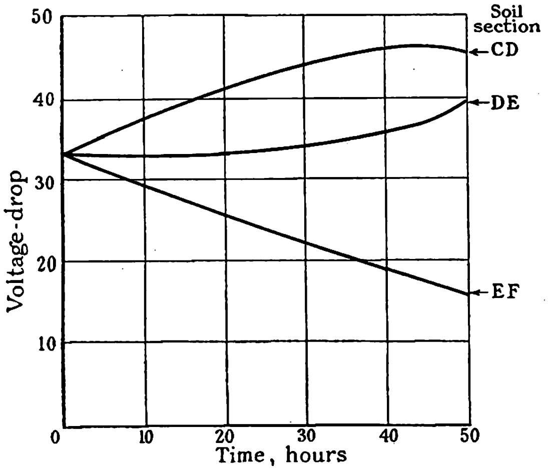

FIG. 3.—Variation of voltage-drop across the individual soil sections with time (see Fig. 2).

Fig. 4 shows the relation between the resistance of the whole of the soil and time, and it indicates that the endosmose increased the resistance considerably. After the experiment the mean moisture content of each section was determined: that of section CD, next to the negative electrode, was 7·1 per cent, that of the middle section DE 9·8 per cent, and that of section EF, next to the positive electrode, 16·5 per cent, the percentages being by weight of soil.

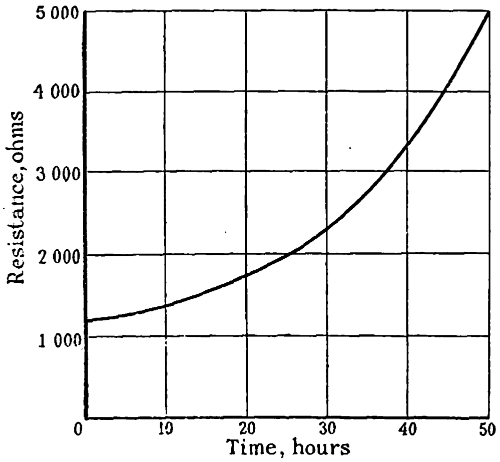

FIG. 4.—Variation of resistance of whole soil with time (see Fig. 2).

Second Electrical Endosmose Experiment.—The arrangement of the apparatus used in the second electrical endosmose experiment is shown in Fig. 5. It consists of sandy loam between two electrodes in a glass funnel, the electrodes being connected in a direct-current circuit. The top electrode was a brass piece that fitted in the neck of the funnel, as shown. It was soldered to the end of a brass rod which passed with appreciable clearance through the funnel tube portion or small end. The bottom electrode was a tin cover that fitted the big end.

A preliminary test was made with the arrangement of Fig. 5(*a*). A direct-current voltage of 200 was applied across the electrodes, the bottom one being positive, and a current of about 0·1 ampere flowed. The moisture of the soil accumulated slowly around the top electrode and rose in the tube portion to a height of about 3 in. It was, therefore, considered interesting to investigate the height to which the water would rise if the soil were supplied with an unlimited amount. For this purpose the arrangement of Fig. 5(*b*) was used. The funnel was placed in a flat dish containing water and its small end was extended upwards with glass tubing and rubber connecting-pieces. A lead weight was placed on the funnel to counteract the lifting effect of water in the tubing.

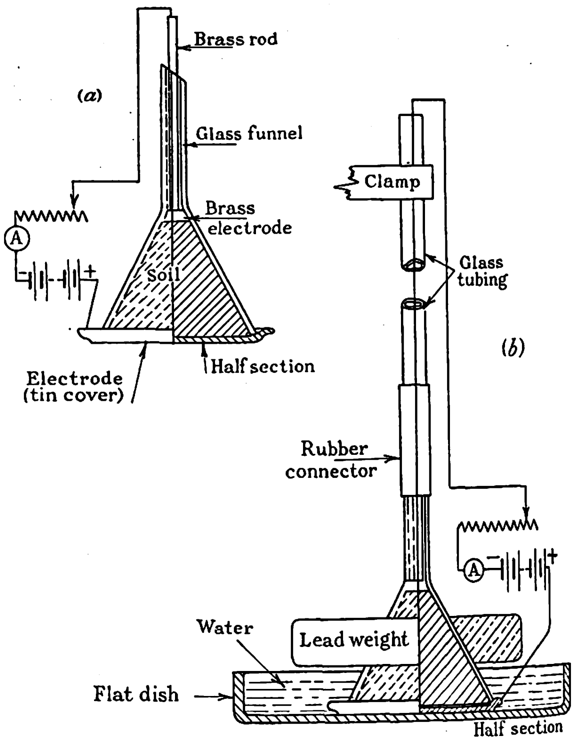

FIG. 5.—Second electrical endosmose experiment.

On applying the voltage of 200, about 0·1 ampere flowed and water rose slowly in the tubing. The results of the experiment are given in Fig. 6 in the form of curves showing relations between head of water and time, and between current and time. The curves indicate that the current decreased, or, in other words, that the soil resistance increased as the head of water increased. Because there were no changes in the soil, either of temperature or of moisture content, it seemed that the increase in soil resistance was due to the head of water, or that the hydraulic back-pressure, which would increase the resistance to the movement of the moisture of endosmose through the soil, had also increased the electrical resistance. The phenomenon was one of a mechanical back-pressure affecting electrical resistance in the same way as an electrical back-voltage.

The conditions were apparently steady after 15 hours with the head of water about 9 ft. and the current about 36 per cent of its initial value. This head of water gives at its base a pressure of 3·9 lb. per sq. in., which indicates that endosmose occurs even against considerable hydraulic back-pressure. Subsequently it was noted that the water would rise higher than 9 ft. without change of conditions except that the counterweight on the funnel was increased. When the applied voltage was removed the water descended slowly in the tube. While the current flowed some electrolytic decomposition of the moisture in the soil occurred, for gas bubbles were continually forming and escaping at the rate of a few a minute through the head of water.

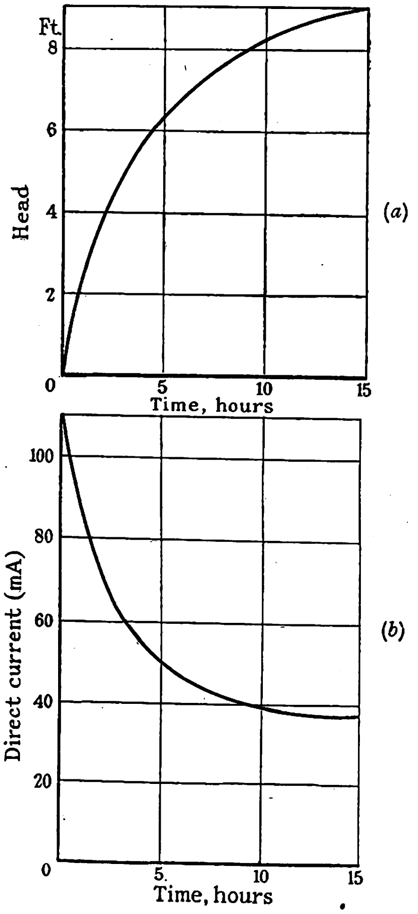

FIG. 6.—Variation of (*a*) head of water, and (*b*) current, with time (see Fig. 5*b*).

(C) RESISTIVITY AND MOISTURE CONTENT.

The relation between resistivity and moisture content was determined for two kinds of soil which are prevalent in the vicinity of the National Physical Laboratory. One kind is top soil having a greyish black colour like garden loam and occurring to a depth of about 2 ft., and the other is bottom soil having a sandy yellow colour. The former is referred to as "top soil" and the latter as "sandy loam."

Samples of the soils, having different moisture contents, were tested by means of the alternating-current ammeter-voltmeter method. The results given in Table 1 indicate the relation between moisture content and resistivity—an important factor, since the resistance of inextensive electrodes, such as driven pipes or buried plates, is proportional to the resistivity of the surrounding soil.

TABLE 1.

Resistivity and Moisture Content of Top Soil and Sandy Loam. Temperature 17° *C.*

Moisture content per cent by weight	Resistivity		Ratio to resistivity at 15 per cent of moisture	
	Top soil	Sandy loam	Top soil	Sandy loam
	ohms per cm cube			
2·5	250 000	150 000	13·2	14·3
5	165 000	43 000	8·7	4·1
7·5	100 000	26 000	5·3	2·5
10	53 000	18 500	2·8	1·75
12·5	27 000	14 000	1·42	1·33
15	19 000	10 500	1·00	1·00
17·5	14 700	7 900	0·77	0·75
20	12 000	6 300	0·63	0·60
25	8 500	4 800	0·45	0·46
30	6 400	4 200	0·34	0·40

(D) RESISTIVITY AND TEMPERATURE.

The relation between resistivity and temperature was determined for sandy loam containing 15·2 per cent by weight of moisture. The tests were made with the alternating-current ammeter-voltmeter method. Temperatures between 0° C. and 20° C. were obtained in a special chamber, and those at and below 0° C. in an ice box. The results obtained are given in Table 2.

TABLE 2.

Resistivity and Temperature of Sandy Loam. Moisture Content 15·2 *per cent by Weight of Soil.*

Temperature	Resistivity	Ratio to resistivity at 20° C.
° C.	ohms per cm cube	
20	7 200	1·0
10	9 900	1·4
0 (water)	13 800	1·9
0 (ice)	30 000	4·2
– 5	79 000	11·0
– 15	330 000	45·9

The soil resistivity increased steadily with fall of temperature until freezing point was reached, when a relatively large increase occurred at constant temperature, presumably owing to the moisture in the soil freezing. Below 0° C. it continued to increase steadily with fall of temperature but at a much greater rate. The results indicate that to obtain reliable earth connections with inextensive electrodes they should be buried at depths greater than that to which freezing conditions penetrate.

(E) RESISTIVITY AND ADDED SALT.

The relation between resistivity and added salt was determined for sandy loam containing 15 per cent by weight of moisture. The salt added was measured as a percentage by weight of the contained moisture. The results obtained are given in Table 3.

TABLE 3.

Resistivity of Sandy Loam with Added Salt. Moisture Content 15·0 *per cent by Weight of Soil. Temperature* 17° *C.*

Added salt (per cent by weight of moisture)	Resistivity	Resistivity as percentage of original value
	ohms per cm cube	
0	10 700	100
0·1	1 800	16·8
1	460	4·3
5	190	1·8
10	130	1·2
20	100	0·95

The first additions of salt were most effective; e.g. the first 0·1 per cent of added salt decreased the soil resistivity by about 80 per cent.

(F) RESISTIVITY AND TEMPERATURE OF SANDY LOAM WITH ADDED SALT.

The relation between resistivity and temperature was determined for sandy loam containing 20 per cent by weight of moisture to which 5 per cent by weight of salt was added. The results are given in Table 4.

TABLE 4.

Resistivity and Temperature of Sandy Loam with Added Salt. Moisture Content 20 *per cent by Weight of Soil. Salt* 5 *per cent by Weight of Moisture.*

Temperature	Resistivity	Ratio to resistivity at 20 °C.
° C.	ohms per cm cube	
20	110	1·0
10	142	1·3
0	190	1·7
– 5	312	2·9
– 15	1 440	13·0

The results of Table 4 for salted soil indicate quite small resistivities over the whole temperature range and no large increase under freezing conditions at 0° C.

(G) RESISTIVITIES OF VARIOUS MATERIALS.

Various materials were tested for resistivity as a matter of interest in connection with the general problem of earthing. The tests made and the results obtained are given in Table 5.

The resistivity of the soils dried at oven temperatures was of the same order of magnitude as that of an insulating material. Soils in their naturally driest condition would, however, contain some moisture and would be

TABLE 5.

Resistivities of Various Materials.

partially conducting. A sample of top soil, in a very dry condition, was taken from the ground surface after several weeks of summer without rain, and was found to contain about 5 per cent of moisture by weight.

The resistivity of coal in the natural lump was of the same order of magnitude as that of an insulating material. That of the coal powdered and saturated with water was high in comparison with values common to soils.

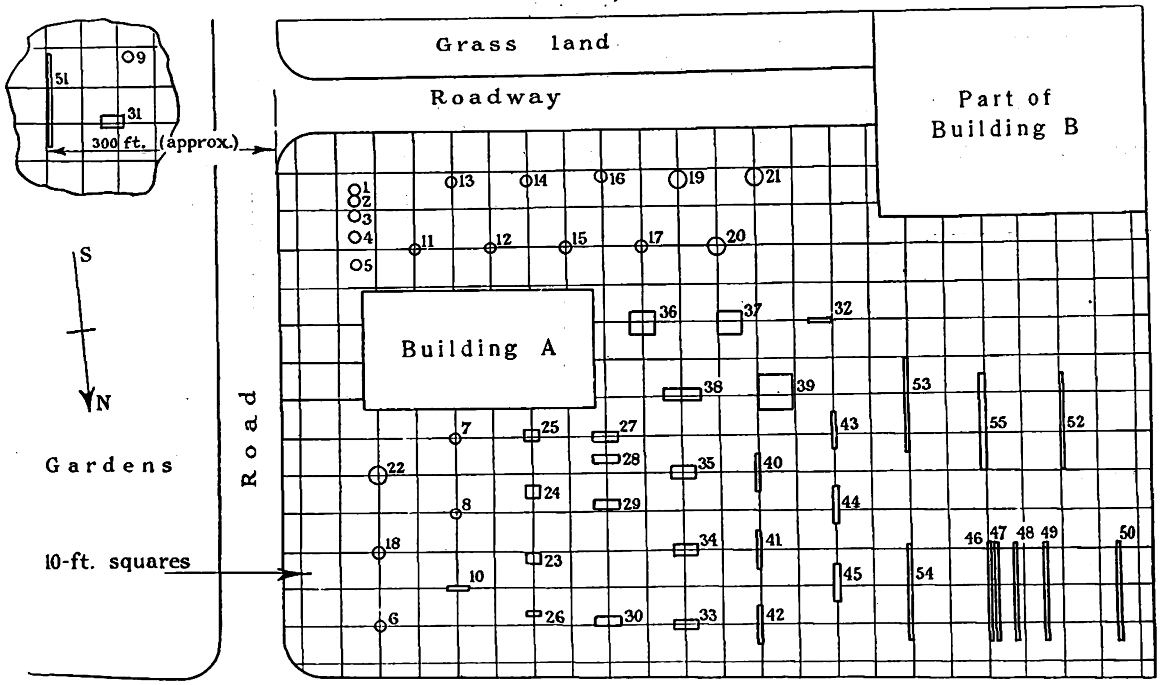

FIG. 7.—Plan of lay-out of earthing electrodes.

The resistivity of coke and ashes was very low compared with soil and was practically independent of moisture content. That of chalk in the natural lump was high, but when the chalk was saturated with water it was of the same order of magnitude as that of soil.

SECTION (2). EXPERIMENTAL MEASUREMENTS OF THE RESISTANCE OF VARIOUS TYPES OF EARTH CONNECTIONS.

(A) VARIOUS ELECTRODES OF INEXTENSIVE AREA.

Various electrodes of inextensive area were placed in a plot of ground and tested in order to determine typical earthing resistances. They were galvanized-iron pipes, wrought-iron plates and copper strips in various sizes, and were tested generally to determine their individual resistances, but in a few cases to determine the effect of distance apart on the resistances of pairs connected in series and in parallel. The individual electrodes were spaced about 20 ft. apart in order that there should be little effect due to proximity, and the pairs were spaced at definite distances apart. All the electrodes were buried except the pipes of 2 in. or less in diameter, which were driven. A pipe and a strip were placed each in a coke bed, and another pipe was salted down with 10 lb. of salt dissolved in water. A plan of the general lay-out of the electrodes is shown in Fig. 7.

The resistance of an electrode of inextensive area depends on (*a*) its shape, dimensions and depth in the ground, and (*b*) the soil resistivity. To obtain earth connections of low resistance the various electrodes would be compared either theoretically or practically as regards (*a*), (*b*) being uniform. Uniform resistivity is assumed in theory as described in the next paragraph, but it could be only very approximately obtainable in practice where the method of comparing the various electrodes would be that of installation and test. Further, the degree of divergence in practice could be hardly determinable. The practical comparison of

electrodes can, therefore, in any case be only roughly approximate, natural undisturbed ground being more suitable in this respect than that which has been "made" or worked for garden purposes.

The resistance of an electrode of known dimensions and position in the ground can be determined theoretically by means of the formula

$$R = \rho/(2\pi C)\ *$$

where ρ is the soil resistivity (assumed uniform), and C is the electrostatic capacity in free space of the electrode with its image above the ground. The formula shows that earthing conductance is directly proportional to C which, being calculable, is valuable as a means of comparing various types of electrodes of inextensive area.

Ground Used.—The plot of ground used is situated within the area of the National Physical Laboratory. It was at one time a garden but at the time of the tests was covered with rough grass.

There were reasons to suppose that the soil resistivity was appreciably non-uniform. The ground had been considerably disturbed for purposes of cultivation. There were the two kinds of soil, viz. top soil and sandy loam, and the results given in Table 1 indicate that the resistivity of the former was rather greater than that of the latter for similar conditions of moisture content and temperature. When the excavations were made to bury the plates, it was noted that the soil moisture increased with depth. Each of these features interfered with the condition of uniform resistivity. The two kinds of soil and the increased moisture content both decreased the soil resistivity with depth.

If an electrode of inextensive area were placed in the ground within a few feet of a metal body such as a

water pipe or the steel framework of a building, its resistance would probably be decreased on account of the proximity. The only body of that kind in close proximity to the electrodes was the steel framework of building A shown in Fig. 7. No electrode was, however, placed nearer to it than about 10 ft.

Seasonal Changes in Earthing Resistance.—The resistance of electrodes of inextensive area is affected by the seasonal changes of climate on account of the influence of the weather on the soil resistivity. Wet or warm conditions will decrease it owing to increasing soil moisture content or temperature. To investigate the magnitude of the seasonal effects on the resistance of the various types of electrodes shown in Fig. 7, tests were made at approximately 2-monthly intervals covering a complete year, September 1925 to September 1926. Particulars of the tests are given in Table 6.

Method of Measurement.—The tests were made by means of the alternating-current ammeter-voltmeter method, the current being obtained from a direct-current supply through a rotary convertor and a transformer. The arrangement of apparatus is shown in Fig. 8. The transformer windings were insulated from one another. The secondary voltage of the transformer, which was variable between 50 and 500 volts, was adjusted in each test to give good meter readings.

The measurement of the resistance of one electrode A requires two other electrodes B and C, the three being spaced not less than about 10 ft. apart. Let the resistances between the electrodes in pairs be respectively R_{AB}, R_{BC}, and R_{CA}. Then the required resistance R_A is given by

$$R_A = \tfrac{1}{2}(R_{AB} - R_{BC} + R_{CA})$$

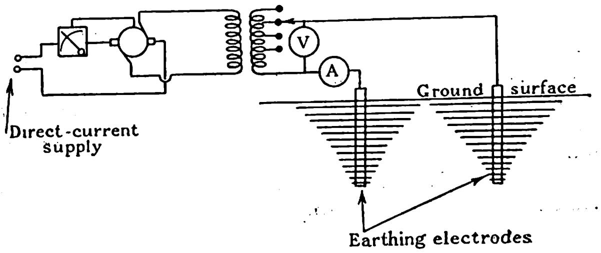

FIG. 8.—Earthing resistance tests. Method of measurement.

The earthing resistance R_1 of the steel framework of building A was first determined by this method. The resistance R_2 of any electrode was thereafter determined by measuring the resistance R between it and the building, the required value being

$$R_2 = R - R_1$$

The resistance R was in many cases quite large compared with R_1, so that R_2 was practically equal to R.

Results.—The results of the tests are given in Table 7 for pipes, Table 8 for plates and Table 9 for strips. The tables give the following particulars of the electrodes:—Their index numbers corresponding to those of Fig. 7; their dimensions and depths in the ground; the measured maximum, minimum and mean resistances covering the year of test; the theoretical resistances calculated on the assumption of a soil resistivity of 10 000 ohms per cm cube; and the ratios of the maximum values to the minimum.

† Placed in a coke bed.
§ Tested once only, in February 1926.

Discussion of the Results.—That the results are somewhat irregular was probably due to the soil resistivity being appreciably non-uniform, as has previously been mentioned. The resistances of electrodes 9 and 31 were, for example, particularly high. They were installed in a small plot of ground away from the main plot and the soil of the former was more sandy in character than that of the latter. The more sandy the soil the greater would be its resistivity and the greater the resistances of electrodes placed in it.

The smallest mean resistance obtained was about 10 ohms and the greatest about 1 000 ohms, which indicates that it is possible to obtain a wide range of values even within a comparatively small area where the soil is roughly of the same nature throughout. The effect of the coke or salt was in each case approximately to halve the resistance. The measured resistances of the electrodes buried shallow were generally greater than the respective calculated values, whereas those of the electrodes buried deep were more nearly in agreement, this being probably due to the soil resistivity decreasing with depth.

The minimum values occurred mostly in November when the ground was very wet after a period of heavy rains, and the maximum in September when the ground was very dry after a period of warm weather without rain. The lowest temperature was noted in January when the ground was covered with melting snow, and the highest in July when the ground was somewhat dry. It appears in the former case that the effect of low temperature in increasing resistance was largely offset by the then very wet condition of the soil and, in the latter case, that contrary conditions prevailed. During the test period no severe freezing conditions were experienced, and the effect of moisture on resistance was greater than that of temperature.

The seasonal variations in resistance of electrodes buried deep were less than those of electrodes buried shallow. The variations were not definitely decreased by the use of coke or salt, the advantage of either being mainly in reducing mean resistances. If freezing conditions had, however, been experienced, the advantage of salt on the variations would probably have been definite. The smallest ratio of the maximum resistance to the minimum was 1·1 and the greatest 3·3, the latter indicating that seasonal changes even under relatively mild conditions may be quite large.

The resistances of electrodes may change owing to causes other than seasonal. After an electrode has been installed the soil takes time to settle around it, and its resistance may decrease on account of improvement of contact. An electrode in soil slowly corrodes and the corrosion may increase the resistance. Tests for the former effect would be complicated by the seasonal variations, and for the latter, apart from similar complications, would necessarily have to be continued over several years.

(B) Various Electrodes of Extensive Area.

Situated near the place of the tests on the inextensive electrodes were two buildings indicated respectively by A and B in Fig. 7, where the former and a part of the latter are shown. Each had a steel framework: the former had also an electric steel-conduit system the tubes of which were in places laid along and clipped to the steel framework, and the latter had also water pipes and a large lead-covered cable. These various types of electrodes of extensive area were tested and the results are given in Table 10.

Table 10.

Various Types of Electrodes of Extensive Area.

Electrode	Earthing resistance
Building A.	ohms
Conduit	2·4
Steel framework	2·4
Building B.	
Water pipe	0·76
Waste-water pipe	7·3
Lead sheath of cable	1·5
Steel framework	2·2

The results indicate that where an electrode is in contact with soil dispersed throughout an extensive tract of land, as it was more or less in each of the cases given in the table, except possibly that of the waste-water pipe, the resistance is considerably smaller than that readily obtainable by means of electrodes of inextensive area. The lowest resistance was 0·76 ohm and was given by the water pipe.

(C) Direct-Current Tests.

Tests were made on electrodes of inextensive and extensive areas with alternating current and with direct current at different voltages in order to investigate the effect of direct-current polarization on field measurements. They were made along lines similar to those of the laboratory experiment made to investigate polarization in soil, as described in Section (1). The various switch operations were made as required and when the current changed with time at constant voltage its initial and final values were noted. The voltages of the direct current were respectively about 50, 6 and 2, and were obtained from a battery which was not earth-connected except through the electrodes during the tests.

The measurements were somewhat inconsistent, as shown by repeat tests giving somewhat different results. Apart from the inconsistency, however, the results generally indicated the following points. The resistances measured with initial values of direct current were about the same as those measured with alternating current. Direct-current polarization was negligible when the positive electrode was extensive in area, but it increased the resistance when the positive electrode was inextensive; the increases were roughly from 10 to 20 per cent of the initial values. The initial direct-current resistance was roughly 5 per cent greater with 2 volts than with 50, but the polarization effect was practically independent of the magnitude of the voltage.

The author thanks Mr. S. W. Melsom for his kindly co-operation in planning the work, and Dr. E. H. Rayner, M.A., for his assistance in preparing this paper.

APPENDIX.

A Theoretical Consideration of the Earthing Resistances of Various Electrodes of Inextensive Area.

Fundamentals.—Let A, Fig. 9, be a body in an infinite medium of specific inductive capacity ϵ and specific resistance ρ.

If A be given a charge Q and C be its capacity to infinity,

$$V = \frac{Q}{C} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If A be a source of current and R its resistance to infinity,

$$V = IR \quad . \quad . \quad . \quad . \quad . \quad (2$$

Eliminating V, we obtain

$$R = \frac{Q}{CI} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

A relation between Q and I is now required.

Let A be enclosed by a spherical surface of radius r; AB the axis of a small conical pencil; ds the area where the pencil cuts the surface; dr a short distance from ds

along AB; $-dv$ the drop in potential along dr; and di the element of current flowing out through ds.

By Ohm's law,

$$\rho di = -\frac{dv}{dr}ds \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

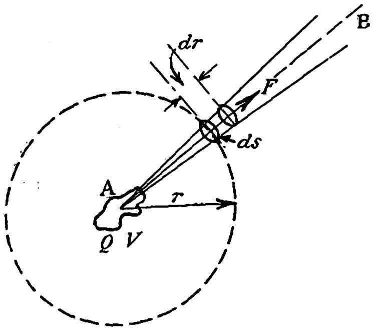

FIG. 9.

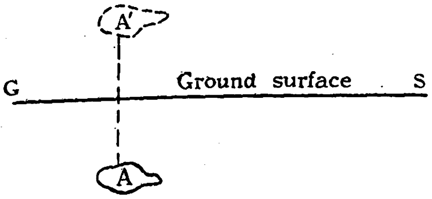

FIG. 10.

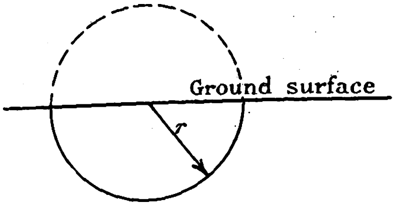

FIG. 11.

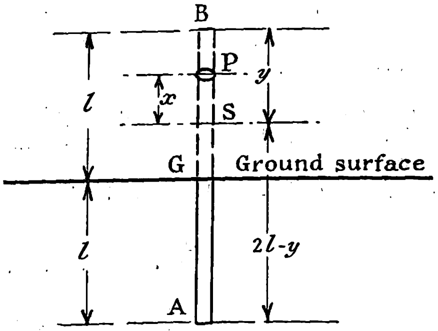

FIG. 12.

The electric force F at ds, by definition, is either

$$-\frac{dv}{dr}\cdot\frac{1}{\epsilon} \quad \text{or} \quad \frac{Q}{r^2}\cdot\frac{1}{\epsilon}$$

that is,

$$-\frac{dv}{dr} = \frac{Q}{r^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

From (4) and (5),

$$\rho di = \frac{Q}{r^2}ds \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

Integrating (6) we obtain

$$\rho I = \frac{Q}{r^2}4\pi r^2 = 4\pi Q$$

that is,

$$\frac{Q}{I} = \frac{\rho}{4\pi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

From (3) and (7) we have

$$R = \frac{\rho}{4\pi C} \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

Equation (8) is the general formula relating resistance, resistivity and capacity for a body in free space.

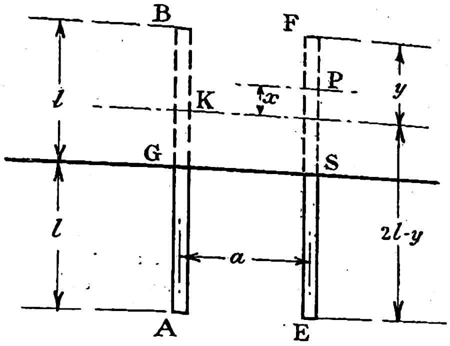

FIG. 13.

If A be considered with respect to another body B instead of to infinity, then (8) would still apply, R being the resistance between A and B, and C their capacity as oppositely charged bodies.

Practical Applications.—Let A, Fig. 10, be an electrode in the ground and A′ its image above the ground surface GS. If A and A′ connected together be considered as one body in free space, then their resistance to infinity would be given by equation (8), where C is their capacity to infinity. Because the conditions above and below GS are symmetrical, the resistance of A alone to infinity is

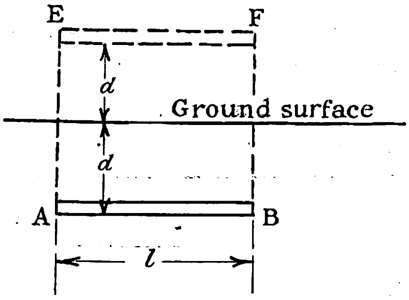

FIG. 14.

$$R = \frac{\rho}{2\pi C} \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Equation (9) is the general formula for calculating the resistances of electrodes of inextensive area, the units of measurement being in centimetres.

Hemispherical Electrode.—A hemispherical electrode with its flat side level with the ground surface is shown in Fig. 11. It with its image is a sphere the capacity of which is equal to the radius or

$$C = r \quad . \; . \; . \; . \; . \; . \; . \quad (10)$$

Driven Pipes.—Owing to the particular geometrical form of a pipe, capacity is not readily calculable. The calculation is simplified, however, by making an initial assumption which, leading to results that are correct within a few per cent of error, is sufficiently accurate for practical purposes. The method of treatment and the assumption given below are due to Prof. G. W. O. Howe.*

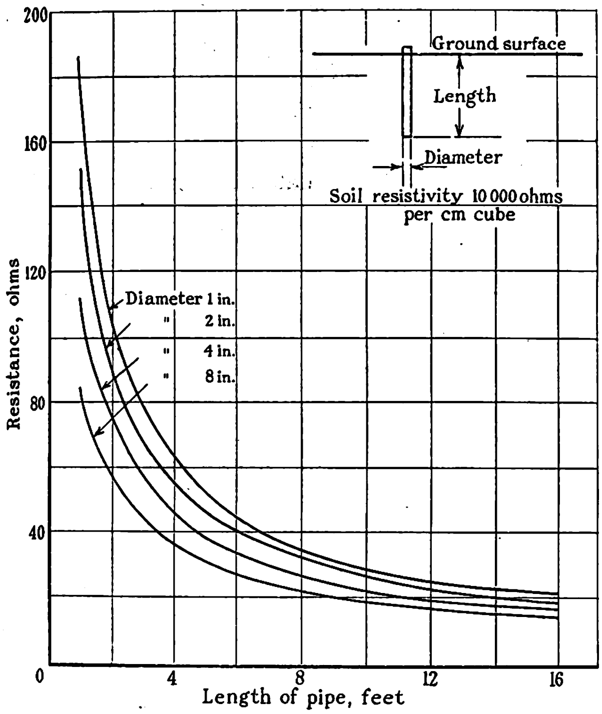

FIG. 15.—Change in resistance of driven pipes with length and diameter.

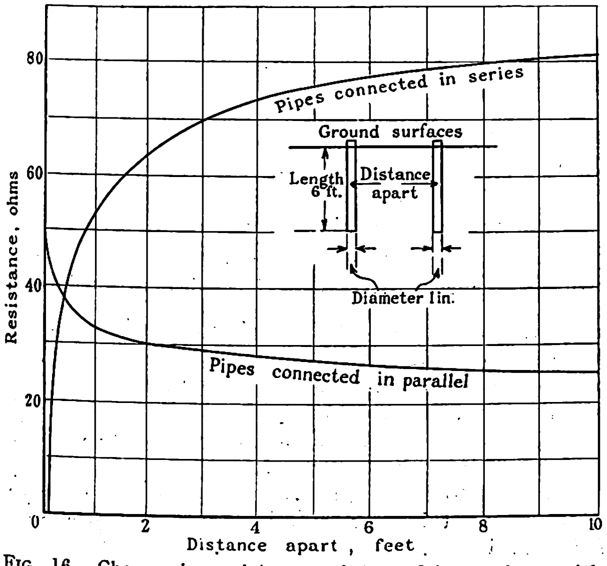

FIG. 16.—Change in resistance of two driven pipes with distance apart.

Let GA, Fig. 12, be a pipe and GB its image. To determine the resistance of GA it is necessary to calculate the capacity of AB in free space.

If AB be a charged body in free space, it is wholly at a certain potential and its charge is unevenly distributed over its surface, being of greatest density at the ends. This condition is difficult to consider mathematically. The assumption mentioned above is that the density of charge is uniform, from which the mean potential of AB may be calculated; the result will be the actual potential very nearly. The charge and potential being known, the capacity of AB is the charge per unit potential.

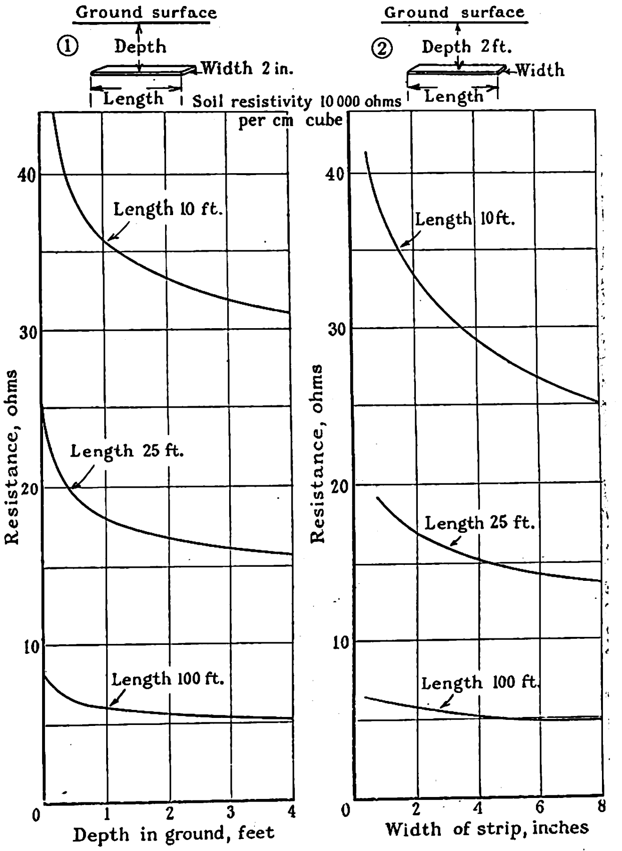

FIG. 17.—Change in resistance of buried strip with (1) length and depth in ground, and (2) length and width.

In Fig. 12, let GA $= l$, BS $= y$, SP $= x$, D be the diameter of the pipe and σ the assumed uniform charge per unit length.

The charge on a length dx at P is σdx.

The potential at S owing to element of charge at P

$$dV_s = \frac{\sigma dx}{\sqrt{\left[\frac{D^2}{4} + x^2\right]}} \quad . \; . \; . \; . \quad (11)$$

---

* "On the Capacity of Radio-Telegraphic Antennæ," *Electrician*, 1924, vol. 73, pp. 829, 859 and 906; "The Calculation of the Effective Resistance of Earth Plates," *Electrician*, 1915–16, vol. 76, p. 353; "The Capacity of Rectangular Plates and a Suggested Formula for the Capacity of Aerials," *Radio Review*, 1919–20, vol. 1, p. 710.

and, owing to the whole of charge, is equation (11) integrated between the limits of y and 0, and $(2l - y)$ and 0, from which

$$V_s = \sigma\left[\operatorname{arc\,sinh}\frac{2y}{D} + \operatorname{arc\,sinh}\frac{2(2l - y)}{D}\right] . \tag{12}$$

The mean potential of AB is equation (12) integrated between the limits of $2l$ and 0, divided by $2l$, from which

$$V_{m1} = 2\sigma\left[\operatorname{arc\,sinh}\frac{4l}{D} + \frac{D}{4l} - \sqrt{\left\{1 + \frac{D^2}{16l^2}\right\}}\right] \tag{13}$$

The total charge on AB

$$Q = 2l\sigma \quad . \quad . \quad . \quad . \quad . \tag{14}$$

The capacity C is the ratio of (14) and (13).

Driven Pipes connected in Series or Parallel.—Let GA and SE (Fig. 13) be two similar pipes at a distance a apart, each being of length l, diameter D, and charge per unit length σ. The mean potential of AB due to its own charge is given by V_{m1}, equation (13). The potential of AB is, however, affected by the charge on EF.

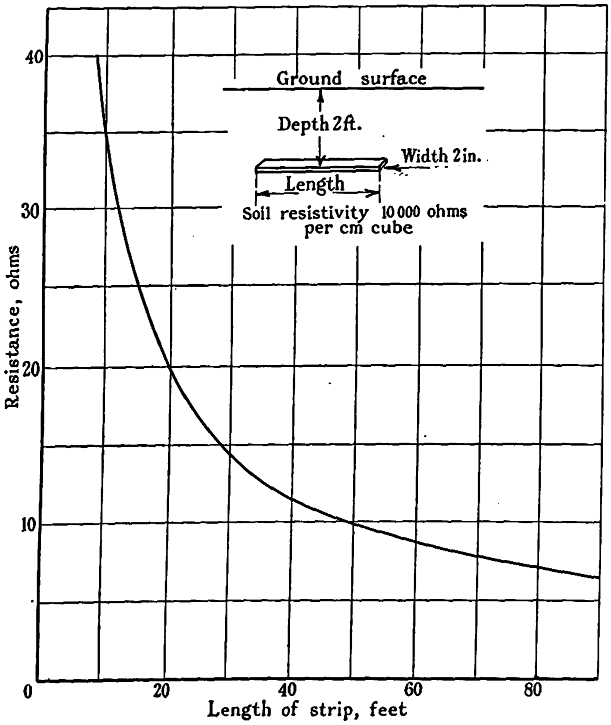

FIG. 18.—Change in resistance of buried strip with length.

The potential at K (Fig. 13) due to element of charge at P

$$dV_K = \frac{\sigma dx}{\sqrt{[a^2 + x^2]}} \quad . \quad . \quad . \quad . \tag{15}$$

Equation (15) being similar to (11) except that $\frac{1}{2}D$ is replaced by a, the mean potential of AB due to charge on EF is, from equation (13),

$$V_{m2} = 2\sigma\left[\operatorname{arc\,sinh}\frac{2l}{a} + \frac{a}{2l} - \sqrt{\left\{1 + \frac{a^2}{4l^2}\right\}}\right] . \tag{16}$$

For two pipes connected in *parallel*:—

$$\text{Total mean potential} \quad V_m = V_{m1} + V_{m2} \quad . \quad . \quad . \tag{17}$$

$$\text{Total charge} \quad Q = 4l\sigma \quad . \quad . \quad . \quad . \quad . \tag{18}$$

$$\text{For } n \text{ pipes} \quad V_m = V_{m1} + V_{m2} + V_{m3} \ldots (n \text{ terms}) \tag{19}$$

$$Q = 2nl\sigma \quad . \quad . \quad . \quad . \quad . \tag{20}$$

For two pipes connected in *series*:—

Total mean potential difference between them

$$V_m = 2(V_{m1} - V_{m2}) \quad . \quad . \quad . \quad . \tag{21}$$

$$\text{Total charge} \quad Q = 2l\sigma \quad . \quad . \quad . \quad . \quad . \quad . \quad . \tag{22}$$

Buried Strips.—To calculate the capacity of a buried strip, the method of treatment is to substitute for the strip a pipe having the same length of periphery, to obtain the mean potential of the pipe by means of the given formulæ and to multiply the result by a correction factor, which is about 1·11 when the width of the strip is about 17 times its thickness.

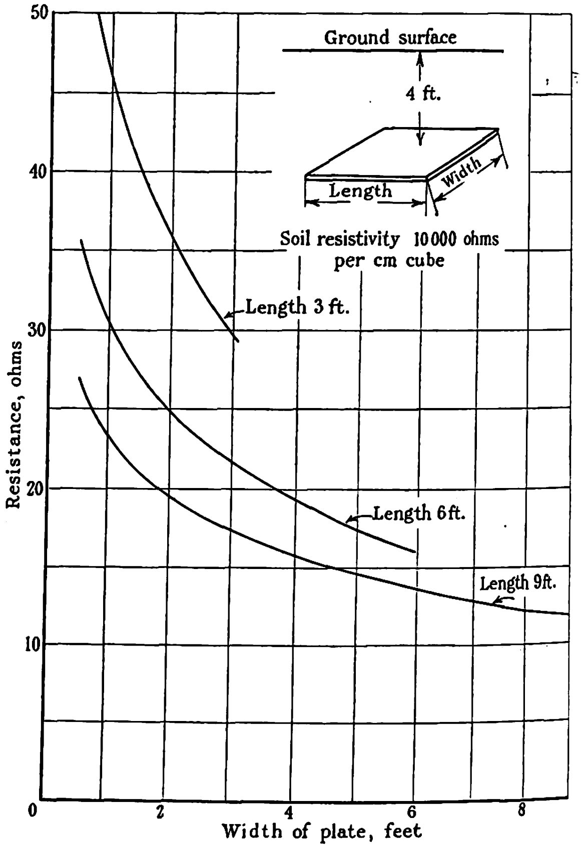

FIG. 19.—Change in resistance of plates with length and width.

Referring to Fig. 14, let AB be the strip of length l, width w and thickness t, buried at a depth d, and let EF be its image.

$$\text{Diameter of equivalent pipe} \quad D = \frac{2(w + t)}{\pi} \quad . \quad . \tag{23}$$

Potential of AB due to its own charge, from equation (13),

$$V_{m1} = 2\sigma K\left[\operatorname{arc\,sinh}\frac{2l}{D} + \frac{D}{2l} - \sqrt{\left\{1 + \frac{D^2}{4l^2}\right\}}\right] \tag{24}$$

K being the correction factor.

Potential of AB due to charge on image EF, from equation (16)

$$V_{m_2} = 2\sigma\left[\operatorname{arc\,sinh}\frac{l}{2d} + \frac{2d}{l} - \sqrt{\left\{1 + \frac{4d^2}{l^2}\right\}}\right] \quad (25)$$

Total potential $V_m = V_{m_1} + V_{m_2}$ . . . . (26)

Total charge $Q = 2\sigma l$ . . . . (27)

Buried Plates.—To calculate the capacity of a buried plate, the method of treatment is to consider the plate as a large number of strips connected in parallel, to obtain by integration the potential of any one strip due to the charge on the whole plate and to obtain, by integrating over the whole width of the plate and dividing by the width, the mean potential of the plate. The result obtained may be given as

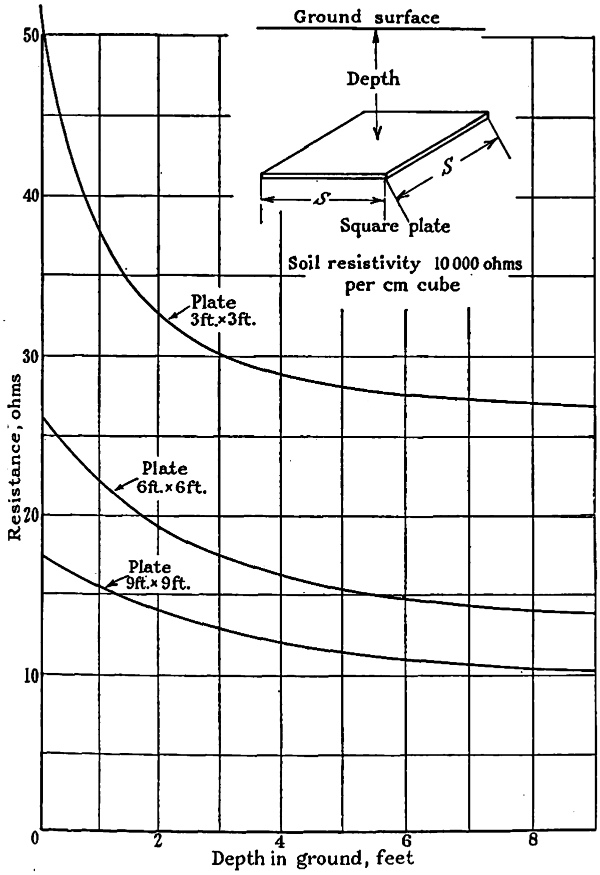

FIG. 20.—Change in resistance of square plates with size and depth in ground.

$$V_{m_1} = 3\cdot 1\sigma\sqrt{(wl_1)}\left(1 + 0\cdot 0375\frac{l_1}{w}\right)^{-1} \quad . \quad (28)$$

where l_1 is the length of the plate and w its width, the formula being approximately applicable between the limits of $l_1/w = 1$ and $l_1/w = 12$.

The total charge $Q = \sigma w l_1$ . . . . . . (29)

The potential of a buried plate due to the charge on its image may be approximately obtained as follows:—

When the plate is in the plane of the ground surface, equations (28) and (29) apply.

When the plate is at a depth d in the ground that is large compared with l_1, the image may be taken to be at a distance of $2d$ from the plate, and

$$V_{m_2} = \frac{\sigma w l_1}{2d} \quad . \quad . \quad . \quad . \quad . \quad (30)$$

When d is neither large nor small compared with l_1, the plate with image may be considered as a strip with image, in which case equation (25) would apply.

$$V_{m_2} = 2\sigma w\left[\operatorname{arc\,sinh}\frac{l_1}{2d} + \frac{2d}{l_1} - \sqrt{\left\{1 + \frac{4d^2}{l_1^2}\right\}}\right] \quad (31)$$

Total potential of plate $V = V_{m_1} + V_{m_2}$ . . (32)

Total charge $Q = 2\sigma w l_1$ . . . (33)

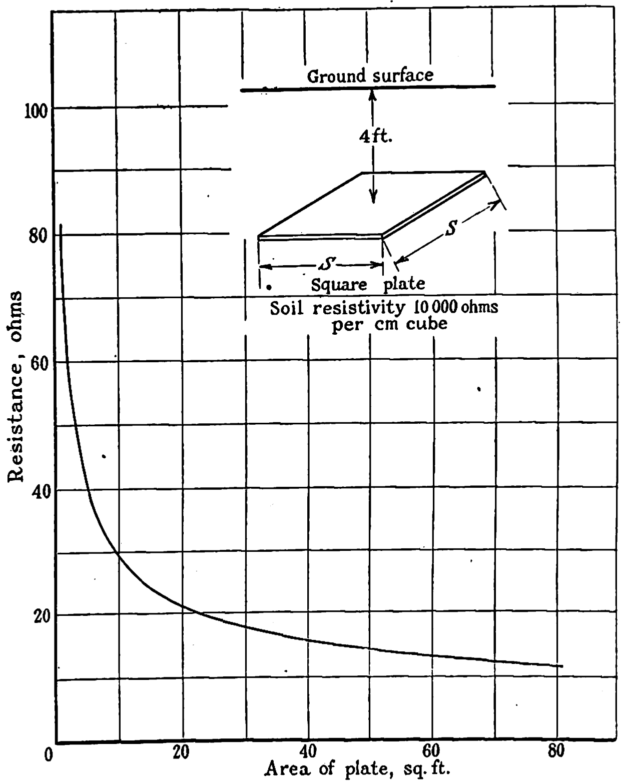

FIG. 21.—Change in resistance of square plate with area.

The method of calculation of either strips or plates connected in parallel or series is similar to that described for pipes.

Theoretical Resistance Curves.—Curves showing relations between the earthing resistances (calculated by means of the various theoretical formulæ), the dimensions and depths in the ground of various types of electrodes, are given in Figs. 15 to 21.

Discussion of the Various Types of Electrodes of Inextensive Area.—The various types of electrodes of inextensive area are compared in Table 11, the relative earthing resistances given in col. 6 of the table being obtained from the curves of Figs. 15 to 21.

The values given in the table suggest the following points:—

(i) Pipes and strips are about equally efficient and are much more efficient than plates. Pipes, which are simply driven in the ground, would, however, be more commonly used than strips, which require a considerable amount of ground excavation for their installation, on account of the low first costs of the former.

(ii) An electrode consisting of two pipes spaced about 5 ft. apart and connected in parallel is much more efficient than one pipe of diameter equal to the sum of the two. A number of small electrodes dispersed in the ground and connected in parallel is more efficient than the same amount of metal less widely dispersed.

(iii) A plate of a given amount of metal becomes more efficient the more it is elongated like a strip.

(iv) The efficiency of a strip or plate is only slightly increased by burying at depths greater than about 2 ft. or 4 ft. respectively, the soil resistivity being assumed to be uniform. It appears, therefore, that the possible variations in soil resistivity with depth are relatively more important with regard to earthing efficiencies than the actual depths of burying. A strip or plate should, when practicable, be buried where the soil resistivity is lowest, if not too shallow.

The sizes of electrodes and the depths of burying are, for practical reasons, generally confined within limits. The dispersion of a number of small electrodes connected in parallel to obtain a low resistance would, for example, be limited by the installation cost or by a minimum size of electrode as regards mechanical strength and durability. The length of a pipe would be limited to that which may be easily driven, and the depth of burying a strip or plate to a moderate amount of ground excavation. Although the thickness of metal of an electrode has no appreciable effect on earthing resistance, yet it should be sufficient to give the electrode a reasonable mechanical strength and service life in the presence of possible corrosion.

TABLE 11.

A Comparison of Various Electrodes.

Electrode	Length	Width or diameter	Depth in ground	Soil excavation †	Relative	
					Earthing resistance	Efficiency §
	ft.	in.	ft.	cub. ft.		
Pipe	6	1	—	—	1 ‡	1 ‡
Strip	10	2	4	80	0·68	1·04
Strip	10	2	2	30	0·72	0·97
Pipe	12	1	—	—	0·54	0·92
2 Pipes *	6	1	—	—	0·59	0·85
Strip	25	2	2	75	0·37	0·77
Pipe	6	2	—	—	0·86	0·58
Strip	10	5	2	30	0·61	0·46
Plate	9	6	4	72	0·59	0·44
		(feet)				
Plate	3	3	8	72	0·59	0·22
Plate	3	3	4	36	0·63	0·21
Plate	6	6	4	144	0·35	0·10

* Two pipes each 6 ft. in length and 1 in. in diameter, spaced 5 ft. apart and connected in parallel.

† The soil excavation has been calculated on the basis that pipes being driven require none; the minimum width of a trench 2 ft. deep is 1·5 ft. and of one 4 ft. deep is 2 ft.

‡ A driven pipe 6 ft. long and 1 in. in diameter has been taken as a standard for the purpose of the comparison.

§ Efficiency is taken to be inversely proportional to earthing resistance and to the volume of the electrode; i.e. efficiency is proportional to the earthing conductance of an electrode per unit volume of metal. The thickness of the metal of each electrode has been taken as 0·25 in.

REPORT OF THE COUNCIL FOR THE YEAR 1929–1930, PRESENTED AT THE ANNUAL GENERAL MEETING OF 15TH MAY, 1930.

REPORT.

The Council, at the Fifty-eighth Annual General Meeting of The Institution of Electrical Engineers, present to the members their Report for the year 1929–30, covering approximately the period from the 1st April, 1929, to the 31st March, 1930. In this connection, the Council desire once more to express the Institution's grateful thanks to its many members who have given their time so freely in promoting its work and activities.

(1) MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since the 1st April, 1929, are shown in a table included in Appendix A.

The following table shows the growth of membership for the last 10 years:—

Year	Membership	Increase
1921	9 449	1 303
1922	10 275	826
1923	10 911	636
1924	11 415	504
1925	11 743	328
1926	12 142	399
1927	12 647	505
1928	13 043	396
1929	13 561	518
1930	14 200	639

(2) EXAMINATIONS.

The Graduateship Examination was held in May and November, 1929, in London, Belfast, Birmingham, Cardiff, Dublin, Glasgow, Hull, Manchester, Newcastle-on-Tyne, Plymouth and Portsmouth, and also in Australia, China, East Africa, India, Malta, New Zealand, South Africa and the Straits Settlements.

During the year a number of candidates were granted permission to satisfy the educational requirements for Associate Membership by the submission of satisfactory written papers or theses in lieu of an Examination.

(3) NATIONAL CERTIFICATES AND DIPLOMAS IN ELECTRICAL ENGINEERING.

England and Wales.—In 1929 the Joint Standing Committee, representing the Board of Education and the Institution, was associated with the final examinations of 120 courses at colleges and schools in England and Wales approved in connection with the above certificates and diplomas.

The final examinations were held during the summer of 1929 and the number of awards was as follows:—

433 Ordinary Certificates.
209 Higher Certificates (including 4 Post-Higher Certificates).
10 Ordinary Diplomas.
4 Higher Diplomas.

Scotland.—The Institution, in conjunction with the Scottish Education Department, has drawn up a scheme for the award of the above certificates and diplomas in Scotland. Final examinations will be held in 1930 for the first time under the scheme.

(4) HONORARY MEMBER.

The Council have pleasure in recording that, as announced at the Ordinary Meeting on the 9th January, 1930, they have elected Sir Richard Tetley Glazebrook, K.C.B., D.Sc., F.R.S., to be an Honorary Member of the Institution.

(5) FARADAY MEDAL.

The ninth award of the Faraday Medal was made by the Council to Sir Ernest Rutherford, O.M., F.R.S.

(6) HONOURS AND DISTINCTIONS CONFERRED ON MEMBERS.

Knighthood.

Page, Archibald (Past President).

C.M.G.

Pitkeathley, Lt.-Col. J. S., C.V.O., C.I.E., C.B.E., D.S.O., R.E. (Associate Member).

M.B.E.

Rogers, E. E. (Associate Member).

(7) DEATHS.

The Council regret to have to record the death of the following 80 members of the Institution during the year:—

Honorary Member.

Ferranti, S. Z. de, D.Sc., F.R.S.

Members.

Angold, A. E.
Baxendale, T.
Baylor, A. K.
Baynes, S. W.
Beaumont, W. W.
Blascheck, C. A.
Cockburn, A. C.
de Warburg, C. H.
Fargues, J., O.B.E.
Field, M. B., O.B.E.
Fynn, V. A.
Hansford, R. V., D.Sc.
Hill, C. W.
Hutchinson, Sir S. H. C.
Irvine, F.
Jackson, Admiral Sir H. B., G.C.B., K.C.V.O., F.R.S.
Jeffery, J.
Jones, J. C. D.
Judd, W.
Kolkhorst, A. O.
Leach, H. L.
Lieb, J. W.
McCarthy-Jones, C. H.
Malcolm, Col. E. D., C.B., R.E.
Marshall, R.
Mayston, W. H.
Mudford, F. J.
Orchiston, J.
Pearson, G. A.
Reid, E. J.
Richardson, J.
Semenza, G.
Sinclair, Col. A.
Swinton, A. A. C., F.R.S.
Thomson, J. S.
Toplis, W. S.

Associate Members.

Amor, F.
Barton, T., B.Sc. Tech.
Beddoe, J. S., M.B.E.
Blagden, A. H.
Cooper, G. P.
Cursetjee, N. J.
Fox, J. T.
Gerhardi, C. H. W.
Higgins, C. H.
Huber, A. J.
Jackson, H. Y. V., M.C.
Ker, D. W.
Lewsley, J. W.
McMahon, J. F.
Malcolm, G. D.
Neff, W. A.
O'Brien, C. C.
Randles, J. T. T.
Rogers, W. R.
Simpson, A. J. G.

Pocock, C. J. D.
Porteus, T. A.
Reddy. P. J.
Willis, W. S.

(8) REVISION OF BYE-LAWS.

The revision of the Bye-laws, to which brief reference was made in the last Annual Report, was completed during the year. The alterations, which principally affect the qualifications for the non-corporate classes of membership, were duly approved at a Special General Meeting of Corporate Members on the 9th May, 1929, and were subsequently allowed by the Privy Council on the 2nd August, 1929.

Such regrading of the membership as became necessary as a result of the alterations has been completed.

(9) INSTITUTION BUILDING.

The Institution continues as in the past to grant facilities for the free use of its Building to kindred societies for the purposes of their meetings, and during the past year nearly 200 such meetings were held.

(10) OIL PAINTINGS.

The collection of paintings in the Lecture Theatre has during the past year been further augmented by generous gifts by Mr. Ll. B. Atkinson, Sir Thomas Callender and The Hon. Sir Charles Parsons, O.M., K.C.B., F.R.S., of oil paintings of Clerk Maxwell, Hopkinson and Swan respectively.

The portraits of Maxwell and Hopkinson are by Mr. R. H. Campbell, and that of Swan by Mr. W. Paget.

The paintings of Ampère and Graham Bell, which, as stated in the last Annual Report, are being given by Mr. E. Garcke and Sir Hugo Hirst respectively, will, it is hoped, be ready for hanging early next Session. The Council have also gratefully accepted from Mr. H. Marryat an offer of a portrait of Ferranti.

(11) MEETINGS.

During the past twelve months, 431 meetings have been held in London and the Local Centres by the members, the Council and the various Committees. A detailed statement is given in Appendix B.

The Premiums awarded by the Council for papers will be announced about the time of the Annual General Meeting.*

(12) INAUGURAL ADDRESS OF SIR THOMAS PURVES.

The delivering of the President's Inaugural Address on the 24th October, 1929, was marked by the fact that by means of telephone land-lines and loud-speakers it was heard simultaneously at meetings of members in London, Birmingham, Cardiff, Glasgow, Leeds, Liverpool, Manchester, Newcastle-on-Tyne, Portsmouth and Southampton. At the commencement of the proceedings the Chairmen of all the meetings spoke in succession and were clearly heard by the 10 audiences.

The vote of thanks to the President for his Address was proposed by Mr. J. Harcourt Williams, who spoke from Manchester, and was seconded by Prof. Magnus Maclean, who spoke from Glasgow.

The Council are much indebted to the Post Office Engineering Department for having made the necessary arrangements and also to Messrs. Graham Amplion, Ltd., for the loan of the loud-speakers used.

(13) LOCAL CENTRES AND SUB-CENTRES.

Reports from the Committees of the Centres and Sub-Centres indicate that the attendances at the meetings and the interest in the discussions, etc., have been well sustained.

In view of the continued increase in local activities which necessarily entails larger expenditure, the Council have found it necessary to increase the scale of grants to the Centres.

The President attended functions and meetings at the Centres at Birmingham, Cardiff, Glasgow, Leeds, Liverpool, Manchester, and Newcastle-on-Tyne, as well as at the Sheffield and Tees-Side Sub-Centres.

On each occasion he addressed those present and was very gratified to note the activities of the various Centres and the evidence of appreciation by the members of the opportunities offered for discussion and intercourse.

Last Session, authority was given for the setting up of a Local Sub-Centre for Hampshire, to function directly under the Council. The inaugural meeting was held at Portsmouth on the 27th June, 1929, when Colonel Edgcumbe, who was then President, addressed the meeting and the first Committee was elected. Meetings are being held alternately at Portsmouth and Southampton.

Full details of the meetings and other activities of the Local Centres and Sub-Centres are contained in the Annual Reports presented each year to the local members.

Local technical libraries, the setting up of which was approved by the Council in 1922, have for some time been in existence at Dublin, Glasgow, Leeds, Manchester and Newcastle. The past year has seen the extension of the scheme to Loughborough and Middlesbrough.

Full particulars of the arrangements for borrowing or referring to the books at these libraries can be obtained on application to the Local Honorary Secretaries.

(14) WIRELESS SECTION.

The interest and activities of the Wireless Section have been well maintained. Seven meetings have been held, at which 12 papers were read. In addition, 5 papers have been published or accepted for publication in the *Journal*. The average attendance at the meetings was 118.

(15) METER AND INSTRUMENT SECTION.

The Meter and Instrument Section is now well established, and seven meetings have been held during the past year, the average attendance being 77. The quality of the papers has been high, and the discussions have been well sustained. The meetings included an informal debate, which was organized with the object of encouraging the junior members to speak.

It is felt that there is still a large number of members who are qualified to join the Section and have, so far, failed to make application for membership. It is therefore desired to remind members of the Institution that the Section has been formed for the reading and discussion of papers on meters, instruments and cognate subjects, and to stimulate interest in these subjects, and it is hoped that all members whose work comes within the scope of the Section will give it their active support.

---

* See page 795.

(16) INFORMAL MEETINGS.

Twelve meetings have been held during the Session, the average attendance being 74 as against 69 last year.

The Informal Meetings Committee again cordially invite members to write to the Secretary indicating subjects which they wish to suggest for discussion. Offers from members to open discussions will also be welcomed and carefully considered by the Committee.

(17) STUDENTS' SECTIONS.

There are at present 3 095 Students on the register of the Institution, and a very full programme of meetings, visits to works and social functions was carried out by the eight Students' Sections, viz. those at London, Birmingham, Glasgow, Leeds, Liverpool, Manchester, Newcastle, and Sheffield. The membership of these Sections has during the Session been augmented by the inclusion of some 980 Graduates under the age of 28, who, as mentioned elsewhere in this Report, are now entitled under the Bye-laws to the same privileges as Students.

It was stated in the last Report that the Council had approved of a Lecture, to be known as "The Students' Lecture," to be delivered annually at each of the Students' Sections. For this purpose it was decided to appoint two Lecturers every other year, each of whom would visit four of the Sections in one Session and the remaining four in the following Session. The first two Lecturers, their subjects and the Sections which have been visited by them this Session, are as follows:—

Lecturer	*Subject*	*Sections*
Lt.-Col. H. E. O'Brien, D.S.O.	"Electric Traction"	Glasgow Leeds Newcastle Sheffield
Mr. F. J. Baldwin	"Overhead Line Work, with special reference to the 'Grid'"	Birmingham Liverpool London Manchester

The Lectures were much appreciated, although the attendance at some of the meetings was disappointing. The aggregate attendances were approximately 480.

In August last a Summer Meeting was organized by the London Students' Section. The party numbered 26 and included, in addition to London Students, members of the Students' Sections in the provinces.

The first part of the meeting was in Northern France, where the party spent two days inspecting the rural electrification schemes of the Société Béthunoise. The party then proceeded to Rheims where the High Tension laboratories of Messrs. Verrières Charbonneaux and the cellars of Messrs. Heidsieck were visited.

The remainder of the meeting was spent in Paris, the programme including visits to the following places:—

- The Ivry Port power station (Électricité de la Seine).
- The factory of the Compagnie Électro-Mécanique.
- Le Bourget Aerodrome.
- The research laboratories of the International Standard Electric Corporation.
- The factory of Le Matériel Téléphonique.
- The Eiffel Tower radio station.
- The repair shops of the Paris–Orleans Railway.

In addition, there were excursions to the battlefields area in Northern France and an all-day visit to the Palace of Versailles.

The Council desire to express their thanks for the hospitable welcome extended to the party on the occasion of the visits to works, etc. The meeting was very successful and thanks are due to Mr. J. Grosselin (Local Hon. Secretary for France) and Major T. Rich, Member, who accompanied the party, for their valuable assistance in arranging the visits, and also to the Hon. Secretary (Mr. L. S. Crutch) and the Committee of the London Students' Section for organizing the Meeting.

(18) STUDENTS' JOURNAL.

The Council have decided, as an experiment over a period of 12 months, to publish a quarterly *Journal* devoted exclusively to the meetings and other activities of the Students' Sections, in regard to which, under the new Bye-laws, Graduates under the age of 28 have the same privileges as Students. It is expected that the first number will be issued in the autumn.

(19) LOCAL AWARDS FOR STUDENTS' PAPERS.

The Council have approved a recommendation of the Papers and Local Centres Committees that one local award be made each year by each Local Centre from its funds for the best local Students' paper. These awards must be regarded as strictly unofficial and will not be recorded by the Institution.

(20) SUMMER MEETING.

A cordial invitation was accepted from the Société Française des Électriciens for the Summer Meeting for 1929 to be held in France, and it duly took place there from the 12th to the 22nd June, the party of visitors including some 135 members and ladies.

The programme arranged by the French society consisted of a stay of four days in Paris and an excursion to the Pyrenees.

The Paris portion of the meeting (12th to 15th June) included visits to—

- The generating station at Saint Ouen of the Compagnie Parisienne de Distribution d'Électricité.
- The generating station at Gennevilliers of the Union d'Électricité.
- The generating station at Ivry of Électricité de la Seine.

The million-volt laboratory at Ivry of the Compagnie Générale Électro-céramique.
The École Supérieure d'Électricité.
The Sainte Assise wireless station of the Compagnie Générale de T.S.F.
The Établissements Belin (tele-photography).
The new generating station at Issy-les-Moulineaux of the Compagnie Parisienne de Distribution d'Électricité.
The 46,000-gauss electromagnet at the Office National des Recherches Scientifiques et Industrielles et des Inventions, at Bellevue.

There were excursions to Versailles, Trianon and Chantilly, and some visits were especially arranged for the ladies, including the Sèvres porcelain factory.

The party were also the guests of the French society, the Compagnie Parisienne de Distribution d'Électricité and the Groupement des Secteurs de la Region Parisienne at a banquet at the Hôtel Continental on the 12th June.

The remainder of the visit consisted of an excursion to the Pyrenees, for which a special train was provided free of charge by the Compagnie des Chemins de Fer de Paris à Orléans and the Compagnie des Chemins de Fer du Midi. The route followed was Paris—Bordeaux—Pau—Lourdes—Toulouse—Paris, with subsidiary excursions to Eaux-Bonnes and the Col d'Aubisque, Gavarnie and Carcassonne. The following works were also inspected:—

The dam and generating station at Eguzon of the Union Hydro-Électrique.
The works at Hourat and the rectifier station at Pau of the Compagnie des Chemins de Fer du Midi.
The Soulom works of the Société des Phosphates Tunisiens.
The works at Luz of the Société Hydro-Électrique de la Cere.
The works at Lannemezan of the Société des Produits Azotés.

At Pau the visitors were entertained at a banquet offered by the South-Western Centre of the Société Française des Électriciens, and at Toulouse they were received at the Capitol by the Mayor and City Councillors and the Toulouse Centre of the French Society.

The Meeting concluded with the return of the party to Paris on the 22nd June.

The thanks of the Institution have been conveyed to all those named above, and the Council wish to place on record their appreciation of the generosity and cordiality with which the party were received throughout the Meeting. The Council especially desire to record their appreciation of all that was done by Mr. Paul Bunet and Mr. J. Grosselin, the President and Director respectively of the French society, who accompanied the party throughout the Meeting and who, through their unfailing tact and courtesy and excellent organization, did so much to make the Meeting the great success it undoubtedly was.

(21) FARADAY LECTURE.

The Faraday Lecture this Session was delivered by Captain P. P. Eckersley, his subject being "Broadcasting by Electric Waves." The Lecture was given at London, Birmingham, Edinburgh, Leeds, Liverpool, Manchester, Newcastle-on-Tyne, Plymouth and Sheffield.

The nine Lectures were attended by a total audience of approximately 7 500, of whom over 5 500 were non-members. The latter figure is a satisfactory indication that the Lectures continue to fulfil their object of bringing electrical science to the attention of the public.

(22) REVIEWS OF PROGRESS.

Continuing the series of reviews of progress in electrical engineering which were published in the *Journal* in 1926, 1927, 1928 and 1929, reviews on the following subjects have been or will be published during 1930:—

Domestic Applications of Electricity.
Electrical Equipment of Automobiles.
Electricity Supply Tariffs.
Electrical Plant and Machinery.
Electro-Physics.
Electric Traction.
Transmission and Distribution.

The reviews to be published in 1931 will be on the following subjects:—

Electrical Measuring Instruments and Sensitive Controlling Apparatus.
Electrical Standardization.
Electricity in Mines.
Electricity Meters.
Electro-Chemistry and Electro-Metallurgy.

(23) SCHOLARSHIPS.

The following Scholarships have been awarded by the Council:—

David Hughes Scholarship.
(Value £50; tenable for one year.)
P. F. Soper (East London College).

Paul Scholarship.
(Value £100; tenable for two years.)
K. H. Gillanders (Brockley County School, London).

Salomons Scholarships.
(Value £50 each; tenable for one year.)
R. B. Smith (Leeds University).
F. W. L. Horner (Municipal Technical College, Belfast).

War Thanksgiving Education and Research Fund (No. 1).

The Council have made grants of £50 from the above Fund for research purposes to each of the following:—

J. A. Clegg (University College, London).
A. F. Wilkins (Cambridge University).

In order further to extend the educational work of the Institution, the Council have decided to establish two Institution Scholarships, which will ultimately involve an annual expenditure of £950.*

A bequest of £1 000 has been received by the Institution under the Will of the late Mr. W. J. Thorrowgood,

---

* See page 796.

Member, the income of which is to be devoted to the establishment of a Scholarship affording training in connection with electrical railway signalling, a branch of engineering with which the benefactor was particularly associated.

The Council have set up a Scholarships Committee, representative of education and industry, to settle the method and conditions of award of these new scholarships and also to deal with all scholarships and similar awards administered by the Institution.

(24) Activities of Overseas Members.

The possibility of increasing the Institution's activities in India and the Dominions has had the careful consideration of the Council, and, as a result of information which has been obtained from the Local Hon. Secretaries in the countries concerned, the Council have decided to encourage the holding of meetings abroad for the reading and discussion of selected Institution papers. Where this, or the holding of social functions, is found practicable, the Council have sanctioned the setting up of Local Advisory Committees, which, it is considered, will be of great value, not only in organizing meetings, but in acting as local sources of information on Institution matters. Financial assistance will be provided by the Institution so as to enable the Committees to carry out their duties more efficiently.

(25) Professional Engineers' Act (Queensland).

Under the provisions of the above Act, which was passed in 1929, Corporate Membership of the Institution is one of the qualifications entitling to registration as a professional engineer in Queensland, Australia.

(26) Local Hon. Secretary for Italy.

In place of the late Mr. Guido Semenza, who was Hon. Secretary of the Institution for Italy from 1903 until his death in 1929, the Council have appointed Mr. L. Emanueli of Milan.

(27) International Relations.

The Council have decided that the Institution should give its official support to the following international technical organizations:—

The International Electrotechnical Commission.
The World Power Conference.
The International Commission on Illumination.

The Institution has also become an Associate Member of the "Commission Mixte Internationale pour les expériences relatives à la protection des lignes de télécommunication et des canalisations souterraines."

(28) Paris International Conference on Large E.H.T. Supply Systems.

The fifth session of the above Conference took place in Paris from the 6th to the 15th June, 1929. The number of countries represented was 29, Great Britain being represented by 46 members. The delegates appointed by the Institution were Mr. P. V. Hunter, C.B.E. (chief delegate), Mr. J. R. Beard, M.Sc., and Mr. Johnstone Wright.

The number of papers read before the Conference was 100.

(29) Anniversary Celebrations and Conferences, etc., of Other Bodies.

During the year under review, the Institution has been represented at Anniversary Celebrations and Conferences, etc., arranged by other bodies, as shown in the following table:—

Name of Body	*Nature and Date of Function*	*Names of I.E.E. Representatives*
École Centrale des Arts et Manufactures, Paris.	Centenary (26–28 May, 1929).	Mr. F. Gill (Past President). Mr. P. F. Rowell (Secretary).
Elektrotechnischer Verein, Berlin.	Jubilee (24–27 Jan., 1930).	Mr. Ll. B. Atkinson (Past President). Dr. A. H. Railing (Vice-President).
American Society of Mechanical Engineers.	Jubilee (April, 1930).	Mr. Gano Dunn (Local Hon. Secretary, United States of America). Mr. W. H. Patchell.
World Engineering Congress, Tokyo, Japan.	Oct., 1929.	Mr. F. Gill (Past President).
Royal Technical College, Copenhagen.	Centenary (30 Aug., 1929)	Mr. E. B. Petersen.
South African College, Cape Town.	Centenary (1–5 Oct., 1929).	Major F. Pickering (Local Hon. Secretary, Cape, Natal and Rhodesia).
Smoke Abatement League of Great Britain.	Exhibition, Manchester (Nov., 1929).	Mr. T. E. Herbert (Chairman, North-Western Centre).
Association of Teachers in Technical Institutions.	Annual Conference, Liverpool (18–21 Oct., 1929).	Mr. S. E. Britton [Chairman, Mersey and North Wales (Liverpool) Centre].
Royal Sanitary Institute.	Annual Congress, Sheffield (13–20 July, 1929).	Mr. S. E. Fedden (Past Chairman, North Midland Centre).

In the case of the first four bodies mentioned above, Addresses of Congratulation were presented by the delegates on behalf of the Institution. A letter of congratulation was also sent by the Institution to the Hungarian Electrotechnical Society on the occasion of the 25th Anniversary of its foundation, which was celebrated at Budapest on the 19th May, 1929.

(30) Annual Conversazione.

The Annual Conversazione was held at the Natural History Museum, South Kensington, on the 4th July, 1929. The attendance was, as usual, very large, nearly 1 850 members and guests being present.

(31) Annual Dinner.

The Annual Dinner was held at the Hotel Cecil, London, on the 6th February, 1930, when over 650 members and guests were present.

An account was published in the May number of the *Journal* (page 651).

(32) STANDARDIZATION OF VOLTAGES.

The Committee appointed by the Council to consider the above question have duly presented a Report covering their terms of reference (which were set out in full in the last Annual Report), and as a result a statement by the Council on the subject was published in the April number of the *Journal* (page 516) and also circulated to the technical Press.

The Council desire to put on record their appreciation of the assistance and co-operation rendered by the Electricity Commissioners, the British Electrical and Allied Manufacturers' Association and the Electric Lamp Manufacturers' Association in the preparation of the Committee's Report.

(33) ELECTRICAL APPOINTMENTS BOARD.

A classified register of members seeking positions, containing particulars of their training and experience, is available for inspection at the Institution offices, and the Secretary of the Board will gladly put employers in touch with highly qualified electrical engineers.

The number of applicants on the register on the 25th March, 1930, was 47, against a total of 36 last year.

The Council earnestly hope that members who are in a position to assist will not fail to make use of the register.

(34) LIBRARY.

During the year, 204 books and pamphlets were presented to the Reference Library by members and others, and 113 volumes have been purchased. The total number of readers for the year was 6 018, of whom 305 were non-members, as against 5 985 and 285 respectively in 1928–1929.

Eighty-six new volumes were added to the Lending Library and 2 462 books were issued to 949 borrowers, the corresponding numbers for the previous year being 2 257 and 1 006 respectively.

(35) GIFTS TO THE INSTITUTION.

The Council express their cordial thanks to the donors of the following gifts to the Institution:—

Donor	*Gift*
Mr. H. Cotton ..	Three wood fuse cases and an early switch.
Mr. C. W. S. Crawley	Carbon brushes used with Forbes "non-polar" dynamo, 1884.
Prof. A. E. Kennelly	Photostat copy of an autograph letter of Michael Faraday dated 19th Feb., 1858, to the late Mr. C. V. Walker, F.R.S., a former President of the Institution.

(36) FARADAY CENTENARY CELEBRATIONS.

It is proposed to celebrate in 1931, during the month of September, the centenary of Faraday's discovery of electromagnetic induction, from which have developed most of the practical applications of electricity. The Institution is closely co-operating with the Royal Institution in the matter and proposes to arrange for an Exhibition at the Albert Hall, London, on strictly scientific lines, with the object of bringing to the knowledge of the public the results of Faraday's discovery. The Institution proposes to contribute from its funds a sum not exceeding £10 000 towards the cost of the Exhibition, instead of asking its members to contribute individually towards this very important celebration, as had been at first suggested.

(37) JUBILEE OF THE INCANDESCENT LAMP.

In connection with the celebrations of the above Jubilee held in America in June 1929, the Council addressed a letter to the International Illumination Commission and other bodies with a view to placing on record Swan's pioneer work on the incandescent electric lamp.

(38) ROYAL COMMISSION ON THE CIVIL SERVICE.

As the result of a letter from the Institute of Physics drawing attention to the absence of scientists from the personnel of the above Commission, the Council appointed the President and Mr. J. M. Kennedy as representatives to attend a conference of Scientific Institutions for the purpose of discussing the matter and deciding what action, if any, should be taken.

(39) SUBSCRIPTIONS OF RETIRED MEMBERS.

In view of the fact that many members have to retire from the profession compulsorily at age 60, but, nevertheless, desire to retain their membership of the Institution, the Council have revised the Rule adopted in 1927 which applied to retired members of not less than 65 years of age, and it now reads as follows:—

> "Any Corporate Member who has reached the age of 60 and has retired from the practice of his profession or business, may apply to the Council to remit his future annual subscriptions, provided that his membership of the Institution has been continuous for at least 25 years. If he desires to have the publications of the Institution he will receive them on payment of £1 1s. per annum."

The Council are glad to note that since the adoption of the original Rule a number of members of long standing have been enabled to continue their membership.

(40) BEQUEST.

The Council desire to record a bequest of £200 to the Institution under the Will of the late Mr. H. L. Leach, Member, of which £100 is to be applied to the Benevolent Fund, and £100 "to the Research Fund of the Institution or to any other purpose which the Council for the time being of the Institution may consider desirable."

The latter amount has been handed over to the British Electrical and Allied Industries Research Association.

(41) "SCIENCE ABSTRACTS."

The Physics volume of *Science Abstracts* for 1929 contains 3 687 abstracts, as compared with 3 355 in 1928. The Electrical Engineering volume contains 2 250 abstracts, as compared with 2 110.

The very slight interest taken in *Science Abstracts* by the general body of members is a matter of considerable disappointment to the Council. The publication, which appears monthly in two sections, namely, Section " A " (Physics) and Section " B " (Electrical Engineering), and consists of full abstracts from the leading scientific and technical journals, and the proceedings of learned societies of the whole world, presents in a form convenient for immediate reference a complete and concise record of the progress of physical science and electrical engineering. It is therefore surprising that, out of a membership of some 14 000, fewer than 1 500 subscribe to *Science Abstracts*, only 779 members subscribing to both Sections and 646 to Section " B."

The Council hope that greater support will be given in future to the publication, which, if ordered in advance, is obtainable by Students of the Institution, as well as by Graduates under the age of 28, at the special rate of 7s. 6d. per annum for both Sections, or 5s. for either the Physics or the Electrical Engineering Section, and by all other members of the Institution at 20s. for both Sections, or 12s. 6d. for either Section alone, the rates charged to the general public being £1 15s. per Section, or £3 for both Sections.

(42) Model General Conditions for Contracts.

The proposed set of Model Conditions " E " for the supply and laying of cables at home have not yet been completed.

(43) Regulations for the Electrical Equipment of Ships.

A number of alterations and additions to the second edition of the above Regulations have been approved by the Council, and they are set out in a supplement, copies of which can be obtained on application to the Secretary.

(44) Regulations for the Electrical Equipment of Buildings.

There continues to be a steady demand for copies of the Ninth Edition of the above Regulations issued in May 1927, which is an indication that they are being more and more widely adopted. The drafting of the Tenth Edition is in progress.

The supplement, issued in June 1928, containing requirements in regard to radio apparatus connected to public or private supply mains has been revised and copies will shortly be available.

Towards the end of 1929 the Council addressed to a number of interested bodies the following letter urging the desirability of steps being taken in the direction of a more general adoption of the Institution's Wiring Regulations:—

" Dear Sir,

" The present policy of National Electrical Development is leading to a very extended adoption of electricity, especially in the smaller private houses, where the users are mainly non-technical people.

" The standard supply now being adopted throughout the country is alternating current at a pressure of 230 volts, and the effects of a shock from alternating current are known to be more serious than in the case of direct current.

" The use of electricity is perfectly safe provided a few simple precautions are complied with—electricity is a good servant but a bad master.

" The chances of a consumer receiving a shock are practically eliminated if the wiring installation is carried out in a correct manner and all electrical appliances are used in the right way. Such appliances and apparatus (including wireless apparatus), which are becoming more and more popular, can be purchased by any consumer and connected to an existing lampholder or plug without essential precautions, particularly as regards earthing, being taken.

" This matter has been receiving the earnest consideration of the Council of this Institution, and they would urge upon your Institution (Association) the importance of safeguarding the public if the development of electricity supply is not to be retarded by avoidable fatalities.

" In this connection the Council have instructed me to draw your attention particularly to the desirability of the 'Wiring Regulations' issued by this Institution being observed. These Regulations have been framed with a view to securing safety from fire and shock, and the Council would appreciate any steps which your Institution (Association) may see their way to take to ensure a more general compliance with such Regulations.

" The Council will be pleased to provide you with any further information or assistance that you may require to secure the desired result."

" I am, dear Sir,
Yours faithfully,
P. F. Rowell,
Secretary."

At the same time the Council also caused the following letter to be published in the technical Press, including a number of architects' and builders' journals:—

" Dear Sir,

Smethwick Fire Disaster.

" The attention of the Council of The Institution of Electrical Engineers has been drawn to newspaper reports of the proceedings at the inquest, which concluded on the 25th September last, upon eleven persons who lost their lives by reason of a fire at premises in Rolfe Street, Smethwick, on the 2nd September.

" Some of the evidence purported to show that the fire was due to a defective electrical installation in a neighbouring building, and in this connection one of the witnesses condemned the use of lead-covered rubber-insulated cables for the wiring of public buildings. This statement has caused great uneasiness in the minds of consulting engineers, architects, electrical contractors and others, inasmuch as the use of lead-covered rubber-insulated cables is permitted by, and the proper methods of installation of such cables are set out in, the 'Regulations for the Electrical Equipment of Buildings' issued by the Institution. These Regulations are recognized by consulting engineers, electrical contractors, electricity supply authorities and the Fire Offices, as representing the best standard practice, and the Fire Offices in particular recommend their use.

"The Council re-affirm, therefore, that they are of the opinion that lead-sheathed cables are both suitable and safe for electrical installations if installed and maintained in accordance with the I.E.E. Wiring Regulations.

"From the evidence given, as reported in the newspapers, there is every indication that the electrical installation which, it is suggested, caused the fire at Smethwick, did not comply with these Regulations."

"I am, dear Sir,
Yours faithfully,
P. F. Rowell,
Secretary."

(45) Electricity Regulations.

During the year under review, the Electricity (Supply) Regulations Committee received from the Electricity Commissioners a proof of the new Code of Safety and Supply Regulations proposed to be made under the provisions of the Electricity (Supply) Acts, 1882 to 1928. These proposed Regulations were largely based upon the draft which was submitted by the Committee to the Commissioners in 1926, and the Commissioners requested the Regulations Committee to let them have, at an early date, any observations which they might desire to offer on the proof. In due course the Committee submitted their observations to the Council, but the matter was referred back to the Committee for them to carry out certain suggestions made by Members of Council. A second report was subsequently made to the Council and this is still under consideration.

(46) Benevolent Fund.

The Committee of Management of the Benevolent Fund of the Institution report that on the 31st December, 1929, the total assets of the Fund amounted to £16 500 17s. 11d., of which £14 242 8s. 4d. was on Capital Account, and £2 258 9s. 7d. in respect of unexpended Income. These figures include legacies of £100 each from the late Dr. C. S. du Riche Preller and the late Mr. H. Louis Leach (Members). The donations and subscriptions to the Fund in 1929 amounted to £2 296 5s. 3d., in which amount are included the proceeds of Golf Competitions organized by the Mersey and North Wales (Liverpool) and Scottish Centres.

Year	Subscriptions and donations received	Total grants made during year	No. of cases assisted
	£	£	
1920	821	341	11
1921	616 809 (Hughman collection)	525	14
1922	632 1 768 (Hughman collection)	776	16
1923	637	1 034	21
1924	1 152	1 323	26
1925	1 241	1 199	30
1926	1 484	1 498	32
1927	1 574	1 307	29
1928	1 998	1 409	32
1929	2 296	1 539	32

In the course of 1929, 99 grants were made to 32 persons, amounting to a total of £1 538 15s. 0d. The table in the preceding column summarizes the operations of the Fund during the last 10 years.

The Council most earnestly desire to bring the Fund to the notice of all members of the Institution. Donations and promises of annual subscriptions of any amount will be gratefully received.

(47) Summary of Annual Accounts.

Excess of Income over Expenditure.—After making provision for contingencies, there is a balance to the good on the Revenue Account for 1929 of £5 242 6s. 8d. This amount, which has been carried to the credit of the General Fund, compares with £6 040 10s. 6d. in 1928.

Assets.—Taking the investments at cost and the Institution Building and lease, the library and furniture, etc., at the values standing in the books after writing off depreciation—

	£	s.	d.
the Assets amount to	186 343	4	10
against Liabilities	10 200	14	3
leaving a surplus of	176 142	10	7
which, in comparison with that of the year 1928, viz.	168 078	2	2
shows an improvement of	£8 064	8	5

The surplus of £176 142 10s. 7d., referred to above is made up as follows:—

Assets.	£	s.	d.	£	s.	d.
Institution Building and lease				73 028	6	10
Investments, cash, etc.				105 706	1	3
Stock of paper, libraries and furniture				7 608	16	9
				186 343	4	10
Less *Liabilities.*						
Trust Fund Accounts	812	5	10			
Sundry creditors ..	4 750	4	2			
Repairs Suspense Account	4 205	9	1			
Subscriptions received in advance	432	15	2			
				10 200	14	3
				£176 142	10	7

Investments.—The investments (including re-investments and conversions) made during the year were as follows:—

	£	s.	d.
£1 000 5 per cent War Stock (1929–47) cost	1 024	10	6
£2 380 4 per cent Consolidated Stock cost	2 000	0	0
£3 000 Birmingham Corporation 4½ per cent Stock (1948–68) cost	2 906	11	0
£3 000 London County 4½ per cent Stock (1945–85) cost	2 936	11	0
£1 000 Bootle Corporation 4¾ per cent Stock (1949–59) cost	967	12	0
£5 000 5 per cent Conversion Stock (1944–64), first instalment of £10 per cent	500	0	0
	£10 335	4	6

(48) THE INSTITUTION AND BODIES ON WHICH IT IS REPRESENTED.

Appendix C shows in diagrammatic form the organization of the Institution and the bodies on which it is represented.

APPENDIX A.

MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since 1st April, 1929, are shown in the following table:—

	Hon. Mem.	Mem.	Assoc. Mem.	Com.	Assoc.	Grad.	Stud.	TOTAL
Totals at 1 April, 1929	13	1 959	5 356	—	287	2 633	3 313	13 561
Additions during the year:—								
Elected ..	1	1	136	4	42	142	767	1 093
Reinstated	—	1	4	—	1	6	41	53
Transferred to ..	—	50	184	132	1 624	880	33	2 903
Total ..	1	52	324	136	1 667	1 028	841	4 049
Deductions during the year:—								
Deceased ..	1	36	25	3	4	6	5	80
Resigned ..	—	9	32	9	52	45	52	199
Lapsed ..	—	7	46	—	55	18	102	228

We beg to report that we have audited the Balance Sheet of The Institution of Electrical Engineers, dated 31st December, 1929, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct, and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

15th April, 1930.

A THERMIONIC VALVE POTENTIOMETER FOR AUDIO FREQUENCIES.*

By W. S. STUART, M.Eng., Associate Member.

(*Paper received* 21*st November*, 1929.)

SUMMARY.

A description is given of a method of measuring audio-frequency potential vectors with the aid of thermionic valves. The arrangement used is a modification of one originally given by A. Pagès, and is adapted for tests on circuits such as artificial lines. A method of estimating the admittance existing between the input potential terminals is described.

TABLE OF CONTENTS.

Introduction.
Description of the circuit.
Admittance between the potential terminals.
General remarks on the use of the circuit.

INTRODUCTION.

The measurement of audio-frequency potential vectors is conveniently carried out by means of the well-known circuit, described by Larsen,† in which the e.m.f. derived from the secondary coil of a variable mutual inductance is added to the potential-drop across a pure resistance in series with its primary coil. The total potential provided by this arrangement, which is thus of the form $(R + j\omega M)I$, where I is the current carried by the resistance and primary coil, is balanced against the potential to be measured, the detector being usually a telephone. Balance is effected by simultaneous adjustment of the resistance and mutual inductance, the former measuring the horizontal component and the latter the vertical component of the potential vector, with reference to the phase of the current passing through the circuit.

Larsen, in the paper referred to above, has drawn attention to the care necessary to avoid the effects of stray capacities, particularly in connection with the detector. The disturbing effects of body capacity when telephones are used are well known to users of a.c. bridges, and while, in the case of the bridge, capacity effects may be annulled by taking suitable precautions, there is little doubt that in the potentiometer circuit here considered the capacity existing between the detector and earth may seriously affect the accuracy of a reading. The effect is particularly marked when the method is used to measure the potential developed in a circuit of high impedance.

The difficulty is removed if use is made of triode valves, in that, since the detector is placed in the anode circuit of a valve, its capacity is not thrown across any part of the circuit containing the measuring instruments.

A scheme involving the use of two triodes for this purpose is shown in its simplest form in Fig. 1, the triodes having identical characteristics. The potential to be measured is applied between the grid and filament of V_1, while an equal and opposite potential, derived from the combination of resistance and mutual inductance, is applied to the grid of V_2. Balance is effected by adjusting for silence in the telephone which is common to both anodes.

A practical potentiometer based on this principle has been described by A. Pagès,* in which a mutual inductance with central zero is used, the arrangement thus permitting the measurement of potential vectors lying within ± 90° of the potentiometer current vector.

In conducting experiments with an artificial telephone line, the author found it desirable to have a potentiometer with which rapid measurements of potential vectors lying in any quadrant could be made, at frequencies up to 4 000 cycles per sec. After experimenting with several circuits of the type referred to above, it was finally decided to adopt one involving three triodes. This circuit, which is described below, is particularly suited to artificial-line measurement but can, of course, be used for the determination of any potential the magnitude of which is not greater than that which the valves can handle.

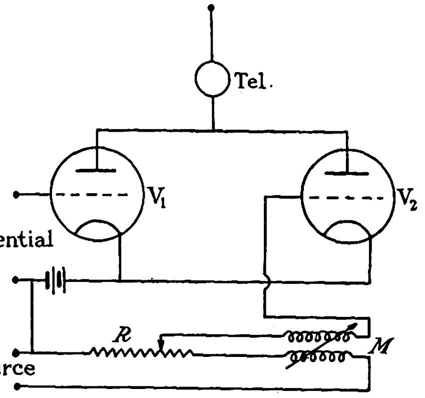

FIG. 1.

DESCRIPTION OF THE CIRCUIT.

It will be seen from the circuit diagram, Fig. 2, that the valve V_2 obtains its grid potential from the resistances R and r, the former consisting of a box with 10 sections and the latter of a slide-wire, while the grid of V_3 is connected to the secondary of the variable mutual inductance M. The primary winding of M is in series

* *Revue Générale de l'Électricité*, 1926, vol. 19, p. 381.

with R and r, the current passing through this circuit being measured by the thermo-ammeter A. This arrangement enables one end of the secondary winding to be always at earth potential and has been found to minimize the effect of impurity due to capacity between the windings. The advantage is also secured that the switches for reversing the component potentials may be transferred to the anode circuits of their respective valves. Any errors introduced by spurious capacity effects in the grid circuits are thus made definite and may be allowed for if necessary.

The anodes of the valves are connected respectively to three identical coils, L_1, L_2, L_3, mutually coupled by being wound on a ring-shaped iron core. Provided that the mutual conductances of the valves are similar, an e.m.f. applied to the grid of V_1 (i.e. between the terminals E and E′) may be balanced by the component e.m.f.'s applied to the grids of V_2 and V_3, when the alternating m.m.f.'s due to L_2 and L_3 exactly balance that due to L_1. Under balance conditions the anode circuits are therefore non-inductive. A fourth winding L_4, connected to a telephone, serves to detect the condition of balance.

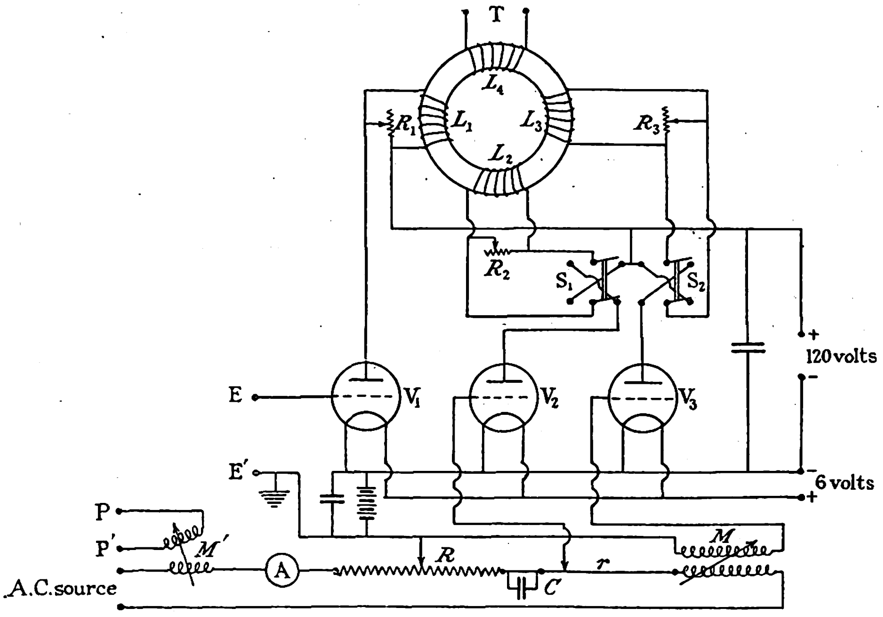

FIG. 2.

It is, of course, essential that the variations of anode current for a given grid voltage, i.e. the mutual conductance, should be the same for each of the three valves. The author attempted to adjust this, in the first place, by varying the filament currents. It was quickly discovered, however, that valves having nominally similar characteristics were actually so different in respect of their mutual conductances that the process of balancing by means of the filament current led, in the case of many valves, to a reduction of the emission below the minimum which could be tolerated. It was finally decided to balance the magnification by means of variable resistances shunting the anode coils as shown. This method was found to be quite satisfactory in practice, since, if the anode coils are tightly coupled, the resistances may be widely different from one another without introducing phase-angle errors.

A variable mutual inductance, shown at M', supplies current from its secondary winding for the circuit under test. In the apparatus as set up by the author the anode coils have 150 turns each, three wires being wound in parallel and uniformly distributed round the ring-shaped core. The latter is built up with 20 laminations of mumetal, having an outside diameter of 5·5 in. and an inside diameter of 3·75 in. The thickness of each lamination is 0·0225 in. The winding L_4 has 500 turns, wound on top of the others. The valves have an a.c. resistance of approximately 3 000 ohms, and with a grid potential of −12 volts pass a current of 12 mA. The anode potential is 120 volts. The resistances R_1, R_2, R_3 are continuously variable and have a maximum value of 5 ohms.

An oscillator of the heterodyne type is used to supply the potentiometer current, which is normally 30 mA. The resistance R consists of 10 sections of 10 ohms each, while the slide-wire r, 1 metre in length, is adjusted also to 10 ohms. The maximum potential which can be balanced by the resistance component is thus 3·3 volts. The mutual inductance M is a standard Campbell inductometer having a maximum value of 11·1 mH.

The employment of a mutual inductance makes the accuracy of the method dependent on an exact knowledge of the frequency. A stretched-wire vibrator,[*] calibrated by tuning-forks, has been used with success, it having been found possible to determine, to an accuracy of ±0·5 per cent, frequencies which are fundamental or are multiples of the fundamental. An alternative method is to make use of a condenser, shown at C in Fig. 2, inserted in the slide-wire circuit. With R and

---

[*] P. K. TURNER: "A Wireless Works Laboratory," *Journal I.E.E.*, 1927, vol. 65, p. 881.

r set at zero, and the filament of V_1 extinguished, a balance can be obtained by adjustment of M. Provided that the phase angle of C is not large, there is no difficulty in arriving at an accurate setting of the inductometer. The frequency is then given by

$$\omega = \frac{1}{\sqrt{(MC)}}$$

ADMITTANCE BETWEEN THE POTENTIAL TERMINALS.

Since one of the most important properties of the 3-electrode valve is the small input admittance of the grid-filament circuit, its utility as a potential-measuring device in association with high-impedance circuits is without question. It is important, however, to know the magnitude of this admittance, so that allowance can be made for it if necessary, e.g. in the measurement of small capacities, and the amount of error introduced by neglecting it, in other cases, known. The admittance of the valve V_1 may be measured in the following way:—

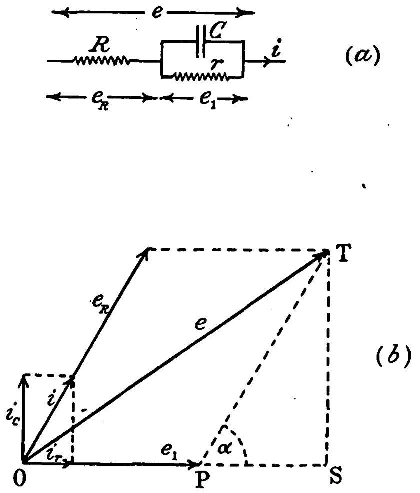

FIG. 3.

The e.m.f. obtained from the terminals P and P′ is measured by connecting these terminals respectively to E and E′. A known pure resistance of the order of 2 megohms is then inserted between P and E and a fresh balance obtained. In this way are obtained the vector voltages which are shown as e and e_1 in Fig. 3(a). In this diagram the valve admittance is represented as a capacity C shunted by a resistance r. The drop across the inserted resistance R is shown as e_R. It is, of course, assumed that the voltage e remains at the same value throughout. Then, referring to the vector diagram, Fig. 3(b),

$$\frac{e_R}{e_1} = R\sqrt{\left[(C\omega)^2 + \frac{1}{r^2}\right]} = \frac{R}{r}\sqrt{[(C\omega r)^2 + 1]}$$

or

$$\frac{(C\omega r)^2 + 1}{r^2} = \frac{1}{R^2}\left(\frac{e_R}{e_1}\right)^2$$

and, since $\tan \alpha = C\omega r$,

$$\frac{\tan^2 \alpha + 1}{r^2} = \left(\frac{e_R}{Re_1}\right)^2 = \frac{1}{r^2 \cos^2 \alpha}$$

or $$r = \frac{Re_1}{e_R \cos \alpha} \quad \text{and in the figure is } R \cdot \frac{\mathrm{OP}}{\mathrm{PS}}$$

also $$C = \frac{\tan \alpha}{\omega r} = \frac{\tan \alpha \,.\, e_R \cos \alpha}{\omega R e_1} = \frac{e_R \,.\, \sin \alpha}{\omega R e_1}$$

and in the figure is $$\frac{1}{\omega R} \cdot \frac{\mathrm{TS}}{\mathrm{OP}}$$

The values of C and r may thus be conveniently obtained by plotting on squared paper the vectors e and e_1 as given by the potentiometer readings. In performing this test on various valves in the position V_1, it was found that the holder and also the cap of the valve contributed in no small degree to the total admittance.* The following figures show the results of tests, at 2 000 cycles, on a valve having the characteristics referred to above. The resistance R used in the grid circuit was of the grid-leak type and had a value of 1·84 megohms.

	C	r	cos α
	μμF	MΩ	
Valve with cap and holder	22·7	31	0·11
Valve with cap only ..	14·6	54	0·10
Valve without cap and holder	12·2	92	0·07

These figures show the desirability of dispensing with the ordinary mounting of the valve, and the apparatus in its final form now has the valve V_1 supported by means of the bulb, so that direct connection can be made to the grid lead which comes through the glass. The valves V_2 and V_3 are held in ordinary holders.

GENERAL REMARKS ON THE USE OF THE CIRCUIT.

In the setting up of the apparatus it is important to guard against the influence of stray magnetic fields. Unless care was taken to keep these components well separated, it was found that a considerable amount of coupling took place between the inductances M and M' and the anode coils, notwithstanding the toroidal shape of the latter.

The anode shunting resistances are set in the following way:—The grid of V_1 is joined to that of V_2, and a potential is applied to both from the resistance box R. With the switch S_2 open, and S_1 closed in the "first quadrant" position, R_1 and R_2 are adjusted until silence is obtained in the telephone. The grid of V_1 is then connected to that of V_3 and a potential applied to both from M, the switch S_1 now being open and S_2 closed in its "first quadrant" position. Adjustment is now made to R_3 for silence. The adjustment is quite critical, and these rheostats should therefore be capable of continuous variation. Care should be taken to earth the common negative connection to the batteries as shown in Fig. 2.

When taking a reading of potential, the quadrant in which the vector lies may be determined from the position of the switches. It will be evident that when these switches are both in the "first quadrant" position the connection to the anode coils should be such that the magnetic effects of L_2 and L_3 are additive, while both are in opposition to L_1. As in the case of the valve voltmeter, the circuit connected to the input terminals must be a conducting one, in order that the grid-bias voltage may be applied to V_1. It will be found desirable to use a bias battery of rather less voltage than is customary when the valves are connected in an ordinary amplifying circuit, since in the present case the external anode impedance is almost zero.

* L. HARTSHORN: *Proceedings of the Physical Society of London*, 1927, vol. 39, p. 108; also G. W. SUTTON, *ibid.*, 1927, vol. 40, p. 14.

The by-pass condensers shown in the circuit diagram are preferably of large size in order to guard against the effects of unduly high resistance in the batteries.

It has been found possible to read values of potential, over the greater part of the range of telephonic frequencies, with a possible error of 1 mV on either scale. At frequencies below 200, on account of lack of sensitivity in the telephone it will be found advisable to employ a slide-wire current of greater value than the normal, or alternatively to use an amplifier in the telephone circuit.

The author wishes to express his indebtedness to the authorities of the University of Leeds for placing at his disposal workshop and testing facilities, and for permission to describe the apparatus.

AN ACCURATE METHOD OF TESTING BENT PERMANENT MAGNETS.[*]

By C. E. Webb, B.Sc. (Eng.), Associate Member, and L. H. Ford, B.Sc. (Eng.).

[From the National Physical Laboratory.]

(*Paper first received 15th October, and in final form 11th December, 1929.*)

SUMMARY.

The application of the search-coil method of measuring H to the testing of bent magnets by the use of jointed coils is fully described. The effects of distribution of magnetizing coils, location of search coils, reluctance of the joint between magnet and armature, and radial variation of magnetizing force are examined and the conditions for the maximum accuracy of measurement are determined.

LIST OF SYMBOLS.

H_m = maximum magnetizing force applied to magnet.
B_m = maximum flux density produced.
H_{res} = magnetizing force acting after magnetizing current is switched off.
B_{res} = flux density after magnetizing current is switched off.
B_r = remanence.
H_c = coercive force.
B_c = local flux density when mean flux density = 0.
A = area of cross-section of coil.
S = number of turns in coil.

INTRODUCTION.

Commercial tests on bent magnets—particularly on magneto magnets of horseshoe shape—are usually carried out by comparison with a standard of similar pattern to the magnet to be tested. The calibration of such standards involves the use of an absolute method of measurement, and presents considerably greater difficulties than the testing of samples of simple ring or bar form owing to the non-uniformity of the magnetic circuit which the bent magnets provide.

The application to horseshoe magnets of the search-coil method for measuring H by the use of flat coils placed inside and outside the magnet at the middle of the bend was suggested by A. Campbell and D. W. Dye,[†] and a further development, by the introduction of flexible coils, was described by D. W. Dye in the *Dictionary of Applied Physics*.[‡]

The method used in the present investigation was the same, apart from slight modifications in the construction of the search coils, as that described by Dye, and the measurements recorded were made with the object of determining the conditions for the highest accuracy by this method.

DESCRIPTION OF THE METHOD.

(1) *Search Coils.*—The measurement of the magnetizing force, H, by means of search coils depends on the fact that, with uniform magnetization, H in the iron is equal to H in the air adjacent to the surface of the iron and may, therefore, be measured by a thin coil placed tangentially very close to the iron, with its axis parallel to the lines of force. The coil is connected to a ballistic galvanometer and the deflection noted when the magnetizing current is reversed or altered, exactly as in the measurement of B.

For bent magnets, therefore, a coil having the shape of the magnet is essential. The accurate determination of the product of cross-section and number of turns, AS, is impracticable, however, on a bent search coil, but may readily be carried out in a long solenoid on a straight coil. Thus for satisfactory calibration, and also to allow of the same coil being used on magnets of different curvature, the coils must be flexible. A winding on a strip of press-spahn or similar material fulfils this condition, but it is difficult to be sure that distortion of the winding does not occur when the strip is bent, with consequent change in the value of AS from that found when calibrating. To obviate this source of error, search coils made up of short, rigid sections flexibly joined together are used. Each section is wound on a glass slip approximately 1 cm long and of a width suitable for the particular magnet under test (normally about 4 cm). The glass slips are first mounted in a cradle of silk ribbons about 5 mm wide, each ribbon passing alternately above and below successive slips, and being attached at the ends to two strips of linen tape. A flexible chain of glass slips is thus formed (Fig. 1). Silk-covered wire of fine gauge (44 S.W.G. usually) is then wound on the glass to form a flexible coil of which one section is shown in the figure. The whole is impregnated with wax to prevent the wire from coming away from the ends of the glass, and each section is covered with a binding of waxed silk for protection.

Two such complete coils are used, one on the outside and one on the inside of the magnet. To make the lengths along the magnet spanned by the two coils approximately equal without affecting the equality of the product AS, small glass rods are inserted between each pair of successive glass slips in the outer coil before winding. Two pairs of these jointed coils are used in the investigation, a long pair each of ten sections, approximately 14 cm in length and having a total AS of 650, and a short pair, each of five sections, approximately 6 cm in length and having a total AS of 280.

---

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[†] "The Magnetic Testing of Bars of Straight or Curved Form," *Journal I.E.E.*, 1915, vol. 54, p. 35.

[‡] Vol. 2: article on "Magnetic Measurements and Properties of Materials," pp. 465, 492.

The *B* search-coil consists of five or six turns of fine wire wound, over a layer of waxed silk, directly on the magnet and covering a length equal to that spanned by the *H* coils, which are placed as close to the magnet as possible, outside the *B* coil.

(2) *Magnetizing Coils and Armature.*—To obviate the labour of winding a magnetizing coil on the magnet for each test, a set of coils was made which could be slipped on over the search coils and connected together to form a continuous winding. These consist normally of four specially shaped coils—two, for the bend, of sector shape, and two, for the limbs, with sloped tops to fit closely against the sector-shaped coils (Fig. 2). These coils are designed to fill the space between the limbs of the magnet as completely as possible.

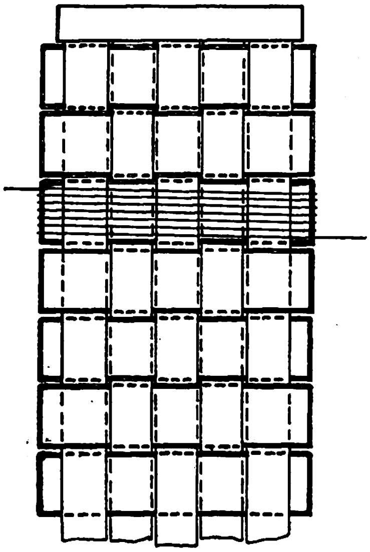

Fig. 1.—Construction of jointed search coils.

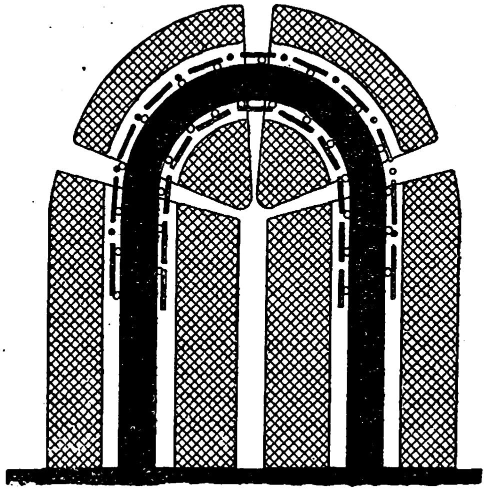

Fig. 2.—Arrangement of magnetizing coils and search coils on horseshoe magnet.

The armature for a magnet of normal length is a flat block built up of stalloy strips placed edgewise to the passage of flux and bolted together. The strips were annealed and subsequently lightly ground to give a flat surface of contact. For short magnets a U-shaped armature of soft iron annealed after cutting, and with ground faces, is used.

(3) *Method of Making Measurements.*—The value of the area-turns, *AS*, having been determined by standard methods for the *H* and *B* search coils, the ballistic galvanometer is adjusted by means of variable shunt and series resistances to be direct-reading for *H* and *B*. The magnetizing current is set to give the required maximum *H*, usually about 400 C.G.S. units, and this, together with the corresponding value of *B*, is measured by reversing the current with the *H* and *B* coils successively connected to the galvanometer. The magnetizing current is next switched off and the resultant values of demagnetizing field, H_{res}, and residual flux density, B_{res}, are measured. Further points on the hysteresis loop are then found by switching on suitable values of magnetizing current and noting corresponding changes of *H* and *B*. From the complete curves thus obtained the remanence, B_r, and coercive force, H_c, are deduced.

Description of Tests Made.

In the course of the investigation, tests were made on three horseshoe magnets having respectively no hole, one hole and two holes on each limb. Particulars of these are given in Table 1.

Table 1.

Magnet No.	Mean length	Section	No. of holes in each limb
	cm	cm^2	
1	23·4	3·55	None
2	27·1	4·4	1—approx. $\frac{3}{8}$ in. diam.
3	32·7	4·0	2—approx. $\frac{1}{4}$ in. diam.

(*a*) *Method of Magnetization.*—To check whether sufficiently uniform magnetization is provided by the made-up magnetizing coils, comparative tests were carried out with the made-up coils and with a winding of stout flexible cord wound as uniformly as possible along the length of the magnet. The results of measurements made on magnet No. 3 with short *H* coils placed first on the bend and secondly on the limb are given in Table 2, cols. (1) and (2). Agreement within 1 per cent between the two tests is shown, which is as good as can be expected on this form of test-piece after completely dismantling the magnetic and electric circuits and setting them up again.

It is not uncommon in testing horseshoe magnets to magnetize by means of coils on the limbs only. Further tests were therefore made, using only the two made-up coils which fit on the limbs. The results, recorded in Table 2, col. (3), show that, with search coils on the limbs, good agreement with the previous tests is obtained for coercive force, but appreciably lower values of B_m and B_r are found. As in this test only the limbs were subjected to the full magnetizing force ($H_m = 400$), this reduction may be due to incomplete magnetization of the bend producing non-uniform magnetization along the limb. The long *H* coils were therefore placed on the bend of the magnet and additional measurements were made both with the complete set of magnetizing coils and with coils on the limbs only. In this case the mean magnetizing force along the bend was raised to the maximum value of 400 (H_m on the limbs being considerably higher with magnetizing coils on the limbs only) and the results, given in Table 2, cols. (2) and (3), show very close agreement between the two tests. To obtain accurate measurements, therefore, it is important to subject the whole length of the magnet to a sufficiently high H_m, to ensure that the remanent flux density and the coercive force reach their maximum values at every point.

Provided that this condition is fulfilled, the location of the magnetizing coils produces a negligible effect even with such a non-uniform magnetization as is provided by coils on the limbs only. In all subsequent tests, therefore, made-up magnetizing coils were used.

TABLE 2.

Search coils	Quantity measured	(1) Uniform flexible winding	(2) Made-up coils	(3) Coils on limbs only
Short—on bend	B_m	14 930	14 910	—
	B_r	10 450	10 430	—
	H_c	63·6	63·0	—
Short—on limb	B_m	14 980	14 900	14 620
	B_r	10 140	10 120	9 640
	H_c	61·4	62·0	61·7
Long—on bend	B_m	—	15 340	15 190
	B_r	—	10 580	10 560
	H_c	—	62·0	62·3

(*b*) *Location of Search Coils.*—Comparative tests were made on each magnet with short search coils located entirely on the bend and also on the limbs, and with long search coils placed symmetrically on the magnet so as to embrace the bend and a portion of each limb. The results obtained are given in Table 3, cols. (1), (2) and (3).

TABLE 3.

Magnet	Quantity measured	(1) Short coils on limbs	(2) Short coils on bend	(3) Long coils	(4) Coils at join of limbs and bend
No. 1	B_m	16 100	16 070	16 030	—
	B_r	10 620	10 620	10 580	—
	H_c	59·1	59·1	59·6	—
No. 2	B_m	15 800	15 860	16 000	16 400
	B_r	10 370	10 920	11 000	11 120
	H_c	49·9	49·2	48·1	44·2
No. 3	B_m	14 900	14 910	15 340	15 890
	B_r	10 120	10 430	10 580	10 770
	H_c	62·0	63·0	62·0	58·0

It will be seen that on magnet No. 1 very close agreement is obtained between the tests on limbs and bend, while the test with long search coils also gives substantially the same results.

On magnets Nos. 2 and 3, however, the remanence values obtained on the limbs are considerably lower than those found on the bend. The tests with the long search coils on these two magnets also, somewhat surprisingly, give values of B_m and B_r higher than those found either on the limbs or on the bend. As there was a small gap between the portions of the magnet covered by the search coils in the separate tests on bend and limbs, a further set of measurements was made on this intervening length at the join of the bend and limb using a pair of very short H coils, about 1 cm long and approximately equivalent to one section of the jointed coils. As the AS value of these coils was small, the accuracy of this test was less than usual, but the results, recorded in Table 3, col. (4), appear to show conclusively that on magnets Nos. 2 and 3 higher values of B_m and B_r and lower values of H_c are obtained at the join of the bend and limbs than on either the bend or the limbs. Thus the material at such a point is appreciably softer than throughout the rest of the magnet. As this portion is included in the length tested by the long coils, the higher values of B_m and B_r recorded in Table 3, col. (3), are doubtless due to this difference in properties.

To show in more detail the variation of flux density along the magnet under various conditions of magnetization, a number of tests were made with localized B coils spaced 1 cm apart along half the length of the magnet. Measurements were made, with each coil, of the flux density at maximum magnetization (B_m), at switch-off (B_{res}), and when the mean B along the magnet was reduced to zero (B_c).

The results obtained on magnets Nos. 1 and 3 are plotted in Figs. 3 and 4 on a base-line having the shape of the axis of the magnet. For each curve the base-line is taken to represent the mean value along the whole magnet of the quantity in question, and the difference from this mean value is plotted normally to the base-line at each point, an excess being plotted outwards and a deficiency inwards.

The curves of B_m show that with made-up coils the bend is appreciably less highly magnetized than the limbs, owing to the limited space available for the magnetizing coils on the bend. The curves of B_{res} and B_c, however, show very constant values on the bend, with a fairly uniform decrease along the limb. A few measurements were also made of the distribution of B along the magnet when magnetized to the point on the negative part of the loop giving the maximum value of the product BH. A curve very similar in shape to those for B_{res} and B_c was obtained. As would be expected, the holes in magnet No. 3 cause considerable local variations in B_m and B_{res}, but have little effect on B_c.

All these measurements of B were referred to the mean value of H for the whole length of the magnet as given by a pair of long coils covering one limb and half the bend. The actual value of H varies to some extent along the magnet, and an attempt was made to investigate these variations, particularly at switch-off (H_{res}). For this purpose two very short H coils were placed successively over the various localized B coils, but owing to the necessity for dismantling the set-up after each test in order to move the H coils there was some uncertainty as to whether identical conditions of joint reluctance were obtained in all the tests. The results, however, indicated clearly that H_{res} had a larger negative value near the end of the limb than on the bend. Thus, although B_{res} is lower near the end of the limb than on the bend, the values of true remanence, B_r, deduced from local tests at the two points would be in much better agreement. In fact, Table 3 shows that on magnet No. 1 tests on the limbs and bend gave exact agreement for B_r. The lower values of B_r on the limbs than on the bend, shown by the same table for magnets Nos. 2 and 3, are explained by the effects of the holes in the limbs of these magnets.

(*c*) *Variation in Reluctance of Joints.*—The reluctance of the joint between the ends of the magnet and the armature influences the demagnetizing field along the magnet when the magnetizing current is switched off, i.e. H_{res}. To determine whether an alteration in H_{res} affects the results, tests were made with the joint reluctance increased by the insertion of paper between the magnet and its armature. The results are given in Table 4 and show that while the value found for the coercive force is unaffected by the magnitude of H_{res}, at least up to $H_{res} = 20$, the apparent remanence decreases as the negative value of H_{res} increases. The decrease, however, is very small for search coils on the bend, but becomes large for search coils on the limbs.

TABLE 4.

Search coils	Quantity measured	(1) No paper inserted	(2) 0·3 mm paper inserted	(3) 0·7 mm paper inserted
Long—on bend	H_{res}	$-7{\cdot}_0$	$-13{\cdot}_0$	$-21{\cdot}_8$
	B_r	10 500	10 480	10 440
	H_c	$62{\cdot}_0$	$62{\cdot}_0$	$61{\cdot}_8$
Short—on limbs	H_{res}	$-1{\cdot}_0$	$-11{\cdot}_4$	$-25{\cdot}_4$
	B_r	9 640	9 360	9 120
	H_c	$61{\cdot}_4$	$61{\cdot}_4$	$61{\cdot}_4$

Curves showing the variation of B_m, B_{res} and B_c along magnet No. 1 were also taken with a very large joint reluctance giving a value of $H_{res} = -30$, and are shown in Fig. 5. A comparison with Fig. 3 indicates clearly the increased variation in B_{res} along the magnet and the almost complete identity of the curve of B_c in the two cases. It will be seen, however, that B_{res} remains nearly constant along the bend, thus explaining the very small change of apparent remanence with increased joint reluctance when the measurements are made on the bend.

(*d*) *Radial Variation in Field.*—The difference between the magnetizing fields inside and outside the bend of a magnet was measured by mounting two short jointed H coils on the bend and connecting them separately to the ballistic galvanometer. The difference was practically a constant percentage of H and its magnitude in the readings of coercive force is shown in Table 5.

TABLE 5.

Magnet	Inner H	Outer H	Mean H
No. 2	$59{\cdot}_1$	$39{\cdot}_3$	$49{\cdot}_2$
No. 3	$76{\cdot}_0$	$50{\cdot}_0$	$63{\cdot}_0$

Appreciable error may be caused by averaging over such a wide range of H where the curvature of the hysteresis loop is large. To indicate the magnitude of such errors, measurements were made on the negative part of the loop in the region of $(BH)_{max.}$ on the bend and limb of magnet No. 1, which give agreement for remanence and coercive force (Table 3). The results in Table 6 show a small effect, though there may, of course, be a genuine difference between the shapes of the loops for bend and limb superimposed upon the error due to averaging over a range of B and H.

	0	− 59·1	− 59·1

DISCUSSION OF RESULTS, AND CONCLUSIONS.

The use of made-up magnetizing coils is first justified by the fact that, although they provide less magnetization on the bend than on the limbs, the comparison with a uniform winding of flexible cord in Table 2 shows identical results with each winding within the limits of accuracy of the measurements. Even with the coil sections on the bend removed, satisfactory results can be obtained, provided the maximum magnetizing force at every point of the magnet is sufficiently large to ensure that the remanent flux density and the coercive force reach the values which they would attain after saturation.

The results obtained at the join of the limbs and bend [Table 3, col. (4)] indicate that some variation in magnetic properties may occur along the magnet, but comparison between the results on limbs and bend in Table 3, cols. (1) and (2), shows very good agreement except for the effect on the values of remanence of the holes in the limbs of Nos. 2 and 3. This may be minimized by plugging the holes with small pieces of magnet-steel, but the effect of this operation is somewhat indeterminate. An alternative and more satisfactory method of avoiding the effects of the holes is to use long search coils covering the bend and the upper part of the limbs but not extending as far as the holes. A comparison of Table 3, col. (3), with cols. (1), (2) and (4), shows that these give results practically unaffected by the presence of holes.

The effect of a large joint-reluctance between magnet and armature, such as might result from badly ground poles, was also shown to be almost negligible on the results obtained with this arrangement of search coils, but to be considerable on those given by search coils on the limbs. Confirmation of the uniformity of the conditions around the bend and their comparative immunity from the influence of extraneous variations is given by the curves of distribution of B_m, B_{res} and B_c along the magnet in Figs. 3, 4 and 5.

The use of long search coils on the bend and upper part of the limbs only, is further justified by the fact that pole-shoes are normally fitted to the limbs of horseshoe magnets so that only the bend and a short part of the limb are fully effective in use.

The magnitude of the radial variation of H observed on the bend (Table 5) shows the importance of obtaining a true average of the values of H at the inner and outer surfaces of the iron. For this purpose, the values of the product AS must be made as nearly as possible equal for the inner and outer H coils, and it is also desirable that they should span the same portion of the magnet, i.e. that the outer coil should be a sufficient amount longer to allow for the greater radius on the bend. The good agreement obtained for the coercive force between the bend and the limb (where the radial variation does not occur) suggests that a satisfactory average of the inner and outer values has been obtained. Moreover, the influence of the radial variation would be less with the long search coils than that shown in Table 5, since the effect on the bend would be diluted by the parts of the coils on the limbs.

The conclusions reached are, therefore:—

(i) The use of made-up magnetizing coils is satisfactory, provided sufficient magnetization is applied along the whole magnet.

(ii) The most reliable results are obtained using search coils covering the bend and a short length of each limb, and avoiding any holes in the magnet. A length of 12 to 15 cm is suitable for the normal size of magnet.

(iii) High joint-reluctance of a magnitude likely to occur in practice produces only a negligible effect on the results if the above arrangement of search coils is used.

(iv) The inner and outer H coils must have as nearly as possible equal area-turns and should be adjusted in length to span the same portion of the magnet.

(v) The results recorded suggest that, when attention has been paid to the previous conclusions, the values obtained are accurate within 2 per cent.

In conclusion, the authors desire to express their hearty thanks to Dr. D. W. Dye, F.R.S., for helpful suggestions and criticisms in the course of the investigation.

DISCUSSION ON

"IMPEDANCE AND POWER LOSSES OF 3-PHASE OVERHEAD LINES." *

Mr. C. G. Carrothers (*communicated*): I notice that the authors confine their calculations to the reactance of the lines to symmetrical 3-phase currents and to the special case of one conductor of a line carrying a single-phase current with earth return. For short-circuit calculations it is more useful to know the reactance of the three conductors of the line carrying a single-phase current in equal parts with earth return, i.e. the reactance of the line to a symmetrical leakage current. In making short-circuit calculations a great deal of complication is avoided if it is possible to ignore the asymmetry of the lines and the difference in direction of the impedance vectors of the various parts of the circuits concerned. Several types of short-circuit calculating table depend for their accuracy on the admissibility of such assumptions. It would therefore be a very useful extension to the report if the authors would examine the errors involved by the approximations commonly made in the calculations of short-circuit currents.

Mr. E. Parry (*communicated*): There appears to be a conflict of evidence as to whether or not the inductance per unit length of a conductor with an earth return varies with the length of the line. I have some records of experiments by Nishi and Mori in Japan, according to which the inductance per unit length, and hence the depth of the virtual earth plane, varied with the length, and thus established the validity of Prof. H. Ho's equations.† On the other hand, the experiments of Mayr ‡ and Rüdenberg § afford evidence to the contrary, and point to the fact that the inductance per unit length is independent of the length of the line. Possibly the authors may be able to account for these discrepancies. Personally I have a suspicion that the cause of the conflict is to be found in the peculiarities of the terminal earth contacts. According to Heaviside || the d.c. resistance between two hemispherical electrodes of radius a placed on the surface of a homogeneous solid is $\rho/(\pi a)$, or $\rho/(2\pi a)$ per electrode, where ρ is the specific resistance of the material. It follows that one-half of the resistance lies between the electrode and the surface at a radius of $2a$, three-fourths at a radius of $4a$ and nine-tenths at a radius of $10a$, and consequently the resistance for a given radius depends materially upon the specific resistance of the soil in the vicinity of the electrode. Also the smaller the electrode the greater the variation in the resistance, for if we compare two electrodes of radii 1 in. and 12 in. respectively, 90 per cent of the resistance lies within a radius of 10 in. in one case, and within 120 in. in the other, but the variation in specific resistance is much greater in a depth of 10 in. than it is in a depth of 120 in. I do not think that the specific resistance of the general mass of earth near the earth's surface varies very much, but if account is not taken of the peculiarities mentioned above it may appear to do so, and different experiments will obtain values for the apparent specific resistance which will show a wide range of variation. The conditions favourable to a good earth connection are rare and are often a matter of considerable difficulty and expense, and for this reason the use of multiple earthing as advocated by the authors is to be commended. Has the earth resistance between pairs of towers on the grid system been measured, and, if so, what are the values? The results of such measurements are often surprising.

Messrs. P. D. Morgan and **S. Whitehead** (*in reply*): Replying to Mr. Parry, an earth current will have a theoretically uniform flow only when the earth plates are infinitely large or infinitely distant. In practice, however, substantially uniform flow, at any rate as far as impedance measurements are concerned, is attained under much less rigorous conditions depending upon the nature of the earth plates and upon the specific resistance of the soil. Tests made in Germany at Doberitz, Oldenburg and Munsingen, which gave a wide variation of local soil conditions, confirmed that, subject to an initial "earth plate resistance" the impedance and mutual inductance of the earth current were proportional to the length of line for lengths of the order of a few km.* On the other hand, it is not surprising if non-uniformity were to be observed when short distances in soil of high resistivity are considered or where local variations in geological structure occur. Our experiments gave agreement with theories based on the assumption of uniform flow, together with terminal earth-plate resistances. In the case of the Runcorn line the earth-plate resistances could not be measured directly, since the earth wire could not be disconnected. The resistances were, however, of the order of a fraction of an ohm by deduction from test-results and from the experience of the Mersey Power Co. Such low values were to be expected since the foundations of many of the towers were submerged in salt water at high tide. A number of measurements

were made on the Bedford–Little Barford line. The resistance from tower to tower was not measured but the subsidiary electrodes were distant 50 and 100 ft. respectively from the tower. Accordingly, the specimen figures given in Table A may be of interest. The impedances in Table A are at 50 periods per sec. As stated in the paper, the average value of the resistance of the earth plate and foundation in parallel was 2·5 ohms. It is to be noted that when the earth resistance was so connected that all the towers (about 50 in this case) were earthed in parallel, the resistance to earth at any given tower showed little variation, the figures of 0·76 and 0·38 ohm representing extreme values observed. It thus appears that the variation mentioned by Mr. Parry is to a large extent removed by multiple earthing and also by the use of earth grillage and Malone anchor foundations as on the "grid" system, several cases occurring where the earth plate was less efficient than the tower foundations. It may also interest Mr. Parry to know that with alternating current the earth-plate impedance is often partly reactive. In the theory developed by us for the effect of an earth wire the error due to this cause was negligible for the cases examined experimentally.

TABLE A.

Type of foundations	Earth-plate resistance	Foundation resistance	Resistance of earth plate and foundations	Resistance to earth with earth wire attached
	ohms	ohms	ohms	ohms
Concrete ..	2·58	1·65	1·25	0·76
Earth grillage ..	No earth plate	4·7	—	—
Malone anchor..	18·8	5·2	4·8	—
Malone anchor..	0·80	0·80	0·80	0·38

Mr. Carrothers raises a matter which it is desirable to include in a discussion of the line constants of overhead lines. The impedance of an overhead line to a symmetrical leakage current, that is, the "zero-phase impedance" in the method of symmetrical co-ordinates for short-circuit calculations, may be deduced from equation (31) of Appendix III in the paper by making $I_1 = I_2 = I_3$ and evaluating $\Delta e_1/I$. This gives the impedance of phase I. In practice, however, the asymmetry of the separate lines is ignored owing to the excessive complication introduced if this is taken into consideration. The error involved is small. For example, on the grid system, assuming an earth resistivity of 10 000 ohms per cm the difference between the zero-phase impedance of the lowest phase of an untransposed line and the impedance of a transposed line which is the mean of the phase impedances in the untransposed case is as follows:—

Single-circuit Towers:—

Impedance per phase (transposed)
$= 0{\cdot}625 + 1{\cdot}61j$ ohms per mile
Modulus $= 1{\cdot}73$ ohms per mile
Impedance of lowest phase
$= 0{\cdot}634 + 1{\cdot}56j$ ohms per mile
Modulus $= 1{\cdot}68$ ohms per mile

Double-circuit Towers:—

Impedance per phase (transposed)
$= 0{\cdot}613 + 1{\cdot}63j$ ohms per mile
Modulus $= 1{\cdot}77$ ohms per mile
Impedance of lowest phase
$= 0{\cdot}595 + 1{\cdot}62j$ ohms per mile
Modulus $= 1{\cdot}74$ ohms per mile

Accordingly we shall merely give here the formula for the zero-phase impedance of a transposed line:—

$$\begin{aligned} Z_0 = R_E &+ \left\{3ww_4/(w + w_4)\right\} + j\omega\Big[A + 2 \times 10^{-9} \operatorname{logh} \\ &\left\{h_1h_2h_3/b(s_{12}s_{23}s_{31})^{\frac{2}{3}}\right\} \\ &- 2 \times 10^{-9}\Big\{w \operatorname{logh}\left(h_4^3h_1h_2h_3/s_{14}^2s_{24}^2s_{34}^2\right) \\ &+ 2j\omega\mu_4 \operatorname{logh}\left(h_4^3/s_{14}s_{24}s_{34}\right)^{\frac{1}{3}}\Big\}/(w + w_4)\Big] \text{ ohms per cm} \end{aligned}$$

The symbols employed are those of Appendix I of the paper, with the addition of the following:—

$$w = \tfrac{1}{2}\pi\omega + 2j\omega \operatorname{logh}(2/\gamma K h)10^{-9} \text{ ohms per cm}$$
$$w_4 = R_4 + j\omega\left\{A_4 + 2\operatorname{logh}(h_4/r_4)\right\}10^{-9} \text{ ohms per cm}$$
$$r_4 = \operatorname{logh}(h_1h_2h_3/s_{14}s_{24}s_{34})10^{-9} \text{ ohms per cm}$$

This formula does not take into account the inductive action of other circuits or of balanced currents flowing in the same circuit. The effect of the latter may usually be neglected in short-circuit calculations. It may be noted that a single-phase short-circuit (the case worked out in detail in the paper) may be represented as the sum of equal positive, negative and zero-phase currents, the components being in phase in the fault phase. The overall impedance is therefore $\frac{1}{3}(Z_0 + 2Z)$, if Z is the balanced 3-phase impedance. If the values already given in the paper for Z and the value for Z_0 given above are substituted, then for single-circuit towers the single-phase impedance should be 1·05 ohms per mile, which is the same as the value for the middle phase directly deduced in the paper. The question as to whether the phase rotation may be neglected and the impedance treated as pure reactances * for short-circuit calculation depends upon the type of system concerned. Calculations have been made for a specimen interconnected system using lines of the single-circuit type, and the conclusion has been reached that the complex nature of the line impedances may usually be neglected except with long lines and complicated systems, if errors of 10 per cent in the absolute values of the short-circuit currents are admissible. It may also be remarked that the zero-phase impedance is two to three times greater than the balanced-current impedance in modern high-voltage lines.

---

* Suggested by Mr. Carrothers (*Electrical Review*, 1929, vol. 105, p. 309).

DISCUSSION ON

"THE ANALYSIS AND MEASUREMENT OF THE NOISE EMITTED BY MACHINERY."*

Western Centre, at Bristol, 11th November, 1929.

Mr. J. M. Bowman: It seems to me that it might have been advantageous if the authors had given some suggestions as to how to prevent noise in various types of machinery. It would have added interest to the paper and would have been useful to engineers in general. I sincerely hope, however, that the authors will continue their research work and ultimately prevent noises in our streets, and so receive the blessings of the Ministry of Transport.

Mr. S. B. Haslam: I was rather disappointed at not getting from the paper more information in regard to the steps which are being taken for the prevention of noise, but I can quite appreciate that this does not come within the scope of the paper and that there are good reasons for its exclusion. Not long ago I installed a 50-kW turbine set in a hospital and the noise effect was rather strange. The occupants of none of the wards near the generating station heard the hum at all, but the wards on the two top stories of an extension at right angles to the main block in which the station was situated were definitely affected by it. The experts who were consulted said that the noise must be due to air vibration, as ground sounds would affect the lower wards. They recommended that the station be insulated from the rest of the building by means of matchboarding with a distinct air space. This method was quite useless, so we tried filling the space with sawdust, but this again did no good. Someone then suggested trying the foundations and, after some trials and worry, a thin layer of a material called "Korfund" was placed under and around the foundations, with entire success. The only place where the hum could be heard was just outside the station. To everyone concerned it appeared to be very extraordinary that what was obviously a ground vibration should miss the two lower stories of the building, and be heard on the two upper stories. So far I have not found or heard of any reasonable explanation, and even the experts admit that little is known about it as yet.

Mr. F. O. Hunt: The paper is of great interest to one who was concerned with somewhat similar problems in anti-submarine work during the War, and I should like to congratulate the authors upon the precision attained in a difficult class of measurement and on the useful attempt to correlate the energy measurements to their effectiveness upon the ear. The investigation was complicated because extraneous noise might have opposite effects. In general, the amount of background noise makes a great difference to the lower limit of audibility, but on the other hand there are cases, especially in some classes of deafness, where a person can hear words spoken in a noisy tramcar but is unable to hear in a quiet room. The matter of total effective noise is closely akin to that of total effective light, for difference of pitch and difference of colour are exactly parallel difficulties. Similar methods should be applicable to both problems, but probably the ear is even more selective than the eye with regard to its most effective range and it also varies considerably in different individuals. I should like to support the authors' plea that extreme silence in motors should not be specified where it is not absolutely necessary. Otherwise, there would be a repetition of the unsatisfactory condition which obtained when 10-ampere and even 5-ampere increment limits were specified for d.c. starting switches. The orders always went to the firms who ignored the specification, because no check was applied to see that the specification was fulfilled.

Mr. J. McK. Knowlson: Most of us are practically concerned with the reduction in the noise of machines already in use, which probably remain as a legacy of our predecessors. Some solution is usually attempted by altering the foundations of a machine. I should like to ask whether the authors could expand their investigations so as to include the subject of the mechanical transmission of noise with various forms of mounting, particularly in consideration of the growth of ferro-concrete buildings, for which it is peculiarly difficult to find a solution. In the case of these buildings, mere height and distance are practically of no assistance in reducing the noise effects of a machine. I hope that the authors will give us, in a few years' time, further information on the subject of machine mountings as well as of machines themselves.

Mr. J. E. Macfarlane: I do not know whether in the course of their work the authors have dealt with clients who have specified freedom from audio-frequency noise, or whether they have any scale whereby a machine can be judged to be free from such noise. On page 122 of the paper mention is made of the "800-cycle standard mile." What does this mean? I should like to know whether this apparatus has been used by any inspecting department for checking audio-frequency noise. Some of the machines with which I have had to deal have passed the "freedom from audio-frequency noise" test. One day a machine was passed as satisfactory and the next day a similar machine, which to my insensitive ear appeared to be equally good, was rejected by the inspector, thus bearing out the authors' contention that individual judgment of sound values varies.

Prof. D. Robertson: The following calculation gives an interesting confirmation of the data of Fig. 1. The hammer of the great bell of the University of Bristol weighs 4 cwt. and falls 4 ft. at each stroke. The energy of each blow is thus about 150 joules, of which part is lost in the recoil of the hammer, and part is wasted in hammering out the metal and in the shock given to the building when the hammer falls. The loud sound dies away in less than 5 seconds, but the initial intensity of the sound is much greater than the average value. If that initial value is estimated as something approaching 100 watts, it is probable that about the right order of magnitude will be obtained. Neglecting reflection and other irregularities this would give 3×10^{-12} watt per cm^2 at a distance of 10 miles, corresponding to a sound pressure of, say, 0·05 R.M.S. dyne per cm^2 (see data on page 99). This is about the value given by Fig. 1 for a sound to be just audible when the frequency is 150 cycles per sec. (that of the bell), and actually the greatest distance at which the bell has been reported as audible is just over 10 miles. The authors' apparatus would be most useful for investigating some of the curious phenomena in the transmission of sound, of which one is the large effect on the range of audibility produced by winds whose velocity is less than 1 per cent of that of sound.

---

* Paper by Messrs. B. A. G. Churcher and A. J. King (see page 97).

Mr. A. M. Willis: It appears to me that in investigations such as those in which the authors have been engaged considerable differences arise, owing to the fact that they have been working without a general standard. Noise, as far as I can understand, affects us individually, each of us having his own idea as to the intensity or volume of any particular sound. An oculist can say, for instance, whether a person's sight is plus or minus normal, as he has a standard of vision. Without a similar standard, I fail to see how the subject of noise can be definitely attacked. I have had some experience of variations in the hearing powers of individuals, and have noticed many remarkable features. For instance, my wife who, unfortunately, is deaf, on certain occasions is able to hear the slightest whisper where I, who am credited with good hearing, cannot hear anything at all. I remember raising this point a few years ago with one of the greatest ear specialists then living. He informed me that he himself was deaf but that he could distinctly hear a partridge rising, where others were unable to do so. In dealing with machinery such as motors, where noise is a matter of some concern, it would be a great advantage to be able to speak in terms of definite units. To-day it is found that two people often have separate ideas on the sound emitted. Many years ago, I gave evidence in an action at Bristol in connection with an alleged public nuisance arising from a noisy motor (the motor in my opinion certainly was noisy). The action seemed to be going against the defendants but the counsel prevailed upon the judge to inspect the motor in order to satisfy himself. After so doing, the decision was given in favour of the defendants and I think that this would not have happened if the judge could have been given some definite figures in sound units. The work which the authors and the Metropolitan-Vickers Co. have done in this connection is, in reality, a public service.

Messrs. B. A. G. Churcher and **A. J. King** (*in reply*): In reply to Mr. Bowman, the reasons for our not giving information on methods of preventing noise in various types of machinery ought, we think, to be fairly obvious. We heartily agree that the reduction of street noise is a most urgent and important matter, but nearly all the noise arises from motor vehicles. Our object has not been to tackle every noise problem that has arisen, but only those that arise in the products of the company with which we are associated. Even the prospect of receiving the blessings of the Ministry of Transport will not deflect us from that course.

We are much interested in Mr. Haslam's description of noise arising from a turbo-set in a hospital building. Vibration is much more likely to be transmitted through the foundations than through the surrounding air, as events showed, but why the sound should appear at the upper stories and not at the two lowest stories is difficult to explain.

Mr. Hunt's point about the practically deaf person who can hear more easily in noisy than in quiet surroundings is interesting. We have come across a few such cases.

In reply to Mr. Knowlson, we intend to go into the question of the transmission of noise with different forms of mounting when we have an opportunity. We quite agree that the use of ferro-concrete enhances the difficulty of sound isolation and constitutes a serious problem.

In reply to Mr. Macfarlane, the requirement that a machine shall have "freedom from audio-frequency noise" is quite new to us. Just what does that phrase mean? All noise is of audio frequency. Is it seriously meant that the machine shall emit no noise whatever, even when run in perfectly quiet surroundings? No manufacturer would be prepared to guarantee that. On the other hand, if the test were made in a noisy machine shop and the observer did not stand too near, many machines of standard design could be deemed "free from noise" for those conditions, as the motor noise might easily be masked by the background of noise. This brings us to the question of standards, a point raised by Mr. Willis, who suggests that we have been working without a standard. We hoped that in the paper and in our remarks we had made the present position clear. The physical measurements, viz. the measurement of the frequency and pressure amplitude of the air-pressure waves that cause the sound, are on a perfectly definite and absolute basis. We have related these to the sensitivity of the average ear and have so obtained the scale of loudness for pure tones given in the paper. What we have not yet developed is a scale of loudness for complex sounds. This is a matter of some difficulty and must necessarily precede the setting up of standards of permissible noise for machines. Furthermore, it is necessary to correlate a large number of observations on machines of various types and sizes before standards of permissible noise can be formulated, since, while complete "freedom from noise" is no doubt the ideal standard, any commercial standard must be capable of being realized without undue difficulty. In other words, a practical standard must be a compromise.

After having taken us to task for working without a standard, Mr. Willis seems to doubt the possibility of a standard, since "each has his own idea of intensity." He then alludes to the oculist's standard for sight. Now sight and hearing obey very similar laws and we do not think that a definite standard for complex sounds is inherently more difficult of attainment than one for polychromatic light. Apart from persons who have undoubtedly defective hearing, the maximum and minimum audible intensities are fairly definite quantities, as shown in Fig. 1 of the paper, which gives not only the average values but the range of variation among persons with normal hearing. Compared with the total range of intensity which the ear can perceive as sound, it is seen that the range of variation is not large. The considerable differences which arise in considering sound intensities are due, we feel sure, much more to lack of judgment than to variations in acuity of hearing. The judge alluded to by Mr. Willis may have been highly competent in legal matters but was not necessarily competent to judge sound intensities. Acuteness of vision does not necessarily make a person a good judge of distances. The persons who are good judges of sound intensities are not necessarily those who have acute hearing but those who are used to listening to sounds of known intensity, which is an experience denied to most people. Apart from all this, there remains the question of the nuisance which a given complex sound creates for different individuals. While standards of permissible noise will have to be settled with reference to the average person, there should undoubtedly be a bias in favour of the temperamentally sensitive individual for situations where a noise has to be endured for long periods.

Prof. Robertson's calculation in regard to the propagation of sound from the great bell of the University of Bristol is of great interest. We have not yet seen any satisfactory explanation of the large effect produced by winds on the range of audibility.

NORTH-EASTERN CENTRE, AT NEWCASTLE, 9TH DECEMBER, 1929.

Mr. F. H. Williams: A method of measuring quantitatively and qualitatively the noise emitted by machinery is long overdue. The authors' solution of the problem is ingenious and it would be interesting, after they have collected and analysed a large amount of data, to have a further paper from them giving the results of their work. It appears from the paper that their measurements have scarcely emerged from the laboratory stage and they have still to decide how to translate these measurements into terms of ordinary acoustical effect. Their system of measurements appears to be based merely upon sound transference by air. The noise emitted by any given machine is transmitted to a given person not only by sound waves through the air, but also through solid objects such as foundations, walls and the human body, as well as by reflection. I should like to ask the authors whether they propose to take any steps to measure the sound transmitted in this way. Up to the present, the decision as to whether a machine is noisy or otherwise has been extremely difficult as, apart from extraneous noises such as are invariably obtained on a test bed, and the difficulty of deciding whether a machine will appear more noisy or less when finally erected, the human ear seems to concentrate subconsciously on certain sounds to the exclusion of others. I have noted, for instance, in connection with rotary convertors, that whereas when standing close to a machine the predominant noise appears to be due to the brushgear, a little further away it is possible to lose this noise and for its place to be taken by one of much lower note due to windage, etc. It would be interesting to know whether the authors in their investigations have taken cognisance of this by plotting polar curves at varying distances from the machine under examination. What is really wanted is some form of apparatus which, while being reasonably portable, would also enable one to analyse fairly easily the effect upon the individual of noises produced by any machine, i.e. to integrate all the sound effects, giving them the relative values which they would appear to have to the human being.

Mr. J. L. Jefferson: Referring to section (2) of the paper and equation (1), viz. $P = \frac{A\rho f}{2r\sqrt{[1 + k^2r_0^2]}}$, the assumption is made that r_0, the radius of the pulsating sphere, is small compared with λ and thus $P = A\rho f/(2r)$ dynes (max.) per cm^2. I consider this to be rather a wide assumption, when one considers the radius of the source of sound in, say, an induction motor compared with that of a sound wave of length equal to 2 ft. or 3 ft. Apparently, this approximate formula for P was used to reduce the intensity measurements to a standard distance of 1 m, and I should have expected this assumption to have effected the reduction to a standard distance of 1 m in the case of larger apparatus. I am interested in one point in the account of the experiments on the measurement of radiation pressure by means of an aluminium disc. On page 106 it is stated that the control produced by the earth's field acting on iron impurities in the aluminium did not disappear when a mica disc and glass framework were used. This statement does not appear to be clear, and perhaps the authors could give us some further information. I should like to call attention to what appears to be a printer's error in connection with Fig. 26. "The readings at A and B are almost identical" should read, I think, "The readings at A and C are almost identical."

Mr. J. C. Read (*communicated*): About 5 years ago I made some tests on the causes of noise in squirrel-cage motors, and though quite simple apparatus was used and the tests were made with a large background of shop noise, enough information was obtained to clear up the problem at that time. The noise was merely picked up on an ordinary carbon-granule microphone placed close to the machine, amplified in a simple single-stage amplifier consisting at that time of 6 valves in parallel, and then recorded by an oscillograph. Fig. B shows a typical oscillogram obtained in this way, from which it will be clear that in spite of considerable distortion the frequency of the principal note can be readily determined, with ample accuracy. Due to the characteristics of the microphone, the amplified current obtained varied slowly and continually between a condition of irregular "mush" and one of a fairly smooth regular wave; by watching for the latter condition on the oscillograph screen it was easy to take the oscillogram at the most favourable moment. Several other types of frequency-measuring apparatus, including one rather similar to that described by the authors, were tried, but on grounds of simplicity the oscillograph scheme was found preferable in practically all cases. I think there is usually one predominating note contributing nearly all the noise, the remaining notes being of little importance; for example, the twice-supply-frequency hum is usually slight, difficult to cure, and not annoying even when of fairly large amplitude. Having then suitably placed the microphone close to the source of the particular predominating note, so that the effect of the latter is large compared with that of extraneous noises, one can find the frequency of this note by taking an oscillogram. In testing squirrel-cage motors in this way, as soon as it had been found how the noise frequency varied with slip and with supply frequency in some typical cases, the right explanations of the causes of the noise could be picked out. When the investigation was shelved in favour of other work, 4 years ago, the effects of different constructions, slot combinations, etc., on both windage noise and noise due to magnetic causes had become clear, and it was thus possible to design to reduce these noises to a minimum with reasonable certainty.

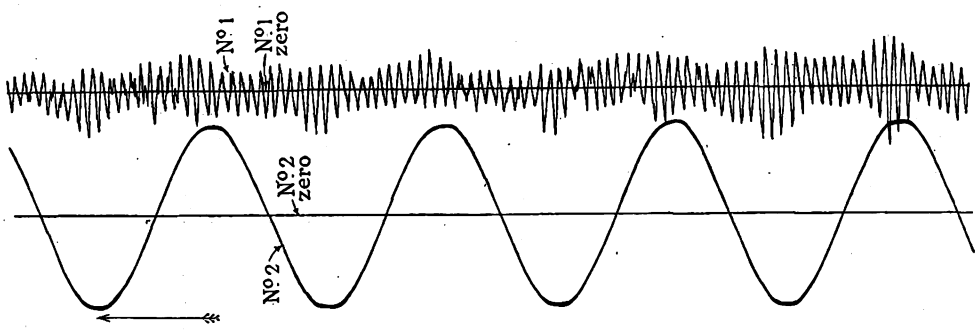

FIG. B.—Sound oscillogram taken on a 10-h.p., 4-pole, 1 460-r.p.m. machine.

Curve No. 1.—Sound wave.
Curve No. 2.—50·7 cycle timing wave.

Messrs. B. A. G. Churcher and **A. J. King** (*in reply*): Mr. Williams raises the question of vibration transmitted by solid substances as contrasted with air-borne vibrations. As far as the consideration of sound intensities at a given point near a machine is concerned, which is the subject of the paper, the only question that arises in regard to solid transmission is transmission through the body of an observer listening at that point. As far as the observer is concerned, all the rest of the sound reaches him by the air, whether it has come wholly by air or partly by solid transmission from the foundations of the machine and along the walls. Experience does not indicate that the body is a good transmitter of vibration. An engineer wishing to listen attentively to a machine puts one end of a pencil between his teeth and presses the other end against the machine to obtain adequate solid transmission to the bones of the head. Or he may take a stick and press one end against the side of the head near the ear. To demonstrate this point further, one of the authors stood on the cast-iron bedplate of a fairly noisy motor-generator set. On stopping the ears, an enormous decrease in noise sensation took place. On stepping off the bedplate on to the concrete foundation with the ears stopped and the head in practically the same position, no change in noise sensation could be detected. Similarly, when stepping on to some wooden flooring close to the machine with the ears stopped, no appreciable change took place. This, we think, disposes of the contention that sound transmission from the floor through the body to the head is an appreciable factor in listening and that our system of measurement ignores a factor of importance. As to the subject of sound transmission through foundations and walls in general, we agree that it is a matter of importance but is not one that primarily concerns the manufacturer of electrical machinery and, furthermore, it is not possible to deal with every aspect of acoustics in one paper. We have taken polar curves on certain machines. The results are very striking in some cases, especially in regard to the directional effects associated with some components. There are many possible reasons for the effects mentioned by Mr. Williams. It is possible that, in noticing the appearance and disappearance of different components on walking away from the machine, he has moved out of the sound shadow cast by the yoke of the machine. Or it may be that on reaching a certain distance the limit of audibility for certain components is reached, the limit being artificially raised owing to the background of noise in the shop. In attempting to point out what is "really wanted" in the way of apparatus, the phrase "to analyse fairly easily the effect upon the individual of noises," etc., prompts us to remind Mr. Williams that for the manufacturer there are two distinct problems in sound measurement. One is the analysis of complex sounds for the purpose of tracing the cause. This has been described in the paper and it chiefly concerns the manufacturer of electrical machinery. The assessment of the sensation produced by the total noise is the other problem and concerns both user and manufacturer. As has been pointed out in the paper, this problem has not yet been satisfactorily solved, the essential difficulty being the establishing of a scale of loudness for complex sounds. The establishing of such a scale must necessarily precede the development of apparatus to measure the sensation produced by complex sounds.

In reply to Mr. Jefferson, we are quite aware of the limitations of the assumption that r_0 is small compared with λ, but the practical consequences are not serious. With small motors the assumption is not far from the truth, and with large ones a plot of the sound field is made if conditions permit. In any case, if the distance at which observations are made is stated, the intensities recorded by the microphone are those which would act on the ears of a person standing there.

Mr. Read's remarks seem to indicate that the whole problem of producing quietly-running motors is much simpler than we have imagined. The oscillogram shown relating to an induction motor has a simplicity we have not found in our work. One wonders whether all the relevant components have been recorded, when it is stated that nearly all the noise is contributed by one predominating note. That is not our experience. Bearing in mind the large variation in loudness with frequency for a given pressure, it is possible to have small-amplitude high-frequency components that contribute largely to the noise but would not be detected in the oscillogram. That is why we avoid the use of oscillograms where possible. We think that if Mr. Read had used apparatus of more suitable characteristics and had interpreted his results in terms of loudness rather than of pressure amplitude, his conclusions would have been considerably modified.

North-Western Centre, at Manchester, 21st January, 1930.

Mr. D. B. Hoseason: With reference to Fig. 26, we are told that the readings at A and B in the vicinity of a motor are almost identical, as also are those at B and D. Therefore those at A and D should correspond. In the column lower down I find that with 225 cycles per sec. a pressure of $0 \cdot 625$ dyne per cm^2 is shown at A, whereas at D the value is $0 \cdot 235$ dyne per cm^2. Presumably there is a misprint in the text. My second point relates to the comparison of the noise from a large piece of apparatus, such as a transformer or a turbo-alternator, with the noise from a small machine, such as a motor. In the case of the small machine, it is stated in the paper that the distance of the microphone is measured from the centre of the machine and that this distance is made large compared with the size of the motor. If it is proposed to measure the noise emitted by a turbo-generator or even a rotary convertor, presumably the distance of the microphone will be made correspondingly large as compared with the measurement for a small motor. Even so, it seems to me that the physical shape of the apparatus emitting the noise will have an appreciable effect upon the distribution of the sound field. The case I have cited is an extreme one, but the same problem is met with on a smaller scale when we endeavour to compare the noise emitted by, say, a 2-h.p. with that from a 20-h.p. motor. It would be interesting to have the authors' views on the comparison of the figures in dynes per cm^2 for the noise emitted from two machines of appreciably different size and shape, when considered as a standard of nuisance.

Mr. D. A. Trickett: If there are any who doubt the value of pure science applied to practical engineering, I think this paper definitely disposes of their doubts. It reflects great credit on the authors that they have been able to measure quantities which we have hitherto believed could not be measured. I have been concerned with my colleagues in years gone by in evolving a technique for the production of silent-running direct- and alternating-current motors. When we had a difficulty with a customer who thought our motor to be noisier than it really was, we longed for an absolute standard which would enable us to say to him, " That is really a first-class silent machine." But now that the authors have placed the means of measuring absolutely the amplitude of each component frequency in my hands, I am a little in doubt as to whether I really welcome the method for use by the arbitrator in such a dispute. I am not at all sure that the method is really as absolute as I at any rate thought it would prove to be when I first read the paper. Considering the results published by the authors in regard to the 10-h.p. 3-phase motor and the turbo-alternator from the point of view of the figure of loudness, the average figure for the 10-h.p. motor is about 30, whereas for the turbo-alternator it is roughly 50. The 3-phase motor would, I consider, be a fairly passable machine but the turbo-alternator would be intolerable. The relation between 30 and 50 did not seem to me to be a true expression of the relative noise or silence qualities of the two machines. In Fig. 1, which is used as the basis for the estimation of the figure of loudness, I see that there can be, for instance, between the pressures of $0 \cdot 1$ and 10 dynes per cm^2, a variation in the figure of loudness which is relatively very much smaller than the corresponding range of pressure of 100 to 1 would appear to indicate. It seems to me that it is a question of what the ear considers to be normal. I have measured these quantities in the past by my ear with the assistance of a simple form of a stethoscope, and by what one would expect to find in the way of noise emitted by a given machine. After all, the question of noise is not an absolute question like that of temperature; it is a question of nuisance. The point then arises as to what is a nuisance and what is not. This is a matter to be decided by the ear, and so in an analysis the ear is the instrument which has to be satisfied. I feel that I would rather trust my judgment in dealing with given conditions than trust to an estimate of what the pressure ought to be under those conditions. If I were dealing with a motor for a library I should want to do everything possible in order to make it absolutely quiet, but if I were sending a motor into a boiler shop the noise emitted by a normal motor would not matter at all. All the conditions ranging between these two extremes are really matters of judgment. At times one's judgment fails and it is necessary to make a second attempt, but I believe that this would still apply if the standards described by the authors were utilized instead of the human ear. I do not wish to disparage the work which they have done, because I think their paper may help us immensely by forming some sort of a standard to which we can refer when we have learned to assess the results for p.

Mr. J. Frith: The measurement of noise is difficult for three reasons. In the first place it is necessary to study the physical aspect, which is perhaps comparatively simple. The rapid advance of wireless has placed in the hands of the authors apparatus which they might not otherwise have had. Then there is the physiological side, for, as another speaker has said, sound has ultimately to be judged by the ear and in that sense it resembles the science of light and illumination, where the peculiarities of the eye have to be studied. And it has also to do with psychology—the effect of noise upon the individual—and this is perhaps the most difficult of the three. We want ultimately to be able to measure the irritation produced in the hearer. I should like to ask whether the authors have studied the noises emitted by fans. They mentioned the ventilating motor, but in our experience it is more often the fan that is at fault. We have found that the main note emitted by a fan is twice the blade-tip frequency, and that a good deal of the noise of a motor comes from ball bearings. One would naturally expect a ball bearing to be quieter, but actually it is noisier than the other type. A standard of noise is much needed. It is impossible to specify absolute silence, because nothing is absolutely silent; one can stipulate that a motor say shall be "reasonably silent," but this stipulation depends so much upon the standard of "reasonableness" by which the machine has to be judged.

Mr. J. M. Jackson: In section (3), on page 99, the authors state, referring to Fig. 1, that the lower full-line curve represents the average minimum audibility for 72 normal ears. Should this read "72 pairs of ears," i.e. were 72 individuals tested? Similarly, the maximum audibility curve was based on 48 normal ears and the same question arises. I am chiefly interested in the practical outcome of the methods which the authors describe. It is hoped that some method will soon be developed sufficiently to be put to regular commercial use. Hints have been given as to possible applications, e.g. the measurement of noises emanating from loud-speakers. The qualities of such instruments in connection with speech are usually sufficiently good for all practical purposes, but when we pass to the realm of art the reproduction is lamentably lacking in quality. Possibly the fact that time, rhythm and form in music are correctly rendered tends to mask the actual absence of tonal qualities. There is certainly plenty of scope here for actual measurements of sound. Referring to section (11) on the assessment of total noise, it is stated on page 122 of the paper that: "It is generally accepted by psychologists that the ear adapts its sensitivity to the strength of the sound which acts on it." Is it not a fact, however, that the will of the individual has something to do with the reception of noise? I am thinking of people who, listening to an orchestra at full blast, strongly object to whispering going on a short distance away. The problem of assessing noise is further complicated by the fact that workers in an office who have always been accustomed to machinery which is running, say, in the same building, are unlikely to object to its noise, whereas in another case the introduction of a comparatively quiet machine will at once cause objection. The questions as to whether a noise is justifiably objectionable and as to the amount of expenditure which can be justified in silencing or reducing it are not easily answerable on a quantitative basis.

Mr. G. A. Juhlin: The interesting feature of the apparatus designed by the authors is, I think, that it enables us to diagnose the trouble in a noisy machine. Our difficulties in the past have been that it was impossible to determine which particular feature in design was responsible for noise, and the difficulties in the way of effecting an improvement were, therefore, very great. The authors have provided a means for analysing the various noises emitted from any apparatus, and the source of the trouble can therefore be determined; in general it is a simple matter to cure a trouble when its cause has been diagnosed. The question of absolute measurement of sound is undoubtedly an important matter, and it is to be hoped that the authors will, by further experimental work, succeed in obtaining an absolute standard of comparison.

Mr. F. Roberts: I have been concerned with the inverse of the case presented by the authors. They have been dealing with the noise received by the microphone and I have been concerned with the noise emitted by a loud-speaker. I have not gone into the subject to the same extent that they have in determining the absolute sound produced by my instruments, but I have found in their work a valuable means of investigating my problems. They have been dealing with rotating electrical machinery, finding the cause of the noises emitted and rectifying them, and this seems to me to be a comparatively simple thing to do. With few exceptions, all the main notes are at frequencies which are multiples of the number of revolutions per minute, and the exceptions may be easily traced, apparently, by going round and tapping with a screwdriver. If for a loud-speaker such as that described on page 121 an attempt is made to relate the peaks found in the response curve to the physical characteristics of the instrument itself, great difficulty is experienced. I should like to ask a question with reference to these curves. The theoretical treatment of loud-speaker operation has been given by Kennelly and his associates, and, as investigated from the electrical side, it leads to certain expectations with regard to a response curve such as that of Fig. 27. On the other hand, the actual response curve obtained seems to be unrelated to this expectation, with the exception, possibly, that the two ends of some response curves show marked peaks. I should be grateful if the authors could indicate how loud-speaker performance may be reconciled with expectation, or show what physical factors are responsible for the numerous peaks they have obtained.

Mr. R. W. Fryer: I am interested in the subject of noise, not as regards large machines, but in connection with meters. It is well known that many people whose homes are connected to an electrical supply are troubled at nights by noises which, it is supposed, are emitted from the meters. A well-known firm of meter manufacturers has been concerned with this problem during the past few years and I can safely say that, as the result of their researches, their meters are now practically noiseless. The apparatus used was not quite so elaborate as that described to us to-night, as it was not their intention to go so deeply into the subject. The object was to find out what was the cause of the noise. After much trouble and toil it was ascertained that it was caused by the vibration of the meter spindle. I should like to ask the authors whether they can give us any information as to their experience of noises emitted from such equipment.

Mr. A. G. Ellis: The paper records a splendid piece of research work, and I should like to pay my tribute in public to the assistance which the results have afforded to those who have had the opportunity of taking advantage of them in matters of design. From the discussion the fact has emerged that what we are really seeking is some unit of measurement. There are two aspects of the case, one being the method of diagnosing the trouble in the case of excessive noise, and the other the provision of some absolute comparative basis of measurement, or commercial standard. The provision of a standard is a practical problem and such a standard would have to be applicable to a commercially acceptable article. It is the purchaser and user of the machine who will have the final say, but unfortunately everyone has different views in this respect. In the long run, I do not think that the authors will find the provision of a standard quite so difficult a matter as it now appears. When scientists first attempted the measurement of light they turned to the homely candle and decided to measure light by "candle power." Can we not conceive of noise being measured by "tin whistle power," or by some similar simple unit? At any rate, I look forward to the time when the authors will have evolved some form of commercial standard by which we shall be able to compare the apparatus we are building. They have shown apparatus which covers tests over a very wide field, from large turbo-alternators down to meters. I am interested in the measurement of noise from transformers, and the problem in that connection is much more difficult than with rotating machines. The table on page 121 indicates how easy it is to diagnose in the case of noise from a rotating machine. The authors separate the various harmonics and then look for a part of the machine (e.g. armature teeth) the frequency of vibration of which corresponds to a particular harmonic. By this means they can relatively easily trace the source of the troublesome harmonic. In a transformer there are no moving parts and it is difficult to isolate the cause of the trouble in the same way. However, very valuable results have up to the present been obtained on transformers, and we look forward to the time when the authors will be able to give us something more absolute in the way of measurement. I anticipate with interest the introduction by the authors of a portable sound meter or noise meter which could be taken to a noisy substation and used on the spot.

Messrs. B. A. G. Churcher and **A. J. King** (*in reply*): Mr. Hoseason's first point has arisen owing to a printer's error. The pressures observed on opposite sides of the motor correspond. The question of defining conditions for testing large machines requires careful consideration and experimental investigation. We have not so far had an opportunity of going into this matter in detail. With rotary convertors, the composition of the sound heard near the machine varies according to whether one stands at the front or the rear of the machine. At the rear the yoke casts a sound shadow for the sound coming from the commutator and brushgear. Only at large distances would this effect become small. One has also to consider whether large distances are relevant, when it is borne in mind that the machine is intended to run in a substation building of limited dimensions. Although we do not wish to minimize the importance of the question in any way, the difficulties are to some extent mitigated by two considerations. One is that the microphone measures the true sound intensity at the point at which it is placed, so that by specifying the point or points at which the measurements are to be made a considerable amount of indefiniteness is removed. The other is that a given error in the observed sound pressure involves a much smaller error in the deduced loudness value. Thus at moderate frequencies an error of 15 per cent in the pressure would cause an error of only 1 in the loudness value. It is altogether doubtful whether a change of loudness from, say, 30 to 31 would be noticeable unless the change was made deliberately and suddenly. This, we think partly answers Mr. Hoseason's question regarding the 2-h.p. and 20-h.p. motors, but he must remember that we do not yet claim to have assessed the loudness of a complex sound but only that of the components.

Mr. Trickett's remarks deal wholly with the question of the assessment of the total noise emitted by a machine and he doubts whether we have succeeded in dealing with this. We would point out, however, that we have not suggested that the work described enables total noise to be assessed and, therefore, disputes as to the relative noisiness of different machines to be settled. In our remarks at the meetings and in the paper (page 123) we have repeatedly called attention to the fact that no satisfactory basis for assessing the loudness of complex sounds has yet been established, and that we hope to give attention to the subject in the near future. It is just such easy assumptions as that taking the average of the loudness values for the different components gives a measure of the total noise that we wish to deprecate. What has been done in the present work is to analyse the complex sound emitted by a motor on a physical basis, to assess the relative importance of each component on a loudness basis and to trace the source of the components. Mr. Trickett raises the question of the permissible limits of noise in a motor for different situations. This is a matter of the background of noise in those situations. When it is possible to assess the total noise made by a motor, it will be equally possible to evaluate the intensity of a background of noise. By considering one in relation to the other, it will be possible to choose a suitable limit of permissible noise.

Mr. Frith calls attention to the second-harmonic frequency emitted by fans. We have found this harmonic in certain types of fan. We have not studied the noise characteristics of fans in general but only those fitted to a motor for ventilation purposes. We have appreciated the misapprehension that may arise as to the relative amounts of noise contributed by the motor and the fan in a motor-driven ventilating fan. We fully agree with Mr. Frith's remarks regarding the need for a standard of noise and the absurdity of specifying "absolute silence" or even "silence."

With regard to the question of the prediction of the performance of loud-speakers, raised by Mr. Roberts, we put the characteristic curve of the loud-speaker into the paper as an example of one of the uses to which our apparatus could be put and not as an indication that we have made a serious study of loud-speaker design. From the way in which commercial loud-speakers are made, both in regard to materials and construction, we should imagine that many factors enter into their operation which could not be taken account of in any reasonably simple theoretical treatment of the subject.

Mr. Juhlin has summed up the situation very well when he points out that once the cause of excessive noise in electrical machines is found, it is, in general, a simple matter to remove it, and further, that the absolute measurement of sound, or, as we prefer to call it, the measurement of total noise, is an important matter.

Mr. Ellis also calls attention to the need for total-noise measurement in connection with transformers. As a matter of fact, the method with which we are experimenting, namely the "reference tone" method, is closely analogous to the photometric example he quotes. The adjustable pure reference tone would correspond to an adjustable standard of monochromatic light, the standard being adjusted in intensity until it appears equal, by ear in the one case and by eye in the other, to the complex quantity under observation. With regard to measurements on site, a portable sound analyser is now being developed and it is hoped that it will be capable of rapid operation. The combining of portability with sufficient range and sensitivity to deal with transformers as well as rotating machines is a matter that requires a good deal of thought and experiment.

DISCUSSION ON

"VOLTAGE CONTROL OF LARGE ALTERNATORS."*

NORTH-EASTERN CENTRE, AT NEWCASTLE, 13TH JANUARY, 1930.

Mr. W. D. Horsley: The paper gives the impression that the ordinary shunt-wound exciter is inherently unstable at low voltages and that separate excitation in some form is essential. As the author himself states, some attention to design details is necessary to guard against instability at light loads, and he also mentions that the shunt-wound exciter is not so inherently unstable as is indicated by the characteristic curve shown in Fig. 1. The ordinary shunt-wound exciter if carefully designed is stable and reliable at all loads. There is no difficulty in designing an exciter and exciter shunt-field regulator for the range of voltage given on page 325 of the paper. It seems to be advisable to retain, wherever possible, the single self-contained exciter. The advantages are that it is simple and reliable and that it conforms to the principle of making the alternator a self-contained unit. These views were expressed by Mr. C. H. Merz in the discussion on a recent paper.† In some circumstances it may be necessary to adopt separate excitation, and for this purpose the double exciter appears to be sound practice, the only disadvantages being that additional sources of breakdown are introduced and the reliability of the excitation system is lowered. A compounding winding on the main poles of an exciter does not improve the inherent stability, but numerous experiments have shown that it does prevent permanent reversal of the exciter voltage when a surge occurs on the alternator. The exciter voltage may be momentarily reversed, but the fact that the current through the compounding winding is maintained in the same direction ensures that the exciter voltage finally builds up to the correct polarity. Even if the exciter is separately excited, the polarity across the rotor slip-rings may reverse when a surge takes place on the alternator. An exciter may also be reversed if resistance is too rapidly inserted in the shunt field-circuit. This is due to the same cause and is also avoided by fitting a light compounding winding. The phenomenon is described in detail in a paper by Mr. J. Rosen.† Compensated windings have been fitted to prevent load instability of exciters, but it is difficult to see how an improvement could be effected by this means, and experience has shown that a compensated exciter may reverse when a surge in the load occurs on the alternator. Instability of alternators when carrying light loads at leading power factor has been experienced and is due to the alternators operating under conditions for which they were not designed. The difficulty is overcome by the use of automatic regulators. Alternators which are designed to run at unity or a leading power factor are quite stable, even without the use of automatic voltage regulators. Alternators having a higher synchronous reactance than that given on page 324 of the paper have operated satisfactorily on a large system for many years, and they are quite stable without the use of automatic voltage regulators. It would be of interest to have the author's views on the limiting value of synchronous reactance. The combined response of the exciter and the alternator at the higher loads is not very much greater for the separately-excited exciter than for the self-excited exciter. At low loads on the alternator the time-constant is much greater and it seems that for general purposes the self-excited exciter gives an adequate response, more particularly as the delay in action of even the vibrating-contact type of voltage regulator is of the order of 1 second.

Mr. J. W. Jackson: Referring to the remarks made in the paper at the foot of page 317, I would confirm the opinion that "a shunt exciter may lose its voltage altogether and then build up with reversed polarity." If this takes place on service load it is clear that during

the period of reversal the generator goes out of service and, in addition to throwing all of its load on to the other generators, calls upon them for a synchronizing current to pull itself into service again. On page 325 the author states that " full load is never thrown on or off," but it is found to be necessary under many conditions of service practice to throw full load off the machine occasionally in order to find out whether the main controlling governor is in order, and this is in many cases the only satisfactory way of dealing with the governor on test. The author's suggestion of providing super-exciters appears to me to be a sound one, and it should permit of the installation of turbo-generators of great stability. Some critics would undoubtedly question the advisability of apparently adding to the complication of the electrical side of the alternator. Before arriving at any conclusion on a matter of this sort, it must, however, be realized that in order to secure equal reliability a storage battery, together with its charging device, is necessary on the other scheme. Those who have used storage batteries for any length of time know that their capital cost is high, that maintenance charges are heavy and that a large sum must be allowed for depreciation.

Mr. F. C. Winfield : In his introductory remarks the author acknowledged that he was an apostle of the stabilized exciter, but on reading through the paper one gathers the impression that he places greatest stress on the need for quick response and a low time-constant in the excitation system to ensure maintenance of voltage in fault conditions. It will be readily agreed that in the larger power stations now in prospect the greatest load unit will be a relatively small proportion of the station capacity and that normal load variations will affect voltage-regulation little, so that there is no need for a particularly small time-constant on this score, even with the very large generators under consideration. The author suggests, however, that quick excitation response is of considerable importance in fault conditions, and that special steps are very necessary in designing the excitation system of the larger generators now building or in prospect. I am not sure that I have quite appreciated the necessity of this from the author's paper, and feel that one should be well assured on the point before agreeing to complicate the exciter system and, presumably, to reduce its reliability. The duration of the low-voltage period which follows a fault may be a function of the time-constant of the generating sets, but it is surely also a function of the speed of switching. Large generating sets imply large stations as well as large and important feeders, and in modern British practice important feeders are usually provided with high-speed pilot wire protection, enabling faults to be cleared in $\frac{1}{2}$ second or less. Assuming this, the duration of low voltage would appear to be half a second plus the time of recovery of the generator voltage after the fault has been cleared. The recovery time will depend on the time-constant of the set but, in any case, I assume this will be a few cycles only, so that it would appear that the time of switching constitutes the major part of the low-voltage period and that the time-constant of the set is of little importance. Going a step further, the paper discusses the voltage response between no load and full load, but in fault conditions the response which really appears to be in question is that between, say, 75 per cent of full load-current and 2, 3, 4 or more times full load. Since the exciter definitely cannot maintain voltage in these conditions, the advantage of a small decrease in the time-constant would appear to be very small. The author's views on this point would be appreciated. The author states that when a severe fault occurs close to the generating machinery in one section of a busbar system sectionalized by reactors it is unlikely that any practical design or mode of operation could maintain full voltage; I would suggest that feeder reactors are a direct solution of this problem. Mainly due to cost, difficulty of accommodation and the additional voltage-drop introduced, the use of feeder reactors has not made great headway in this country. One of our most serious troubles in large station practice to-day is the spreading of the disturbance from a fault on one feeder due to the falling out of step of synchronous plant on other feeders. Busbar reactors limit the magnitude of fault current satisfactorily from a switchgear point of view, but with a fault close to the busbars of a large station loss of synchronous load on the busbar section directly connected to the fault appears to be almost inevitable and frequently occurs on adjacent sections. It would be interesting to know whether the author has ever considered as an alternative to the combination of a main and an auxiliary exciter, a combination of a main exciter and an auxiliary booster, that is to say, a main exciter capable of supplying maximum generator field-current at, say, 75 per cent normal voltage together with a reversible booster, such as is sometimes used for d.c. feeder regulation. The main exciter would operate at approximately constant voltage and would also supply the booster excitation, which would be automatically controlled in the usual way. At a cursory glance, it would appear that such a combination would give even a smaller time-constant than the arrangement using an auxiliary exciter, since only the time-constant of the booster would enter into consideration.

[The author's reply to this discussion will be found on page 792].

NORTH-WESTERN CENTRE, AT MANCHESTER, 18TH FEBRUARY, 1930.

Mr. G. A. Juhlin : Most engineers operating turbo-alternator plant will agree that separate excitation of the exciter is the system which gives the most satisfactory operating conditions. The requirements regarding the excitation of modern machines have increased in difficulty with the increase in size, not only of the alternator but also of the system generally. The author describes a system whereby a double exciter set is used, a small machine being provided for excitation of the main exciter. We have adopted a slightly different system; a small exciter is driven from the turbine at 750 r.p.m. This small exciter is of the permanent-magnet type. I am in agreement with most of the points brought forward by the author. The question as to what should be termed "super-excitation" is somewhat debatable. It is our general practice to be conservative as regards the margin on the exciter, and I would suggest that 15 per cent is on the small side. Possibly the author has taken this value merely to illustrate the point. We recently put into operation a large frequency changer, and as this machine connects to an extensive power system the maximum voltage used on the exciters is $2\frac{1}{2}$ times the normal value, in order to obtain a very rapid response in case of heavy overloads. The rate of building-up of the exciter voltage (i.e. the response of the exciters) was 630 volts per sec. up to about 90 per cent of the full voltage. Considerably higher figures than this can be obtained by increasing the ceiling voltage of the exciters, and by specially constructing the exciters themselves so as to minimize the time required to build up the exciter voltage. The author has clearly indicated the difference in type between machines designed 15 years ago and those designed to-day. The machine with a high armature reaction and poorer regulation than that of the older type of machine is necessary if large high-speed units are to be produced. It would be uneconomical, and in some cases impossible, to produce a large high-speed machine with the characteristics of those built 15 or 20 years ago, nor would these machines be desirable from an operating point of view on account of the large short-circuit currents which would be obtained, and which would unduly stress not only the machines themselves but the switchgear on the system. It is of interest to note that the tendency in America seems to be towards machines with heavy armature reaction. Some investigations have recently been made on a system of paralleling machines at the load end with a view to obtaining better stability.

Mr. W. Jackson: In explaining the oscillogram of alternator field-current shown in Fig. 19, the author states that the fall in exciting current, at the instant of breaking the short-circuit, is not so sharp as the rise in stator voltage, because of the presence of mutual circuits. While I can appreciate the importance of these mutual circuits in helping to determine the rate at which the exciting current rises following the commencement of the transient period, I have difficulty in appreciating their effect during the fall of current, unless the author intends that the small interval of time represented by the fall is to be accounted for as the time during which the electromagnetic energy stored in the short-circuited stator is dissipated in the mutual circuits. Even then I should have difficulty because of the time-constant of from 2 to 4 sec. mentioned in connection with these circuits. I should be glad if the author would help me on this point as I should have expected the stored electromagnetic energy to be dissipated in the arc occurring at the switch contacts when the short-circuit was broken, and the small interval of time elapsing during the fall in exciting current at this instant to correspond to the duration of the arc. On page 330 of the paper it is stated that in calculating the combined response of alternator and exciter following a sudden increase in load from 40 to 80 per cent of full load, it is sufficiently accurate to use the alternator time-constant for the new load. As, however, there is a difference of at least 1 sec. between the time-constants at 40 per cent and at 80 per cent of full load, and as 1 sec. is an appreciable percentage of the total time-constant at the latter load, I should have considered it to be more accurate and equally simple to take the average value over the period of change, especially in view of the detailed and accurate nature of the investigation which leads to the derivation of the time-constant variation curve.

Mr. H. Topley: I should like the author's opinion on a question of operation of a plant with which I think he is familiar. The conditions are a 32 000-kW, 11 000-volt, 50-periods per sec., 1 500-r.p.m. alternator stepping up to 33 000 volts, and a 1 000-kW 400-volt auxiliary alternator provided on the same shaft. The arrangement of main and service exciters is as shown in Fig. 4, but in addition to supplying the field of the main exciter the service exciter supplies the field of the auxiliary alternator. The question is what would be the effect upon the main alternator voltage of a sustained short-circuit on the stator of the auxiliary generator, with or without a voltage regulator. The effect of the variation of the ordinary load on the auxiliary generator is another point which demands consideration. I have examined the service exciter and find that there is a mutual winding which is used in connection with the voltage regulator. I should like some explanation of its use.

Mr. A. L. Lunn: When reading the paper I gained the impression that it would be of more interest to the designer than to the user, but the manner in which the author has presented his paper has reminded me of one or two experiences which may be of interest. It has been stated that as the alternator load is increased or decreased the voltage can be controlled and maintained within reasonable limits when separately-excited exciters are used. To some extent I agree with the author that under normal operating conditions it is possible to maintain a fairly constant pressure when a small extra load is thrown either on or off the alternator, but I should like to have his opinion on the advisability or otherwise of maintaining normal voltage on an alternator which is suddenly called upon to carry an abnormal overload with the frequency below normal. Under such conditions most automatic voltage regulators will clear themselves, and in power station operation it is usually considered that the best policy is to allow the alternator voltage to fall with the frequency. With alternators running in parallel it is obviously the best practice to operate the most efficient plant at the highest power factor. This applies particularly to systems where a modern and a much older station are linked together. The wattless current passing between the two stations should be reduced to a minimum and, if possible, be carried on the least efficient set. The following occurrence would seem almost incredible had one not actually witnessed it. A 2 000-kW 1 500-r.p.m. turbo-generator with a shunt-wound exciter and a voltage regulator applying a positive or negative boost (as required) into the exciter field, was running in parallel with two high-speed reciprocating engines each driving an 800-kW alternator when, owing to a defect in the voltage regulator, the polarity of the exciter was reversed and built up in the opposite direction. The supply was maintained and the voltage was restored to normal in seconds, the alternator apparently having slipped a pole. The remarkable feature of this incident was that outside the power station no one reported or appeared to have noticed any irregularity on the supply—not even the attendants in charge of the rotary substations. Another experience occurred in connection with a turbo-alternator of 6 000 kW and 3 000 r.p.m. with a shunt-wound exciter. When passing along the switchboard it was noticed that the machine had lost its field, and a dynamo attendant was observed wiping the exciter commutator with a rag which was afterwards found to be oily. Fortunately, at this time other sets were operating in parallel and by regulating the field rheostats the exciter built up again, in this case in the right direction.

Mr. S. Garbutt: It is stated on page 317 of the paper "that there is a difference of opinion among operating engineers as to whether the excitation of machines should be allowed to increase when a fault occurs close to the generating machinery." If an automatic voltage regulator without any compensating windings on the main control coil is in operation it will increase the excitation, when a fault occurs, in endeavouring to maintain the busbar voltage at the particular value for which the automatic voltage regulator has been set. In view of the above remarks it might be interesting to know whether it is possible to meet the requirements of the operating engineers who do not desire increased excitation in the event of a fault close to the generators and yet require automatic voltage regulation during normal conditions. It might also be of interest to know whether the voltage regulation of generators of, say, 50 000 kVA capacity is generally automatic. I have noticed that some firms manufacture turbo-alternators which have control both on the exciter field and also on the alternator field, that is to say, rheostats are connected in both field circuits. Is the manufacturers' object to obtain greater stability of excitation? With regard to the new exciter mentioned by the author, is it necessary to insert as much resistance in the exciter field-circuit for the main contacts of the automatic regulator to operate on as in the ordinary type of exciter? In the ordinary type of exciter it is necessary to insert sufficient resistance in the exciter field to bring the no-load voltage down to 60 per cent of normal busbar voltage, in order that the automatic regulator may take care of all voltage variations from no load to full load. What is the voltage range at the exciter terminals from no load to full load of this new type of exciter? A considerable amount of difficulty was at one time experienced in manufacturing the main relay coil of a certain type of vibrating-contact automatic regulator if the ratio exceeded 1 to 3.

Mr. O. Howarth: Does the author advocate attempting to maintain the voltage when phase-to-phase faults occur on the system, and when such faults persist for 1 or 2 seconds? The voltage regulator is connected across a pair of phases which may not be appreciably affected by a particular fault. There appears to have been no development in the method of connecting voltage regulators. Is it not time some arrangement was made whereby the voltage of at least two pairs of phases would be included, so that wherever the fault might occur the voltage would be maintained? With regard to machines in parallel on a set of busbars in a station without reaction between them, would the author suggest the use of a regulator on each machine with the usual power-factor compensating device? Here again it seems to me that trouble will arise if the voltage across any pair of phases is to be maintained. How is the power-factor compensation on the regulators to be arranged?

Mr. T. B. Somerville (*communicated*): Many operating engineers have experienced, at some time in their career, some unusual phenomenon for which no altogether convincing explanation has been forthcoming, and others, I think, do not realize how precarious are the conditions under which their machines are working. All will be reassured, after reading the paper, by the knowledge that the "hit and miss" stage in machine design has now been passed, at all events as far as the excitation system is concerned. The paper is chiefly of interest to me in so far as it brings into prominence the requirements and responsibility of the automatic regulator. Regarding speed of response, the automatic regulator may in many cases be as important a source of sluggishness as the exciter and the alternator field. Indeed, I will go so far as to assert that operating engineers wishing to improve their generating plant by increasing the rapidity with which necessary changes to the excitation are effected, can often obtain considerably greater improvement by installing a quicker-acting regulator than they could by changing the method of exciting the exciter field. To illustrate this assertion, I propose to make a comparison between the results obtained with the imaginary regulator of Fig. 24 and the results which would be possible on the same machine, using a regulator of a type with which I have had some experience. I know that the author had no particular regulator in mind when preparing Fig. 24, and that he has introduced the delay of 1 sec. merely to illustrate the manner in which the curves in Fig. 21 must be modified to allow for the time required by any automatic regulator to operate. The comparison should be no less interesting on this account, however, as I have seen in this country many automatic regulators which would give a much less satisfactory performance than that of Fig. 24. From Fig. F, which indicates the time taken by the contacts of the quick-acting regulator to cease beating after the imposition of a reduction in the voltage across the regulator control coil (the regulator having first been floated in the light-load position), it will be noted that the voltage disturbance illustrated in Figs. 21 and 24 would cause a complete

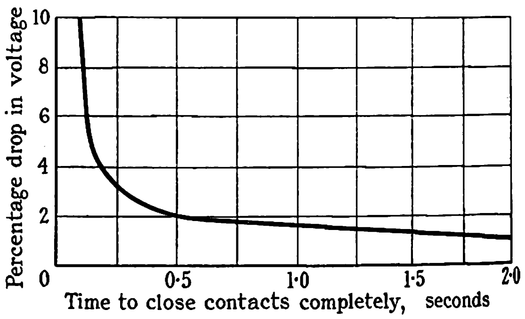

FIG. F.

closure of the contacts in 0·2 sec. If we now draw the curves to show the actual alternator-voltage variations as in Fig. 24, but commencing to rise only 0·2 sec. after the initial voltage-drop, we find that the voltage disturbance using this regulator and separate excitation is actually less, both in magnitude and duration, than when using the imaginary regulator and what the author describes as " super-separate " excitation. Furthermore, there is not a great deal to choose between the effect obtained when using the imaginary regulator with separate excitation and that obtained with the quicker-acting regulator and shunt excitation. The actual regulator used in the preparation of this response curve had been in use on a 500-kW turbo-alternator with direct-coupled shunt-connected exciter, but it is interesting to note that, in this particular, it does not differ very much from the regulators recently installed on a 30 000-kW frequency changer having separately-excited exciters. In practice, the regulator is required to commence re-opening its contacts shortly before the exact normal voltage is resumed, so that the return to normal is asymptotic rather than abrupt as illustrated. No one is concerned, however, at the slight delay in restoring the last 1 or 2 per cent. It may interest some to know by what means the regulator is enabled to short-circuit the rheostat in so brief a space of time, and then re-insert sufficient resistance for the new load condition immediately normal voltage is restored, at the same time avoiding what is known as " hunting." Taking the no-load position of the regulator control lever as zero and the lower position at which the regulator contacts are completely closed as 100 per cent down, we find that as the alternator load increases slowly from no load to full load, the regulator control lever moves slowly downward from zero position to perhaps 80 per cent down, at which point the contacts are opening and closing sufficiently to give full-load excitation. In order to prevent hunting, the movement of the regulator control lever is necessarily damped. Without such damping, a fraction of 1 per cent rise or fall in voltage would result in completely opening or completely closing the regulator contacts immediately, and the alternator voltage would swing rather rapidly up and down above and below normal. Accordingly, the piston of an oil-filled dashpot is connected to the regulator control lever, and the amount of damping adjusted to prevent hunting. This dashpot is connected to the regulator control lever by means of a flexible leaf spring, so that it does not prevent a rapid movement of the lever in the event of a sudden disturbance to the voltage. Let us suppose that the alternator is on no load, so that the regulator control lever is in the zero position. Half of full load is now suddenly switched on. The resultant drop in voltage causes the regulator control lever to move rapidly to 100 per cent down, or lower, thus closing the regulator contacts completely. The dashpot piston moves more slowly downward, and by the time the voltage is restored almost to normal it has reached the 40 per cent down position. Under the action of the leaf spring connecting the dashpot piston to the regulator control lever the latter now moves up to the 40 per cent down position, which it reaches when the alternator voltage is back to normal. In the 40 per cent down position the regulator contacts open and close sufficiently to give correct excitation for half load. In this way the actual voltage variations of the alternator after a sudden increment in load can be made to approximate very closely to the curves in Fig. 21. With regard to reliability, no doubt some operators will be filled with remorse after reading this paper, when they realize that they may have suspected their automatic regulator on account of peculiar behaviour which was possibly due to some inherent weakness or peculiarity in their machine. In a recent instance this proved to be the correct explanation. The automatic regulator was observed and reported to have varied the beat of its contacts in a manner which was not considered to be justified by any simultaneous fluctuations in the load. This so-called erratic behaviour of the automatic regulator, although not producing noticeable disturbances in the alternator voltage, eventually resulted in the automatic regulator being left out of commission until such time as it could be attended to. In the following few days the machine completely lost its excitation on two occasions. Nevertheless, automatic regulators, however reliable they have proved to be, cannot be truthfully described as infallible. Indeed, in my opinion, as the automatic regulator is sometimes the weakest link in the chain of voltage control of an alternator from the point of view of speed of response, so it may be also from the point of view of reliability. If, in order to obtain quicker response from the machine, we make available to the automatic regulator a wider margin of excitation in excess of actual full-load requirements, the results of incorrect operation may be correspondingly more serious, and, if the operating engineer is to enjoy any peace of mind at all, these results must be guarded against. In the past it has been common practice to install with each automatic regulator a cut-out arranged to operate in the event of excessively high or low voltage, cutting the automatic regulator out of action and leaving the machine on (usually) half-load excitation. Such cut-outs usually operate in the event of a system fault, thus cutting the regulator out of action at a time when it is most desirable to keep it working, and in order to make such unwanted operation less frequent it is usual to arrange the cut-out with a very coarse setting. With this necessarily coarse setting, the protection afforded against the results of faulty operation of the automatic regulator is, in my opinion, inadequate for present-day conditions. Consider, for example, the case of two machines in parallel each under the control of a separate automatic regulator, one of which becomes faulty. The healthy regulator operates in such a way as to maintain approximately normal voltage and thus prevents operation of the regulator cut-out. One of these machines may easily have its excitation reduced to a value which is not sufficient to hold it in synchronism. To take another example, suppose that a system fault occurs and that this is followed by a large loss of load. The regulator cut-outs operate due to low voltage, leaving the machines on half-load excitation. At the abnormally light load, particularly if a long unloaded feeder remains connected to the machines, the voltage may quite easily rise to a disconcerting value, which would have been prevented if the automatic regulators had remained in operation. I have recently been responsible for the introduction of a new form of protective cut-out, which does not operate unless the voltage disturbance is actually caused or maintained by faulty operation of the automatic regulator. This cut-out can therefore be set sufficiently fine to give adequate protection without running the risk of unwanted operation. In the case of parallel-running machines each under the control of a separate regulator, a faulty regulator would be cut out of operation immediately, leaving the others in service and the voltage normal. I entirely agree with the author that separate excitation of the exciter field is well worth while, not only on account of the increased speed of response, but also for the vast improvement in stability which is obtained. A difficulty which I have experienced with some exciters is that it is not possible to choose a point on the rheostat corresponding to a definite value of excitation. The excitation obtained at a given point depends not only on whether the rheostat has been brought up or down to the point, but also very largely on how far the rheostat has been moved up or down before being brought back to the given point. This effect, which is referred to on page 319 of the paper, is presumably due for the most part to hysteresis, and is exaggerated by the use of steel in the magnetic circuit. I assume that no advantage is to be gained by the use of hard magnetic steel when the exciter is to be separately excited, but I should like the author's confirmation on this point. From the point of view of the automatic regulating equipment, I consider it a distinct advantage to be able to rely on obtaining always the same value of excitation for any given point on the rheostat, at normal speed.

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT NEWCASTLE AND MANCHESTER.

Mr. H. W. Taylor (*in reply*): Mr. Horsley stresses simplicity, reliability and the desirability of making a self-contained unit, and it was to meet these requirements that the stabilized exciter described in the paper was introduced, as the only alternative where quick response is desired is separate excitation from a battery. In particular, the reliability of the arrangement has been proved by the service it has given since it was introduced a few years ago. The question of using a compound winding with the exciter has already been reviewed on page 338 in reply to a previous discussion. In reply to the question as to what is the limiting value of synchronous reactance, I would say that one of the obstacles to further increase in synchronous reactance has been the extra losses which take place in machines with short air-gaps. These losses have been studied during the last two or three years and have been much reduced. With this advance in the art of design, together with improvements in regulators, values of synchronous reactance 25 per cent higher than those indicated in Fig. 15 of the paper are now possible. The delay in the action of the vibrating-contact regulator is of an order less than 1 sec., as shown by Mr. Somerville later in the discussion.

Mr. J. W. Jackson's remarks are interesting in that he indicates the inherent disadvantages of using a battery as an alternative to the service portion of the stabilized exciter.

In reply to Mr. Winfield, the double machine discussed in the early part of the paper was introduced to improve both stability and response, but in order to give it a name which was not too verbose it was decided to call it a "stabilized exciter," although it fulfils both the functions mentioned. I agree with the suggestion that quick response is not so necessary when protective devices function properly, but line faults are sometimes sustained owing to the defects in protective devices, and in such cases a quickly responding exciter and a quick-acting regulator are valuable in holding together the various parts of the system. The recovery of line voltage after a heavy fault which requires excitation beyond the capacity of the exciter can be determined from the curves in Fig. 20, using the time-constant corresponding to the load left on the system when the fault is cleared. The time for recovery will be more than a few cycles. The advantage of super-excitation and quick response upon the occasion of a prolonged fault is that while voltage may not be maintained there is a large amount of leakage flux built up in the machine, and this, upon removal of the fault, appears as a larger percentage of line voltage. The booster excitation scheme suggested by Mr. Winfield might be more responsive under ordinary load conditions, but it does not admit of such a degree of super-excitation as the usual arrangement. The possibility of super-excitation depends upon the voltage range which can be obtained from the exciter, and the machine which in this scheme is varied in voltage seems to have only one-quarter of the range of the exciter described in the paper.

In reply to Mr. Juhlin, the 15 per cent margin between maximum excitation requirements and maximum excitation voltage was taken as the minimum which would be considered reasonable, having regard to the stable range of voltage which can be obtained from a shunt machine. One of the aims of the paper was to establish a method of reference for exciter voltage response, and it might be more satisfactory to give this as a percentage per second of the excitation voltage required by the alternator for full-load operation, rather than with reference to a voltage which includes a further 15 per cent margin, as do the curves plotted in Fig. 7. In this connection it would have been interesting if the response of the exciter for the frequency-changer, given as 630 volts per second, had been given as a percentage of the exciter voltage for maximum normal operation. Towards the end of his remarks Mr. Juhlin has done well to emphasize the technical reasons which have contributed towards the design of modern machines, as it is sometimes suggested that, inasmuch as a lower short-circuit ratio produces a machine of somewhat small mechanical dimensions, this type of design is adopted for purely commercial reasons.

In reply to Mr. W. Jackson, the oscillogram from which Fig. 19 was taken contained a record of stator current, and this showed that no arcing took place at the switch.

In further explanation of the statement that the initial shape of the record of field current is due to the presence of mutual circuits, I would say that, when the short-circuit is removed, the rotor excitation circuit and the mutual circuit, formed by the solid mass of the rotor, both carry transient currents which, at the instant of breaking the short-circuit, have in combination a value which reduces the magnetizing effect of the previous steady current to a value corresponding to the voltage which appears at the open-circuited terminals. The shape of the field-current record will therefore be different from that of the alternator voltage record, and this difference can be made more pronounced during the first few cycles if, for the purpose of experiment, the alternator field current is given a long time-constant. I think that Mr. Jackson has misread the paragraph on page 330 regarding the calculation of combined response of alternator and exciter, but in further explanation I would say that as regards the alternator it is correct to use the time-constant from Fig. 20 for the new load conditions when once they are established, because, although we are calculating the alternator voltage variation, the variations are not large. In the case of exciter response the exciter voltage varies over a wide range and, due to saturation, the exciter response varies appreciably. For the sake of simplicity in calculation, however, an average value of the exciter response is taken over the range involved in adjusting the alternator excitation for the new load.

In reply to Mr. Topley, the service exciter which, in the case he cites, also excites the auxiliary alternator at constant voltage is liberally rated for the extra duty and is made with a saturated field and a long gap so that variations in the exciting current of the auxiliary alternator do not produce any appreciable variation in the main alternator voltage, even though there is no regulator in service. No provision is made for excessive excitation of the auxiliary generator in case of faults, so that no abnormal demands come upon the service exciter if that alternator be short-circuited. With regard to the mutual windings which Mr. Topley has noticed on the main exciter, I would refer to Fig. 6 and point out how sudden is the drop in voltage compared with the rise in voltage on a separately-excited exciter. The use of an additional circuit on the field spools, short-circuited on itself, adds a small but similar delay on both the rising and falling curves and, lessening the disparity between them, increases the range of a given design of voltage regulator.

In reply to Mr. Lunn, I think that the regulator and exciter should be allowed to continue to operate as long as the voltage is available from the exciter to maintain normal voltage, even though the speed or frequency has fallen. The experience of Mr. Lunn and other operating engineers who have contributed to the discussion seems to indicate that exciter instability is frequently met with.

The requirements mentioned by Mr. Garbutt to eliminate the increased excitation in the event of a fault near the station are met by the use of a stabilized exciter without provision for super-excitation. I consider it to be good practice to install a small turbo-alternator rheostat in addition to an exciter rheostat wherever a stabilized exciter is not employed. With regard to regulator operation with a stabilized exciter, resistance should be inserted to reduce the alternator voltage on open-circuit down to about 75 per cent instead of the lower value usually adopted when a shunt exciter is used. The exciter voltage range depends, of course, upon the alternator and, as stated in the paper, for the typical turbo-alternator (see Fig. 15) and, allowing for hot and cold conditions of the alternator field, the approximate exciter voltage range would be at least 4 : 1. The operation of the regulator relays is improved when a stabilized exciter is used, by exciting the relay coils from the constant voltage of the service exciter.

In reply to Mr. Howarth, arrangements are available whereby a regulator can be made to maintain constant the average voltage on all three phases. This can be extended so that the regulator compensates or compounds for the average current of the three phases. With regard to single-phase fault conditions, however, it is a mistake to suppose that the three phase windings of an alternator act like three separate reactions and that voltage is maintained on the healthy phases. A single-phase fault will depress the voltage on all three phases, and a regulator connected to any of them will give satisfactory operation under these circumstances.

In reply to Mr. Somerville, we like to think that the " hit or miss " epoch in electrical machine design was passed many years ago. His comparison between the response, on the one hand, of a separately excited exciter when the action of the regulator is delayed to illustrate a method of calculation, and, on the other hand, of a shunt machine with the regulator operating normally, seems without meaning. I agree that the response curve given in his Fig. F is typical of the vibrating-contact type of regulator, but this curve does not warrant his suggestion that, in plant already installed, improvement can be obtained by changing the regulator rather than by changing the method of excitation. With regard to cut-outs, it is not, in my experience, necessary to install these to take care of faults in the regulator, as failure of the regulator is rare when it is given regular attention, and the suggestion that it is a weak link (there must, of course, always be a weakest link) in the chain of generation is not justified. Cut-outs, however, are installed to put the regulator out of action when the busbar voltage has been considerably depressed for a lengthy period and when, to all intents and purposes, the station is out of action and generators have fallen out of step, and large increases in the excitation of the coupled machine would only lead to further difficulties. Mr. Somerville's confirmation of hysteresis effects with shunt-wound exciters is welcome, and I think that these effects will be more pronounced if hard magnetic steel be used for the pole cores.

PROCEEDINGS OF THE INSTITUTION.

794TH ORDINARY MEETING, 5TH DECEMBER, 1929.

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 28th November, 1929, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

The President announced that during the month of November, 1929, 22 donations and subscriptions to the Benevolent Fund had been received, amounting in the aggregate to £19. A vote of thanks was accorded to the donors.

A Lecture was delivered by Dr. H. Norinder entitled "Surges and Over-Voltage Phenomena on Transmission Lines, due to Lightning" (see page 525).

After the delivery of the Lecture and some remarks by Dr. G. C. Simpson, C.B., F.R.S., Mr. B. L. Goodlet said that he had frequently heard it stated that we in England are not paying much attention to the problems of lightning and transient phenomena generally, and that we have no impulse generator and cathode-ray oscillograph suitable for such work. He showed three slides to prove that we are not ignoring the problem. These slides illustrated (1) an impulse generator to give a voltage to earth of 1½ million volts, (2) an impulse spark-over of more than 1 million volts on an insulator chain, and (3) a cathode-ray oscillogram of an impulse spark-over.

A vote of thanks to Dr. Norinder, proposed by the President, was carried with acclamation, and the meeting terminated at 7.15 p.m.

795TH ORDINARY MEETING, 12TH DECEMBER, 1929.

(Joint Meeting with the British Section of the Société des Ingénieurs Civils de France.)

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 5th December, 1929, were taken as read and were confirmed and signed.

A paper by Messrs. L. A. E. Sékutowicz and A. Evain, Members of the French Institution of Civil Engineers, entitled "The Electrical Plant and Network of the Société Electrique de la Sidérurgie Lorraine" (see page 413), was read on behalf of the authors by Mr. Roger T. Smith and discussed.

The meeting terminated at 7.5 p.m. with votes of thanks to the authors and to Mr. Roger T. Smith for presenting the paper, which were moved by the President and carried with acclamation.

796TH ORDINARY MEETING, 19TH DECEMBER, 1929.

Colonel Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 12th December, 1929, were taken as read and were confirmed and signed.

A paper by Lieut.-Col. S. E. Monkhouse, R.E.(T.R.), and Mr. L. C. Grant, Members, entitled "The Heating of Buildings Electrically by means of Thermal Storage" (see page 657), and a paper by Mr. T. G. N. Haldane, M.A., Associate Member, entitled "The Heat Pump—An Economical Method of Producing Low-Grade Heat from Electricity" (see page 666), were read and discussed.

The meeting terminated at 7.55 p.m. with a vote of thanks to the authors, which was moved by the President and carried with acclamation.

INSTITUTION NOTES.

Revised Supplement to the Wiring Regulations.

The Council have approved the issue of a revised Supplement to the Ninth Edition of the I.E.E. Regulations for the Electrical Equipment of Buildings. This Supplement relates to radio receiving and valve amplifying apparatus connected to the supply mains, and is in substitution for the corresponding supplement issued in June 1928, which is now withdrawn. Copies can be obtained, free of charge, from the Secretary of the Institution, for insertion in existing copies of the Ninth Edition of the Regulations.

The Benevolent Fund.

On the last page of the cover of this issue of the *Journal* will be found particulars of certain publications, etc., which are on sale on behalf of the Benevolent Fund.

Council's Nominations for Election to the Council.

The following have been nominated by the Council for the vacancies which will occur in the offices of President, Vice-President, Honorary Treasurer, and Ordinary Members of Council on the 30th September, 1930:—

President. (*One Vacancy.*)

C. C. Paterson, O.B.E.

Vice-President. (*One Vacancy.*)

R. K. Morcom, C.B.E., M.A.

Honorary Treasurer. (*One Vacancy.*)

E. Leete.

Ordinary Members of Council.

MEMBERS. (*Five Vacancies.*)

F. W. Crawter.
A. Ellis.
E. W. Hill.
W. Riggs.
R. P. Sloan, C.B.E.

ASSOCIATE MEMBER. (*One Vacancy.*)

R. Grierson.

ASSOCIATE. (*One Vacancy.*)

J. F. W. Hooper.

Premiums.

The following Premiums for papers have been awarded by the Council:—

The Institution Premium (*value* £25).

H. H. HARRISON.	"Developments in Machine Telegraph Systems and Methods of Operation."

The Ayrton Premium (*value* £10).

B. A. G. CHURCHER and A. J. KING.	"The Analysis and Measurement of the Noise Emitted by Machinery."

The John Hopkinson Premium (*value* £10).

L. C. GRANT.	"The Breaking Performance of High-Power Switchgear and of a New Form of Quenched-Arc Switch."

The Kelvin Premium (*value* £10).

T. G. N. HALDANE, M.A.	"The Heat Pump—An Economical Method of Producing Low-Grade Heat from Electricity."

The Paris Premium (*value* £10).

H. A. HUMPHREY, D. M. BUIST and J. W. BANSALL.	"The Steam and Electric Power Plant of Imperial Chemical Industries, Ltd., at Billingham."

A Premium (*value* £10).

S. W. MELSOM, A. N. ARMAN, B.Sc.(Eng.), and W. BIBBY, B.Sc.(Eng.).	"Surge Investigations on Overhead Lines and Cable Systems."

A Premium (*value* £10).

T. W. ROSS and H. G. BELL.	"Recent Developments in the Protection of Three-Phase Transmission Lines and Feeders."

A Premium (*value* £10).

E. H. SMYTHE and E. G. WEEKS.	"Low-Temperature Carbonization of Fuel, with special reference to its combination with the production of electricity (English Practice)."

A Premium (*value* £5).

BERNARD LEGGETT, M.R.C.S., L.R.C.P.	"The Medical and Surgical Applications of Electricity."

A Premium (*value* £5).

J. C. PRESCOTT.	"The Capacity Effect and Natural Free Period of a D.C. Armature."

A Premium (*value* £5).

H. W. TAYLOR.	"Voltage Control of Large Alternators."

A Premium (*value* £5).

W. WEST, B.A.	"A Measurement of the Sound Pressures on an Obstacle." "The Pressures on the Diaphragm of a Condenser Transmitter in a Simple Sound Field."

WIRELESS SECTION PREMIUMS.

The Duddell Premium (*value* £20).

J. E. P. VIGOUREUX, M.Sc.	"The Valve-Maintained Quartz Oscillator."

A Premium (*value* £10).

Captain P. P. ECKERSLEY and N. ASHBRIDGE, B.Sc.	"A Wireless Broadcasting Transmitting Station for Dual Programme Service."

A Premium (*value* £10).

G. SHEARING, B.Sc., and Captain J. W. S. DORLING, R.N.	"Naval Wireless Telegraph Communications."

The awards for papers read before the Meter and Instrument Section and also for Students' papers will be announced later.

Institution Scholarships.

As mentioned in the Annual Report, the Council have established two Institution Scholarships, to be known as the Duddell and the Ferranti Scholarship respectively. It is proposed to make the first award of each Scholarship this year. The conditions of award are as follows:—

THE DUDDELL SCHOLARSHIP.

(Founded as a memorial to the late William Duddell, C.B.E., F.R.S., a former President of the Institution.)

Conditions of Award.

(1) The Duddell Scholarship in Electrical Engineering is tenable for three years and will be awarded only to British subjects who are the sons of parents of limited means, and who fulfil the required conditions. Preference will be given to candidates whose fathers or a near relative are, or have been, members of The Institution of Electrical Engineers.

(2) Candidates must be under 19 years of age on the 1st July in the year in which the award is made. Each candidate must be nominated by a Corporate Member of the Institution and have passed the Matriculation Examination of a British University or an examination exempting from the Matriculation Examination.

(3) The successful candidate will be required to take up a whole-time day course in Electrical Engineering which would normally be taken at a University, College, etc., in The British Empire, and

(*a*) he must be, or forthwith become, a Student of The Institution of Electrical Engineers, and

(*b*) he must not concurrently be the holder of any other Scholarship.

(4) In making the award consideration will be given to the candidate's school record, Matriculation or exempting examination results, and general personality.

(5) The annual value of the Scholarship is £150, payable in equal quarterly instalments, and subject in each case to the Professor or Teacher under whom the holder of the Scholarship is studying certifying that he is working satisfactorily.

(6) Instalments may be withheld or forfeited in the event of an unsatisfactory report being received from the Professor or Teacher concerned. A Scholarship will be cancelled and any unpaid instalments forfeited if the holder should relinquish his electrical engineering studies.

(7) An award of the Scholarship will be made annually.

(8) Nominations must reach the Secretary of The Institution of Electrical Engineers not later than the 15th June on forms, copies of which are obtainable from the Institution.

(9) The Scholar will be required to commence his studies at the beginning of the Session next following the award.

THE FERRANTI SCHOLARSHIP.

(Founded as a memorial to the late Dr. S. Z. de Ferranti, F.R.S., a former President of the Institution.)

Conditions of Award.

(1) The Ferranti Scholarship in Electrical Engineering is tenable for two years and will be awarded only to British subjects who fulfil the conditions set out below. Preference will be given to candidates whose fathers are, or have been, members of The Institution of Electrical Engineers.

(2) Each candidate must be nominated by the Professor or Teacher under whom he is working, or has worked, and satisfy the following conditions:—

(*a*) He must be a Student or Graduate of The Institution of Electrical Engineers and have been such for not less than two years.

(*b*) He must have undergone a whole-time day course in electrical engineering of at least three years, and have graduated or obtained a final certificate or diploma appertaining to such course approved by the Institution.

NOTE.—Consideration will also be given to candidates who have, for any reason, been unable to take a whole-time day course of study, but who have obtained the degree of B.Sc. with 1st or 2nd Class Honours, and who have satisfied the Examiners in electrical engineering subjects.

(*c*) He must be under 26 years of age on the 1st July in the year in which the award is made.

(*d*) He must undertake to carry out whole-time research or post-graduate work of a nature and at an establishment approved by the Council of the Institution.

(3) The Scholarship may at the discretion of the Council be awarded as a Travelling Scholarship, with a view to study abroad at some approved institution, laboratory, or works.

(4) Except in the case of a Travelling Scholarship the recipient of the Scholarship must not concurrently be the holder of any other scholarship.

(5) The annual value of the Scholarship is £250, payable in equal quarterly instalments, and subject in each case to the Professor or responsible authority under whom the holder of the Scholarship is studying certifying that he is working satisfactorily.

(6) Instalments may be withheld or forfeited in the event of an unsatisfactory report being received from the Professor or responsible authority concerned. A Scholarship will be cancelled and any unpaid instalments forfeited if the holder should relinquish his electrical engineering research or other post-graduate work.

(7) An award of the Scholarship will be made annually.

(8) Nominations must reach the Secretary of The Institution of Electrical Engineers not later than the 15th August on forms, copies of which are obtainable from the Institution.

(9) The Scholar will be required to commence his research or other post-graduate work at the beginning of the Session next following the award.

Letter from Kelvin to the late Dr. Kapp.

The Institution has acquired from Mr. Kilburn Scott a very interesting letter, reproduced in facsimile on pages 798 and 799, written by the late Lord Kelvin (then Sir William Thomson) to the late Dr. Gisbert Kapp, which is evidently in reply to an inquiry as to whether there was a rational theoretical method of calculating the ampere-turns on the field magnets of a dynamo to produce a given excitation. In reference to this letter Mr. Llewelyn B. Atkinson contributes the following note:—

"In November 1885 Mr. Kapp read a paper before the Institution of Civil Engineers dealing with the design of dynamos as they were then being made, in which he gave a formula for the magnet winding in terms of the ampere-turns on the magnet and of what he, for the first time, called the magnetic resistance of the iron of the magnet, the air of the air-gap, and the iron of the armature.

"In a footnote he states that although he had used this formula for some time it was an empirical formula, and that only recently Sir William Thomson had given him explanations which showed that the formula was a rational one. I surmise that the letter now reproduced is the explanation referred to. Colonel R. E. Crompton in his "Reminiscences" states that in 1881–2, in working on the subject of dynamo-design improvement, and after consultation with Sir William Thomson, Fleeming Jenkin and others, a formula was arrived at showing that the variation in e.m.f. of a dynamo as affected by the magnetization was dependent on the quantity

$$\frac{4\pi \times \text{ampere-turns}}{\text{Air-gap} \times 2}.$$

This formula is similar in form to that given at the end of Thomson's letter, but was not, as far as I know, published. The formula therefore is a confirmation of the one communicated to Colonel Crompton's firm several years earlier and on which a large number of the machines of that date were being manufactured by him.

"An analogy will explain the idea underlying this letter, which idea certainly was not generally appreciated until Kapp's paper was read. If a magnet be pushed into a circular closed conducting circuit of uniform material and section, an e.m.f. will be set up. This will be of the same value in every element of length and there will be no difference of potential between the individual lengths. If, however, the conductor is of different sections or of different materials in selected parts, then, the current being the same at every part of the circuit, each element of length will not use up (so to speak) its own e.m.f. and differences of potential will exist between parts of the circuit. In the case of a solenoid of infinite length, considered by Maxwell and referred to by Thomson (page 284, vol. 2, 2nd edition of Maxwell's treatise), or its equivalent, a toroid magnetic ring, the magnetic force is treated as being in air and the windings uniformly distributed, and, corresponding to the uniform wire above mentioned, there is no magnetic difference of potential inside the winding. Thomson's letter explains how, if the solenoid surrounds in part a material of infinite permeability and in part there is an air space of small permeability, the whole magnetic force produced by the solenoid concentrates on this air space. In the actual case the material, iron, is not of infinite permeability, but of a permeability much greater than air, and this gives rise to the modified form of the equations which Kapp had reached empirically. In May 1886, a paper was read before the Royal Society by the brothers John and Edward Hopkinson, which completed the subject and which treated the magnetic circuit in the manner suggested by Thomson in this unpublished letter, and placed dynamo design, so far as the magnetic circuit was concerned, on a perfectly sound scientific basis."

Elections and Transfers of Members.

At the Ordinary Meeting held on the 13th March, 1930, the following elections and transfers were effected:—

ELECTIONS.

Associate Members.

Baldwin, Percy Noel St. J., Lieut.-Commdr.R.N.,B.A.
Bearcroft, Ernest Charles L., Captain R.M.
Booth, John Arthur.
Brown,John Hugh H.,M.A.
Cameron, Gregor Stuart.
Dale, William Bourne.
Edgley, George Wilfred.
Fleming, Elliott.
McKenna, John Joseph.
Mackenzie, John Peacock, Captain R.S.
Nutt, Alfred.
Padmore, Bertram Read.
Rawlinson, William Ferdinando, D.Sc.
Semenza, Marco.
Shaw, Sydney.
Wager, Albert James.
Welman, Herbert Loftus, Lieut.-Commdr. R.N.
White, Arthur Edwin.
Winstanley,HenryMurray.
Wood, Percy Thornton.

Associates.

Fawcett, John William.

Tell me if there is anything you do not understand this letter & I shall try to make it clear by further explanation

Yacht "Lalla Rookh"
R.Y.S.

Portsmouth
July 24/85

Dear Mr. Kapp,

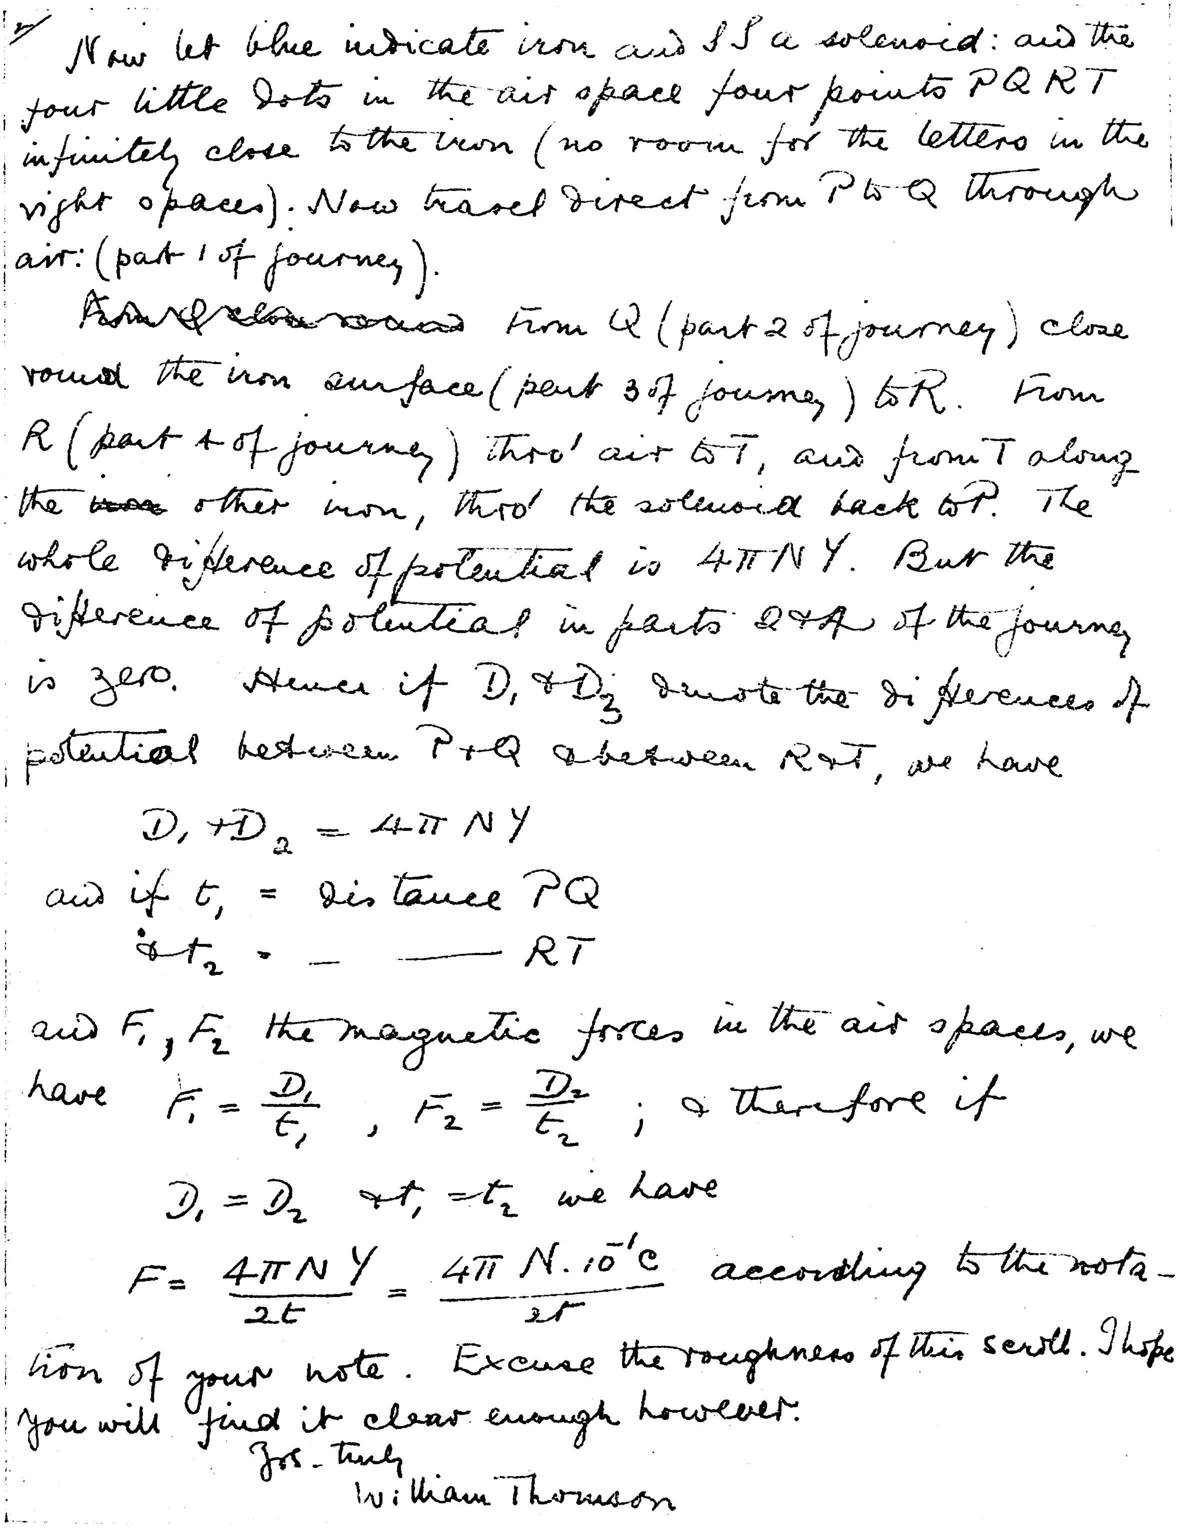
I am sorry that your letter of the 20th of June has been so long unanswered. I have been so incessantly occupied ever since it came, that I have till now not been able to find time to write on the point to which you refer.

The general principles to be found in Maxwell & perhaps some other books and in my own papers show that

$$4\pi N.\gamma$$

is the difference of magnetic potential thro' a solenoid (γ being the strength of the current in C.G.S. absolute ~~units~~ units and N the number of turns) the line of the circuit being wholly through air.

Now if the magnetic permeability (or conductivity for lines of magnetic force) of iron were infinitely great, the magnetic potential is equal all over the surface of each piece of iron, and in the air infinitely near it



Now let blue indicate iron and S S a solenoid: and the four little dots in the air space four points P Q R T infinitely close to the iron (no room for the letters in the right spaces). Now travel direct from P to Q through air: (part 1 of journey).

~~And close round~~ From Q (part 2 of journey) close round the iron surface (part 3 of journey) to R. From R (part 4 of journey) thro' air to T, and from T along the ~~[illegible]~~ other iron, thro' the solenoid back to P. The whole difference of potential is $4\pi NY$. But the difference of potential in parts 2 & 4 of the journey is zero. Hence if D_1 & D_2 denote the differences of potential between P & Q & between R & T, we have

$$D_1 + D_2 = 4\pi NY$$

and if t_1 = distance PQ

& t_2 = — —— RT

and F_1, F_2 the magnetic forces in the air spaces, we have $F_1 = \frac{D_1}{t_1}$, $F_2 = \frac{D_2}{t_2}$; & therefore if

$D_1 = D_2$ & $t_1 = t_2$ we have

$$F = \frac{4\pi NY}{2t} = \frac{4\pi N . 10^{-1}c}{2t}$$

according to the notation of your note. Excuse the roughness of this scroll. I hope you will find it clear enough however.

Yrs. truly

William Thomson

RECENT DEVELOPMENTS IN THE PROTECTION OF THREE-PHASE TRANSMISSION LINES AND FEEDERS.

By T. W. Ross and H. G. Bell, M.Sc. Tech., Associate Members.

Paper first received 10*th June*, 1929, *and in final form* 6*th June*, 1930; *read before* The Institution 9*th January*, *before the* South Midland Centre 20*th January*, *before the* North-Eastern Centre 10*th February*, *and before the* Western Centre 17*th February*, 1930.)

Summary.

The problems associated with the protection of transmission lines and feeders have in recent years become of great moment, and much development of the art has resulted. Some of the difficulties which have arisen in practice are emphasized and some of the methods of overcoming them are described. The design and lay-out of distribution systems, the earthing of the neutral point and the application of arc-suppression coils are briefly discussed, more particularly in their relation to problems of protection. Factors which influence the choice of protective systems are considered and the requirements of schemes to meet the exacting conditions of modern transmission systems are surveyed.

The several methods of obtaining discriminative protection are then reviewed. Commencing with modern designs of time-discriminative overcurrent relays, emphasis is laid upon the importance of a definite minimum time characteristic and upon correct methods of obtaining directional features. The special requirements of such relays when applied to give sensitive earth-fault protection are indicated, and means of obtaining a suitable polarizing voltage are explained; a description of sensitive earth-fault relays of the wattmeter type is also given.

The theory and application of impedance relays is discussed, with reference to definite-impedance and impedance-time relays. A method of compensation for voltage-drop across the arc resistance of a fault is indicated. The field of application of low-voltage release relays is defined and the method of their use illustrated.

Attention is then directed to the advantages of pilot-wire feeder protection, and the limiting features of older forms are mentioned. Typical modern opposed-voltage and circulating-current methods which are giving satisfactory service on modern systems are described in some detail. The new field of direct-current pilot-wire protection is discussed; the main classifications of this type of gear are defined and examples are given. The paper concludes with a description of a novel and flexible method of protection for duplicate and multiple parallel feeders.

Introduction.

Electrical energy has become such an essential factor in the life and well-being of the community that a very heavy responsibility rests upon supply authorities to maintain the supply under all conditions. This becomes ever more difficult with the growth in size of supply undertakings because of the larger short-circuit currents possible and the continual extension of systems. A failure of insulation at any point on such large systems may cause widespread disturbance and dislocation of supply unless the faulty unit is rapidly isolated. This can only be achieved by a carefully considered lay-out of the network and the correct choice and application of protective gear.

There is perhaps no other branch of electrical engineering in which so much ingenuity has been displayed as in the design of protective systems and devices, a considerable number of which have been tested under practical conditions. In many cases, however, theoretically promising schemes have proved to be unsatisfactory in practice owing, as a rule, to incorrect operation resulting in the cutting out of healthy feeders in addition to or instead of the faulty ones, rather than to failure of the gear to clear a fault. Such unwanted operation is in some cases the result of the abnormal conditions which exist during short-circuits, and the lack of appreciation of such conditions at the time the gear was designed. In other cases the heavier disturbances consequent upon the growth of the supply system have resulted in the incorrect operation of protective gear which under less onerous conditions gave entire satisfaction.

During the last 15 years the science of correctly protecting machines, transformers and feeders, so as to combine the necessary sensitiveness with stability, has been gradually developed, and the methods successfully applied to smaller machines and transformers have been found to apply, with slight modifications, to the larger units used to-day. The extension of high-voltage networks has, however, introduced entirely new factors into the question of feeder protection and it has been found that the methods hitherto used are no longer suitable for many e.h.t. feeders.

Modern Conditions.—Of the many causes which have combined to increase the difficulties of feeder protection, the exceedingly heavy faults which occur in the large networks of to-day constitute perhaps the chief. The fault currents are carried not only by the faulty sections but also by healthy sections, so that it becomes necessary to provide either balanced gear which will remain stable, or other discriminative gear which will retain its correct discrimination with much heavier through-currents. At the same time these heavy fault currents demand protective gear which will provide for rapid clearance, not only on account of the damage that may be caused in the neighbourhood of the fault but also to diminish the liability of synchronous plant falling out of step, with the consequent risk of extensive dislocation.

The extension of feeder networks, combined with the higher voltages at which they are operated, has resulted in larger charging currents in the lines and cables, and when balanced protective gear is in use these currents are of importance as they represent, under healthy conditions, an out-of-balance similar to that which exists during a fault. These currents also assume higher values in healthy feeders during fault conditions on other parts of the system, owing to the rapid voltage-change which sets up transient disturbances of frequencies much higher than the normal. Quite independently of this, other currents are induced in or find their way into the pilot cables. For satisfactory stability, balanced systems of protection must be compensated for all such conditions.

In many cases feeder networks, instead of receiving, as formerly, a supply from a single point, have now a number of feeding points, and as a result the direction in which fault currents may flow in certain of the feeders depends upon the position of the fault on the network. A similar consequence arises from the increasing use of ring mains, and although this introduces no additional difficulty where balanced protection is used, yet where other types of protective gear are employed directional relays must be installed. The increasing complexity of feeder networks also introduces new difficulties into the forecasting of the distribution of fault currents in the various feeders under all conditions, and very careful computations are necessary in many cases. When it is remembered that the opening of a switch at one end of a faulty feeder may cause a complete redistribution of fault currents in the entire network, the care necessary in the correct relaying of a complicated system will be appreciated. In certain cases where the capacity of connected generators may be varied considerably, fault currents at times of light load can actually be less than normal load current under maximum load conditions. Special schemes must be developed to provide for such requirements.

In this country balanced protective gear has been practically standard for the short feeders which have been in service. The greater distances which have now to be covered by feeders render the use of pilot wires and special cables prohibitive in many instances, and consequently non-pilot methods not requiring special cables must be used in many installations. It is desirable that such methods should give protection comparable with that obtainable with shorter feeders.

SYSTEM ARRANGEMENTS.

There are many factors in the design and lay-out of distribution systems and switchgear which materially influence the effectiveness of the protective measures, and these should be given due consideration when a system is planned. Such a course will in many cases result in more satisfactory protection with less complicated gear. The introduction of reactances, for instance, between different parts of a system is often helpful in limiting the short-circuit current which would otherwise be heavy enough to cause disturbance to the whole system, and the use of reactors is becoming more common, particularly at tie points, where the effect upon the voltage regulation of the system is less pronounced than if reactors were used in series with individual feeders. Special switching arrangements are often responsible for introducing difficulties and, although such arrangements are usually designed with a view to meeting possible emergency conditions, it is desirable to give due consideration to the question of protection before finally deciding upon them.

Neutral Points of Systems.—It will be agreed that the adoption of an insulated neutral or, if earthed, the method of earthing used, will have considerable effect upon the nature of the disturbances which may arise under fault conditions. There is, however, some difference of opinion as to the relative merits of an insulated versus an earthed neutral, and whilst in America the practice is to earth solidly, Continental engineers favour the insulated neutral. The practice in this country is to earth the neutral point, and current-limiting resistances are largely used for this purpose on e.h.t. systems up to 33 kV. This is done on the assumption that most faults start as faults to earth and that, by reducing the current which can flow to earth, less disturbance will arise. There is, however, a danger in applying this method to the higher-voltage systems, since the resistance, by maintaining the voltage on the faulty phase, will cause a rise in pressure between the healthy phases and earth. This may result in the development of an earth fault on one of these phases at any point on the system. It is also possible that transient voltages may be present which can add to the fundamental voltage and thus increase the strain on the insulation of the sound phases. Again, at the higher voltages earth faults very quickly develop into short-circuits between phases, when, of course, the earthing resistance cannot limit the magnitude of the current. The short-circuit between phases may, in many cases, be prevented by quick clearance of the earth fault, but this can often be more easily accomplished by allowing a greater current to flow and so help in the operation of the relays. It would appear that it is preferable to have a solid earth connection for voltages above 20 kV, but an expression of opinion from operating engineers on this important point would be welcome.

If an earthed neutral is decided upon, the question of earthing at more than one point very often arises. From the protection engineer's point of view, the earthing of the neutrals of the transformers at several points on the system has much to commend it, not only because it limits transient excess voltages but also because it facilitates the application of some relay schemes described later. The opposition of telephone authorities may, however, have to be overcome before multiple earthing can be employed. In this connection it is of interest to recall a statement by Messrs. Johnstone Wright and C. W. Marshall in their recent paper * to the effect that "After examining the subject from every standpoint, it has been definitely decided that the earthed neutral system is better than the insulated neutral system as regards non-interference with communication circuits."

Arc Suppression.—The practice of operating with an insulated neutral which is common on the Continent has not proved entirely satisfactory, and with the object of obtaining an improvement in the operation of such systems a number of arc-suppression or Petersen coils have been installed since 1920. The device consists of an iron-cored reactance having a number of tappings connected to a suitable tapping switch. The coil is connected between a neutral point and earth and its inductance is adjusted by means of the tapping switch so that at the fundamental frequency it resonates with the electrostatic capacity to earth of two phases of the network. When an earth fault takes place, therefore, there will be no current flowing to earth through the fault and an arc cannot be maintained. The result is that in the case of a flash-over on an insulator the probability is that the fault will clear itself without the necessity of tripping the circuit breakers. There will also be little or no danger of an abnormal rise in voltage between the healthy phases and earth, such as results from the repeated formation and extinction of an arc. Even where the fault is caused by a breakdown of an insulator, the arc is extinguished and the possibility of excessive strain on the insulation of healthy phases is less than would be the case if the system had an insulated neutral and no arc-suppression coil. This method has perhaps greater possibilities when applied to overhead lines than to cable networks, because earth faults on the former are usually caused by the flash-over of an insulator, in which case the suppressor would prevent the arc doing damage and the fault would probably clear itself.

---

* "The Construction of the 'Grid' Transmission System in Great Britain," *Journal I.E.E.*, 1929, vol. 67, p. 685.

Where arc suppressors are used, no single-phase failure of a permanent character can be cleared by selective relays since no earth-fault current flows in the faulty phase, and the system must be operated with one phase at earth potential until the fault can be located and the faulty section isolated.

A further development of this method of earthing permits the use of selective relays for the isolation of faulty sections whilst retaining the advantages resulting from the use of the arc suppressor. A relay having a suitable time-delay is energized from the suppression coil and operates to connect the system to earth either directly or through a resistance, should an earth fault persist on any line. The system then becomes temporarily an earthed system and the faulty section can be isolated by suitable protective gear. Fig. 1 shows such an arrangement and also the distribution of the fault current flowing before the system is earthed through the resistance. It should be noted that the arc-suppression coil is so adjusted that resonance is obtained between the inductance of the coil and the electrostatic capacity of the healthy phases. This is indicated in the diagram by the distribution of the current and the fact that no current flows into the fault. Theoretically, this arrangement is very attractive and it is at present being installed or operated by several supply companies operating abroad. The operating experience now being accumulated will show whether these advantages are obtained in practice.

The greatest difficulty in applying arc-suppression coils is the necessity of adjusting the inductance when an alteration is made in the number of feeders in service. This can be overcome if each section of the network is provided with an arc-suppression coil of sufficient inductance to compensate for the capacity of that section. The coil can then be switched at the same time as the network section is switched, without affecting the remainder of the system.

Experience has proved that satisfactory operation can be obtained on a system of overhead lines with a dissonance of as much as 30 per cent. If, therefore, there are several arc-suppression coils on such a system, very little adjustment of the turns is necessary to meet ordinary operating conditions.

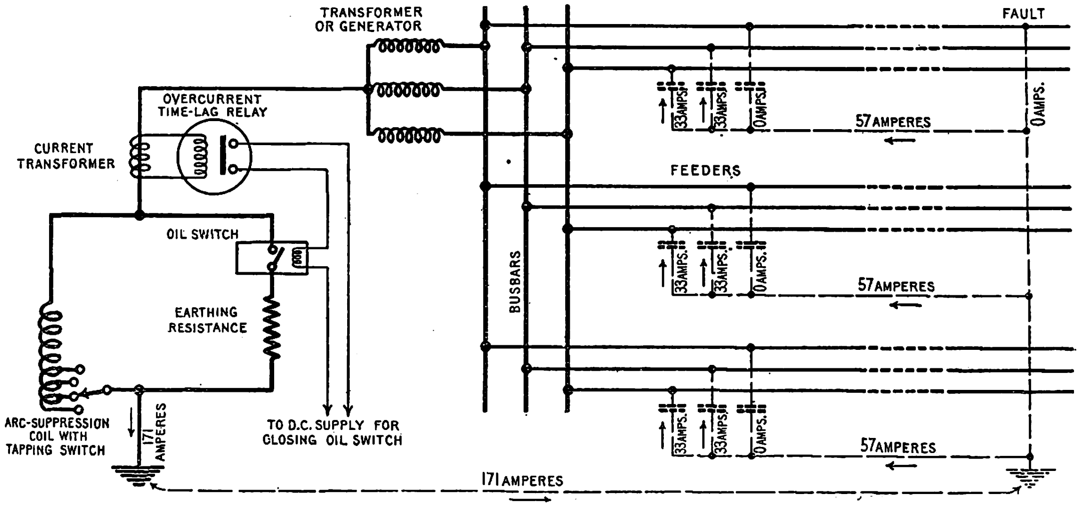

Fig. 1.—Arc-suppression coil with automatic auxiliary earthing device.

The Choice of Protective Systems.

The supply engineer called upon to choose protective gear for his special requirements finds himself faced with a bewildering array of relays and different types of gear. In a paper such as this it is impossible to describe all in detail, but an attempt is made to indicate the lines along which modern protective methods are developing, and to set out as clearly as possible the relative merits of each. This, of course, can only be carried out in a very general sense, since, before the correct choice can be made for any particular case, full consideration of all the special circumstances must be made.

The capital cost and maintenance charges on protective gear are generally regarded as a type of insurance premium, and the amount of money allocated for this purpose will largely be determined by the value placed upon the continuity of the supply at all points. For instance, the additional expense of pilot wires for certain protective schemes, which undoubtedly possess many advantages, cannot in many cases be justified, and other discriminative methods may have to be substituted. It may be necessary to take into consideration the liability of a feeder to breakdown, the existence of alternative routes of supply, the importance of the load, the liability of a fault to cause extensive disturbance and any other special conditions.

Discriminative Time and Directional Protection.—One of the first attempts to obtain the selective or sequential tripping of circuit-interrupting devices was the grading of ordinary circuit fuses, the heaviest fuse being used nearest the source of supply. This method failed because at heavy overloads the different fuses ruptured simultaneously and their discriminating features disappeared. This lack of discrimination is even more pronounced in the case of the so-called " time-limit fuses " often used for shunting the trip coils of circuit breakers. This is because the additional time for the operation of the circuit-breaker mechanism allows more time for the rupturing of the heavier fuses. Time-lag trip coils having mechanical time-lag mechanisms have also been tried and found to be unsatisfactory, but in this case the failure has been due more to defective design than to any fundamental weakness.

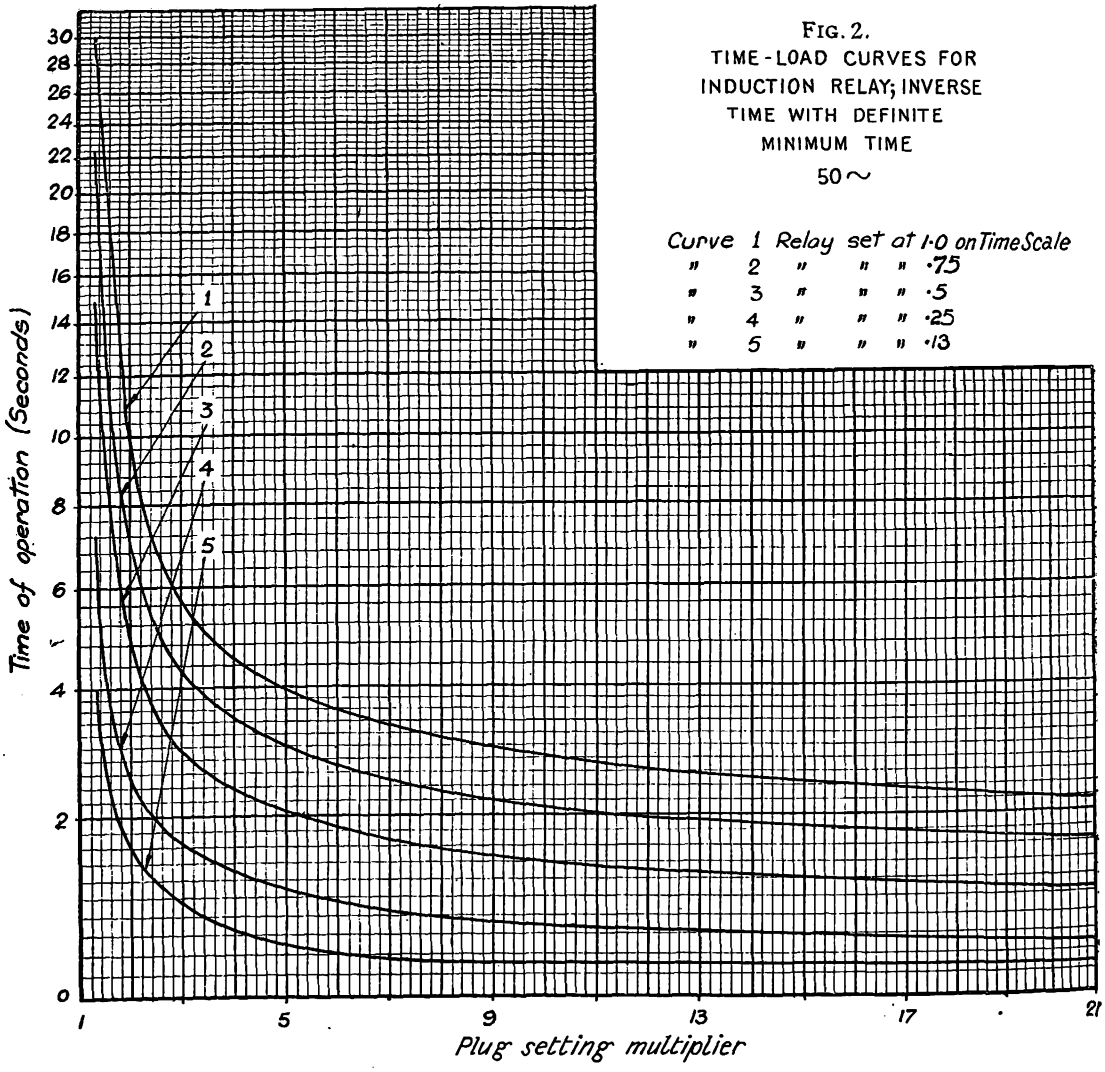

FIG. 2.
TIME-LOAD CURVES FOR
INDUCTION RELAY; INVERSE
TIME WITH DEFINITE
MINIMUM TIME

FIG. 2.

The earlier time-limit relays were much more satisfactory but they were not, as a general rule, sufficiently accurate to allow of short time-intervals between successive circuit breakers. Time-limit relays are of two types, (*a*) " definite time," and (*b*) " inverse time," the former having a time-limit entirely independent of the value of the current and the latter having a time-limit which varies inversely as the current.

The necessity of disconnecting faulty feeders with the shortest possible delay, so that the disturbance to the system shall be minimized, demands that the time-interval between successive circuit breakers shall be as small as possible. Time-delay relays must therefore be sufficiently accurate to allow of close time-settings. The maximum time that can elapse between the short-circuit occurring and the operation of the circuit breaker without affecting the synchronous plant, is usually assumed to be of the order of 2 seconds. It is, however, difficult to estimate the effect which every short-circuit will have upon the stability of a system, and this figure is quite arbitrary. Allowing that the circuit breaker takes 0·25 sec. to clear the fault after its trip coil is energized, the successive relays must have a time-interval of at least 0·5 sec. between them. If the maximum time is not to be more than 2 seconds, it will then be possible to get discrimination with 5 circuit breakers in series, and there are relays available which are sufficiently accurate for such settings.

Definite Minimum Time-Limit Relays.—Probably the simplest and best relay for this purpose is the induction overcurrent relay which is generally of the inverse time-limit type but must be designed with definite minimum time features. The latter feature is necessary to assure that sufficient time is allowed for discrimination with the largest short-circuit current. Characteristic curves for this relay are shown in Fig. 2, and it will be seen that while for the smaller overloads the time varies inversely as the current, at the heavier overloads it becomes approximately constant and independent of the value of the current. An accuracy of plus or minus 5 per cent in the operating time of the relay is usually obtainable with an instrument of good design, and this is ample for correct discrimination. Moreover, the extreme simplicity of design achieved in some relays assures the retention of this accuracy over long periods. A further important consideration is that the accuracy is obtainable with an operating coil which has a comparatively low impedance. This is of great importance when relays have to operate from current transformers of the bushing type, which are generally suitable for only a small secondary output. Standard induction relays can now be obtained the operating coils of which require only 2 to 3 volt-amperes, and in special cases the burden on the current transformer can be reduced to less than 1 volt-ampere.

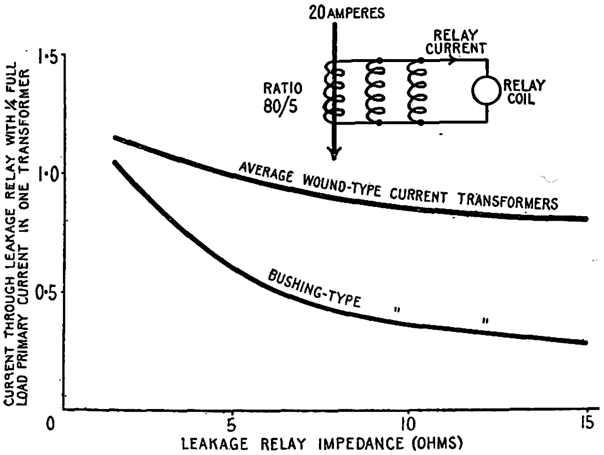

FIG. 3.—Distribution of current between relay and idle current transformers.

Low-impedance relays are also desirable if they are to be used as earth-fault relays on the residual-current principle, because when connected in this way part of the residual current will be shunted by the secondary windings of the two current transformers connected in the healthy phases and hence is not available for operating the relay. It will be apparent that the distribution of the secondary current between the relay coil and the two current-transformer windings will depend upon the relative impedance of the two paths, and if the relay has a comparatively low impedance its effective sensitivity will be increased. The curves in Fig. 3 show how the relation between the earth-fault current and relay current varies with the impedance of the current transformers and relays. It will also be seen that when bushing current transformers are used, a relay having a very low impedance is essential, if reasonable settings are to be obtained. The impedance of current-transformer secondary windings may be greatly increased if the cores are made from any of the recently developed high-permeability iron alloys, but these materials are as yet comparatively expensive and their application is in consequence limited. In many cases, however, they offer sufficient advantages to justify the extra cost involved.

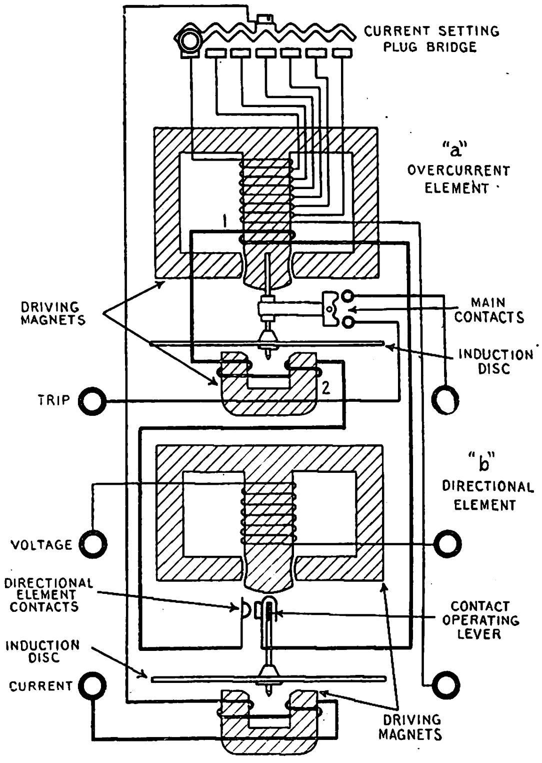

FIG. 4.—Directional overcurrent relay.

Directional Overcurrent Relays.—When graded time-limit protection is applied to ring mains or interconnected networks, in which fault current can flow in both directions, it is, of course, necessary for the relays to have directional features, in addition to the usual overcurrent and definite minimum time characteristics. Ordinary wattmeter-type relays are unsatisfactory for the purpose as the operating torque of such relays is proportional to the power factor and the voltage, both of which may be low during fault conditions. A sensitive instantaneous wattmeter element is, however, necessary in a directional overcurrent relay to indicate the direction of power flow, with an additional overcurrent time-limit element for time discrimination. Sometimes the contacts of the directional relay are connected in series with the contacts of the overcurrent time-limit relay, so that both sets of contacts must close before the circuit breaker can be tripped, but this practice is not recommended as it may cause incorrect tripping. This is due to the possibility of the overcurrent relay having its contacts closed when the fault power is flowing in the direction to open the directional contacts and after the fault has been removed by some other circuit breaker, the direction of power flow suddenly reversing before the overcurrent relay has reset. This can be overcome by arranging that the overcurrent relay cannot commence to operate until the power flow is in the required direction. A diagram of a directional overcurrent relay embodying the latter feature is shown in Fig. 4.

It will be seen from the illustration that the relay consists of two separate elements mounted in a single case, "a" being the overcurrent inverse-cum-definite minimum time relay, having characteristic curves as shown in Fig. 2, whilst "b" is a sensitive wattmeter element which operates instantaneously. The contacts of the latter element are so connected that they complete the circuit between the secondary winding of the top electromagnet (1) and the bottom electromagnet (2) of the overcurrent element "a." The latter cannot start to operate until the directional element contacts are closed, thereby allowing current to circulate through the secondary winding and so set up the moving field necessary to produce a torque in the relay movement. The secondary winding (1) is designed to give sufficient induced voltage at the lowest current setting to ensure satisfactory operation through the directional contacts.

The directional or wattmeter element has very little bias or spring control and therefore is entirely free to operate in either direction when the power flowing is as low as 4 per cent of normal, even if the voltage has fallen to 1 per cent of normal. It will thus be seen that under the most severe short-circuit conditions the directional element will correctly indicate the direction of power flow and will only allow the overcurrent element to operate when the flow is in the desired direction. The relay is therefore virtually a directional current relay as distinct from a directional power relay, and its time characteristic is a function of the current only. Fig. 5 is a single-line diagram of a ring main with overcurrent directional relay protection, with graded time-limits.

Directional Earth-Fault Protection.—When applying the directional overcurrent relay to earth-fault protection on the "residual-current" principle, the question arises of energizing the leakage relay potential element from a voltage corresponding to that of the faulty phase. The method sometimes employed of using a directional relay in each phase and connecting the contacts in parallel,

these being connected in series with the contacts of the residual-current relay, is unsatisfactory, as the power flow in the healthy phases may be in the opposite direction to that on the faulty phase and would then give incorrect selection as to direction.

There are, however, several methods by which it is possible to obtain a voltage for the directional element that will have the correct phase relationship with the faulty phase, and these are indicated in Figs. 6 and 7. The simplest method is that shown by Fig. 6(*a*), but this can only be applied if the neutral point of a power transformer is available.

The second method, shown in Figs. 6(*b*) and 6(*c*), is much more flexible and can conveniently be used whenever there is a voltage transformer available. The auxiliary transformer [Fig. 6(*b*)], which has a ratio of 1 : 1, is only necessary when the main voltage transformer is connected star/star. A delta-connected tertiary winding on the latter [Fig. 6(*c*)] can be used instead of the auxiliary transformer. It should be noted that it is essential to earth the neutral point of the voltage-transformer primary winding, and it is preferable to use shell-type voltage transformers or 3 single-phase units in order to avoid errors due to magnetic interaction.

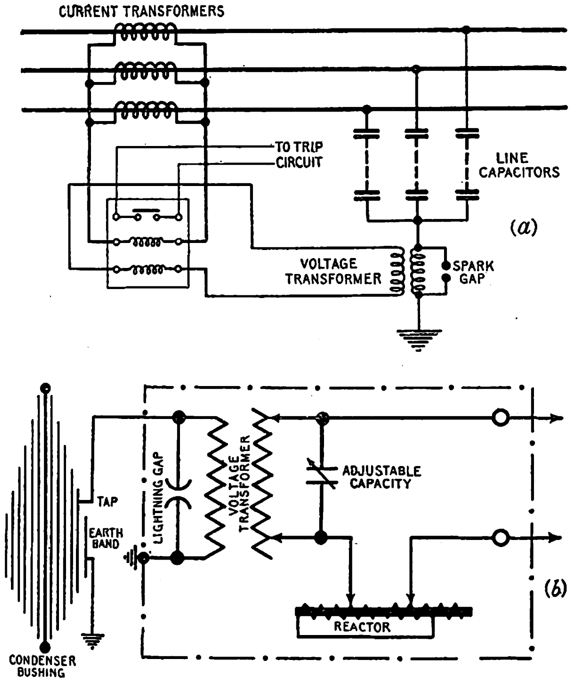

Fig. 7.—Connections for directional relays for earth-fault protection.

It will be understood that so long as equal voltages exist between each phase and earth, no voltage will appear between the two points in the delta winding where the relay is connected, but when one phase is connected to earth a voltage will be present which under the most favourable conditions will have a value three times as great as that across each phase of the delta winding under healthy conditions.

The third method [Fig. 7(*a*)] is practicable only on systems operating at 22 kV or above, and depends upon the use of condensers suspended from the lines. Normally the currents in the condensers of the three phases will sum to zero and the voltage transformer connected between the star point and earth will not be energized. With an earth fault on any line, however, this symmetry will be upset, and a secondary voltage can be obtained from the voltage transformer; this voltage will be of the same phase as the normal voltage of the faulty line.

In the case of lines of 88 kV and above, a voltage can be obtained from the condenser bushings of oil circuit-breakers or power transformers by the method indicated in Fig. 7(*b*). The charging current of each bushing is utilized by connecting a voltage transformer in parallel with the last stage of the bushing. The normal charging current is thus divided between the last stage of the bushing and the voltage-transformer winding, so that a secondary voltage can be obtained, which will, however, differ in phase from the line voltage. It is therefore necessary to correct for this phase difference and this is done by means of a network consisting of capacity and inductance, as shown in the diagram. When used for earth-fault protection, three of these devices will be required with their output circuits connected in series. Normally the three voltages will produce no resultant, but under earth-fault conditions this balance will be disturbed as already described.

It will be appreciated that in all these methods the voltage across the relay voltage winding is zero until an earth fault occurs.

THE APPLICATION OF WATTMETER-TYPE RELAYS TO EARTH-LEAKAGE PROTECTION.

On Systems with Insulated Neutral.—One of the drawbacks to an insulated system is that when a fault takes place between one phase and earth there is usually insufficient fault current to operate ordinary overcurrent relays, and therefore earth faults must remain on the system until they are cleared by manual operation of the circuit breakers, or until they develop into faults between phases. There are two distinct reasons why it is undesirable to allow earth faults to remain on the system, (*a*) because in the case of overhead lines the arc may be carried by a breeze until it strikes another phase and so causes a short-circuit, and (*b*) because an "arcing earth" can cause a considerable voltage-rise on the healthy phases and can also cause unnecessary damage by burning. By employing arc-suppression coils it is possible to avoid these difficulties, but even in these circumstances it is very often an advantage to clear persistent earth faults automatically. The fault current on an insulated system is, of course, the charging current due to the electrostatic capacity of the healthy phases of the whole system and will be approximately in quadrature with the voltage producing it. While it is possible to use ordinary non-directional earth-leakage relays which would be operated by such charging currents, correct discrimination is not always possible owing to unsymmetrical charging currents also appearing in the healthy feeders. A type of directional relay has, however, recently been designed, which, while sensitive enough to operate on the charging current between the two healthy phases and earth, will remain perfectly stable for short-circuits between phases and simultaneous earth faults on two separate phases, as well as on healthy feeders connected to the same busbars. These relays can be connected as indicated in Figs. 6 and 7.

In order to obtain sufficient sensitivity for satisfactory operation on the comparatively small capacity charging currents which may exist on some systems, the relay is designed to be operated by the product of the residual current and residual voltage of the line. As the fault current will be greatest at the switching points nearest the fault, the relays on the faulty feeders will have greater operating torque and it becomes possible to dispense with the overcurrent relay element which is used for directional overcurrent relays and obtain both time and directional selective tripping with a single element.

As already explained, the directional feature is also essential to prevent incorrect operation of the relays protecting other outgoing feeders connected to the same busbars as the faulty feeder, because on an insulated system the fault current must return as charging current through the sound phases of all the feeders, and consequently will energize the residual current coils of all the relays. In the case of the healthy feeders such return current will, however, be 180° out of phase with the fault current in the faulty feeder.

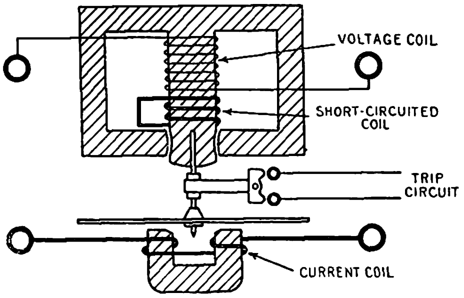

FIG. 8.—Internal connections of earth-fault relay for insulated systems.

When the neutral point of the system is insulated from earth, a comparatively high-resistance earth fault will always establish a practically constant residual voltage which will be almost in quadrature with the earth-fault current. The relays must therefore be designed to operate as reactive power relays having a torque which increases as the sine of the angle between current and voltage. A relay designed in this way will therefore have a torque proportional to $IE \sin \phi$, and as E and ϕ are practically constant the torque will actually vary as the fault current. It is thus possible to use an inverse time-delay relay with definite minimum time features, and thus obtain time discrimination as indicated in the characteristic curve, Fig. 2.

Fig. 8 gives the internal arrangements of the relay, which has the usual voltage and current elements similar to a wattmeter, but with an additional winding, short-circuited on itself, on the voltage element. This latter winding modifies the phase angle of the magnetic flux of the voltage element so that the relay will operate as a reactive power relay. The current coil of such a relay will have an impedance of approximately 1 ohm and, if set at 0·15 ampere, will operate, for example, with 6 amperes earth-fault current when connected to average 33-kV bushing current transformers. Relays of this type are not suitable for the protection of sections of ring mains or closed networks having insulated neutral points, because the direction of the reactive power will vary according to the position of the fault, owing to the distribution of the return fault current through the healthy sections. It is, however, possible to make use of these relays in protecting parallel feeders, as in this case the direction of the return fault power is always such as to give correct selectivity.

On Systems with Earthed Neutral.—As the earth-fault current will in most cases be nearly in phase with the voltage between the faulty phase and earth, an ordinary wattmeter type of relay can be used for directional earth-fault protection. The relay should be connected as indicated in Fig. 6 and will have load/time characteristics similar to those of the reactive power relays for insulated neutral systems. Time and directional discrimination is thus embodied in the same relay and, moreover, an increased sensitivity is obtained since part of the operating torque is provided by the voltage coil, thus allowing a lower-impedance current coil to be used. As the system neutral is earthed the direction of the fault power will always be known and the relays can be applied in the protection of all types of networks.

IMPEDANCE OR DISTANCE RELAYS.

As networks grow in size and as more linking-up between systems takes place, it becomes more difficult to obtain satisfactory protection by overcurrent and directional time-limit relays and, unless pilot wires or special cables are provided, dependable discrimination is practically impossible. This is due to two main causes, (*a*) the possible variation of feeding points, and (*b*) the greater number of substations in series. The former difficulty can to some extent be overcome if the relay times are re-graded whenever the feeding point is altered, but to overcome the latter difficulty would necessitate longer maximum time-delays than are practicable. The impedance relay, however, offers a solution to this problem and in the last few years many such relays have been installed.

The principle which governs the design of all impedance relays is that the relation between the fault current and the voltage at the point where the relay is connected will depend upon the impedance of the feeder or line between that point and the fault, or $Z = E/I$. Thus a relay having a current element the torque of which is opposed by the torque of a voltage element could be so designed that it would only close its contacts if the ratio E/I were less than the impedance of the section of line or feeder to be protected. Such a relay would, therefore, only operate for faults in its own section, since with more distant faults the torque of the voltage element would overcome that of the current element and produce a torque in the reverse direction. There is, however, a practical difficulty in applying such relays, as, owing to the variable resistance of the arc, it is impossible to estimate correctly the exact impedance of the feeder, with the result that the relay must be adjusted for an impedance greater than that represented by the latter.

Successive relays will thus overlap each other and might operate for faults within a part of the next section, but this is overcome by introducing a time-delay feature which causes the operation of the relay to slow down as the distance between it and the fault increases. A fault close to the relay would therefore cause quick operation to trip the circuit breaker before the slower-acting, more distant relay could operate.

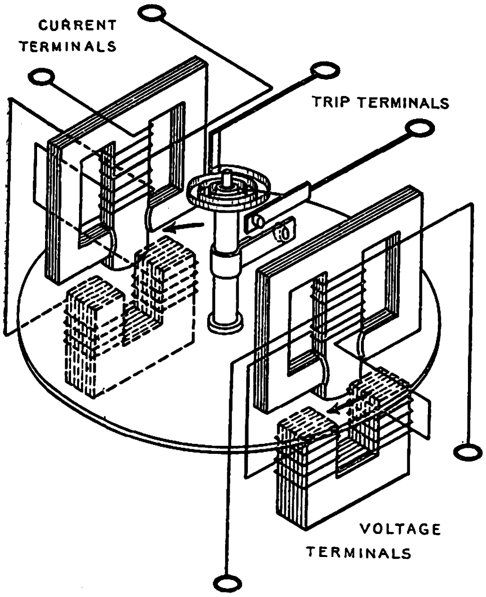

Fig. 9.—Induction-type definite impedance relay.

Definite Impedance Relays.—Fig. 9 is an isometric view of a relay of this type, which may be called the "definite impedance" type, and Fig. 10 shows time/distance curves for two relays in series. From the latter it will be seen that the relay is set for an impedance 15 per cent greater than that of the feeder. The relay, which is of the induction type, has two elements operating on a single disc, the current element producing a torque which tends to close the contacts, while the torque of the voltage element tends to open them.

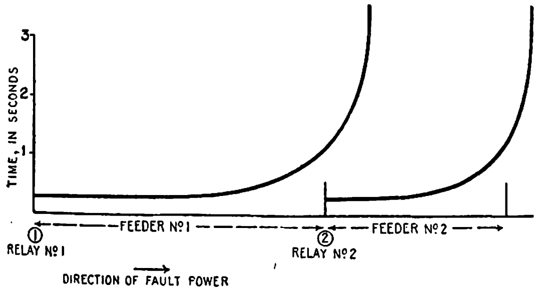

Fig. 10.—Characteristic curves of definite impedance relay.

One of the difficulties in the design of impedance relays of this type is that the voltage element must be designed to operate over a large range of voltage. This is due to the fact that at comparatively low voltages it has to produce a torque equal to that of the current element at comparatively high currents, and has also to withstand full voltage continuously under normal conditions. It has therefore been found necessary to use an "economy" reactance connected in series with the voltage coil and to short-circuit it by an instantaneous auxiliary relay when faults occur. By this means the voltage element of the impedance relay is kept cool during normal conditions and yet has sufficient operating torque at low voltage to compare with the torque of the current element. The value of this reactor must be so proportioned that when it is in series with the voltage element the latter will produce sufficient torque to overcome that of the current element at loads below the setting of the auxiliary relay.

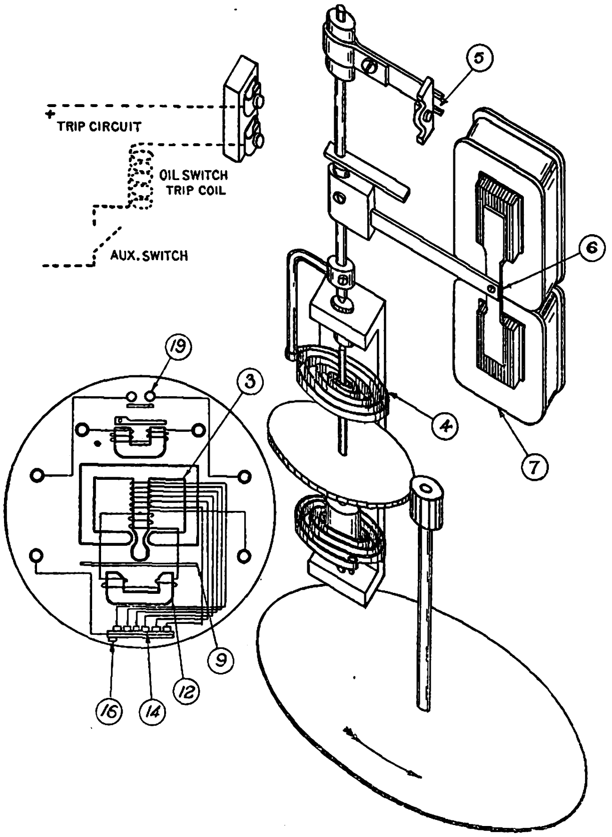

Fig. 11.—Diagram to illustrate action of impedance element of impedance-time relays.

Impedance-Time Relays.—Fig. 11 is an isometric view of another type of impedance relay which may be called the "impedance-time" relay, because its selective feature entirely depends upon the time-delay between relays in series. The relay is so designed that the time-delay is proportional to the impedance between the relay and the fault, that is, the more distant the relay the slower will be its operation.

The driving element of the relay operates on the induction principle, and the restraining element on the attracted-armature principle. The induction element comprises electromagnets (3) and (12), the resultant magnetic field from which reacts on the eddy currents induced in the non-magnetic disc (9) and produces a torque tending to rotate the disc against the braking effect of a permanent magnet. The brake magnet provides the control necessary to obtain a disc speed proportional to the driving torque. The spindle of the disc is geared to a counter-shaft and to this is attached the inner end of a spiral spring (4). The outer end of this spring is fixed to a bent lever the movement of which controls the position of the moving contacts (5) mounted on an entirely separate shaft, on which is also fixed a flat armature of soft iron (6) which is normally held against the face of the restraining electromagnet energized by the voltage coil (7).

The position of the moving contact is therefore under the joint control of the current and voltage elements of the relay, and at the end of its travel the moving contact bridges the two fixed contacts (19). On the occurrence of a fault the disc will rotate at a speed depending upon the current value and so wind up the spring (4) which accumulates a rapidly increasing torque tending to force the armature (6) away from the electromagnet (7). At the same time the pull exerted on the armature by the voltage-restraining coil prevents movement of the moving contact until the spring has been wound up sufficiently to force the armature away from the attraction of the electromagnet. This takes a time which is, in consequence, proportional to the pull of the voltage coil and inversely proportional to the speed of the driving disc. The time is therefore proportional to the impedance between the relay and the fault.

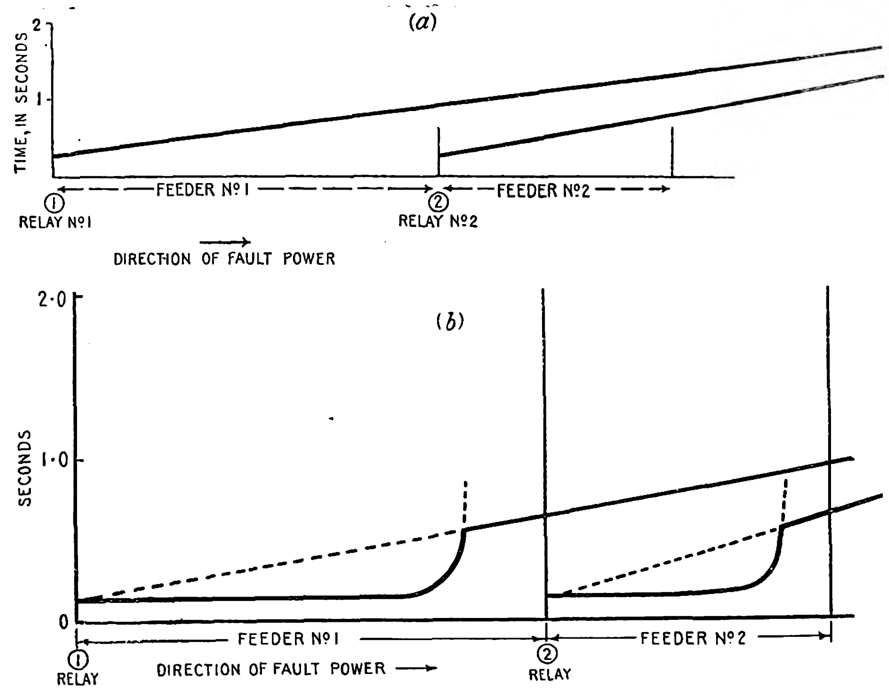

FIG. 12.—Characteristic curves of impedance relay.

(a) Impedance-time relay. (b) Combined impedance relay.

The method of applying this relay is to adjust the setting values of the current and voltage elements so as to produce operation of the relay with a maximum time-delay of not more than, say, 0·8 sec. for all faults on the particular line being protected. This means that the relay will operate in 0·8 sec. when the fault is at the remote end, but with decreasing time as the position of the fault is nearer to the relay (see Fig. 12, which gives the time/impedance curves for two relays in series). The settings are adjusted by means of tappings on the current coil and an adjustable resistance connected in series with the restraining coil.

The design of the restraining element of this relay is such that "economy" reactances are not necessary. Both relays are suitable for simple radial feeder systems having no complications other than several switching points in series, but it is of course necessary on ring mains or loop systems to have directional features which should be applied in a similar manner to that already described for directional overcurrent relays.

It is desirable at this point to compare the characteristics of the two relays just described and to investigate their fields of application. In the first place, whilst the definite impedance relay operates more quickly than the impedance-time relay for faults over the greater part of the feeder, it makes no provision for variation in the fault impedance beyond the 15 per cent overlap already mentioned. It is usually assumed that for phase-to-phase faults the impedance value remains nearly constant for a given length of feeder, but this does not hold good for earth faults, when the impedance of the earth return may vary considerably.

The impedance-time relay has the advantage that variation in the fault impedance does not prevent the relay from operating, although it may somewhat increase the operating time. In fact, each impedance-time relay acts as a "back-up" relay to the next in the sequence, so that, even if the correct circuit breaker fails, the fault will still be isolated in a slightly longer time.

A relay which would combine the characteristics of both these relays would appear to have a slight advantage, and this arrangement is adopted in some cases. The characteristic curves for such an arrangement are shown in Fig. 12(*b*). It is doubtful, however, whether the advantage gained justifies the extra complication, and the authors consider that the impedance-time relay meets most conditions.

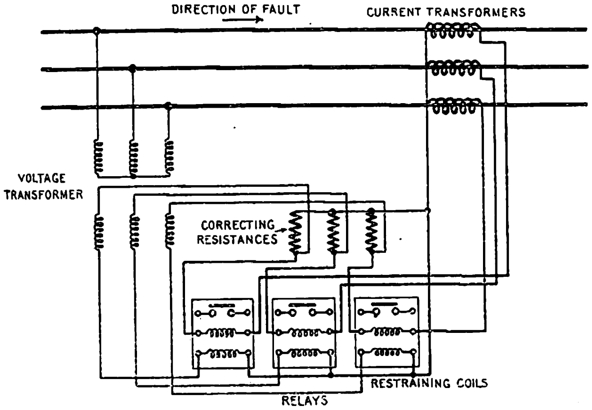

Fig. 13.—Impedance relays. Correcting device for arc resistance.

Since the voltage plays a large part in the discriminating feature of impedance relays, it is essential that the voltage across the restraining coil should accurately reproduce the voltage on the line at the point where the relay is connected. To this end it is necessary to have two distinct sets of relays for the protection of earthed systems, one set connected for phase-fault protection and the other for earth-fault protection. The reason for the different connections is that a phase fault affects the voltage of two or three phases, while an earth fault involves one phase only. Thus, while the current coils of both sets of relays are connected in series on the respective phases, the restraining coils of the phase-fault relays must be connected across phases and those of the earth-fault relays between each phase and earth. In this connection it should be noted that earth-fault protection cannot be obtained by means of impedance relays unless the system neutral is connected directly to earth or through a comparatively low resistance, otherwise insufficient voltage gradient occurs along the line and the difference in potential between the relays at the various switching points is too small for discriminative operation. It is preferable to use single-phase potential transformers for impedance relays and particularly for earth-fault relays, but if 3-phase transformers are contemplated they should be of the " shell " type as opposed to the " core " type. The reason for this is that with the " core " type of construction the flux in the limbs connected to the two healthy phases tends to maintain an appreciable secondary voltage in the limb connected to the faulty phase.

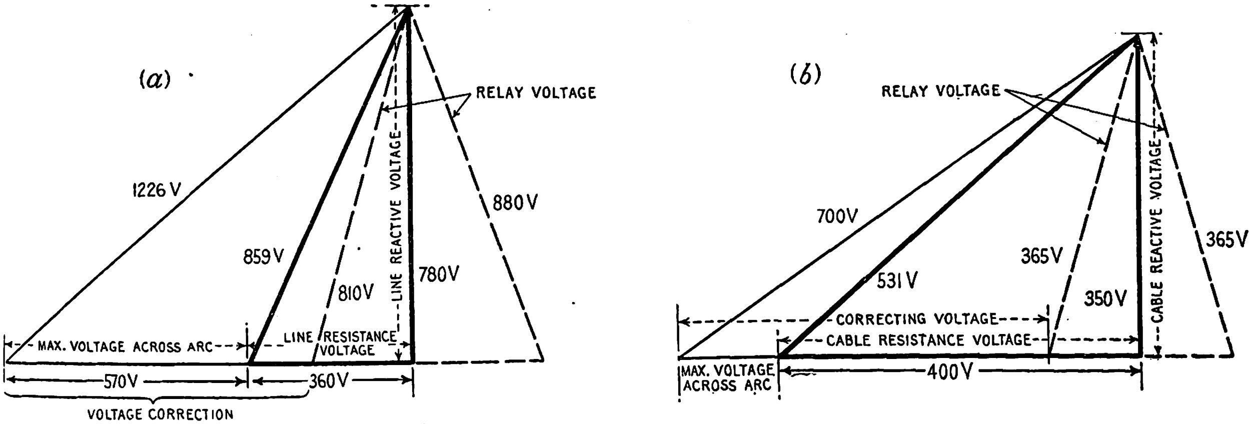

Fig. 14.—Vector diagrams of correcting device for arc resistance.

(*a*) Overhead line. (*b*) Cable.

Effect of Resistance of Arc.—Mention has already been made of the variable resistance of the arc which may accompany a fault and the fact that this variable factor must be taken into consideration when, as in the case of the impedance relay, discrimination depends upon the apparent impedance of the line between the relay and the fault. It might be as well to point out here that there is very little or no inductance in an arc, and that it is only the resistance which is in question. Fortunately for the success of the impedance relay the resistance-drop across an e.h.t. arc is comparatively small, and the variable factor resulting therefrom can be compensated for in such a manner that its effect upon the operation of the relay will be negligible. In estimating the effect of the arc resistance on the apparent impedance of the line or cable it is, of course, necessary to take into consideration both the resistive and reactive components of the line drop. One method of effecting compensation for arc resistance would be to design the relay so that it only measures the reactive voltage instead of the impedance voltage. This, however, is difficult, if not practically impossible, to accomplish, and in some relays a compromise has been made in that the relay is more sensitive to reactive voltage than resistive voltage. Such relays are, however, comparatively complicated or fail in the essential point of reasonably quick discriminative operation. A simple and effective method has, however, recently been developed which can be applied to any impedance relay and which reduces the variable effect of the arc to negligible proportions. The compensation consists of an adjustable resistance connected in series with the current coil of the relay (see Fig. 13). From the diagram it will be seen that the potential-drop across this resistance is applied to the restraining coil in such a direction that it opposes the resistance component of the impedance voltage. By adjusting the value of the resistance it is possible to compensate entirely for the resistance component of the impedance of the line or feeder and, in addition, reduce the error due to the maximum variation of the arc.

Tests which have been carried out indicate that the voltage-drop across even long arcs does not exceed 3 per cent of the normal voltage and that this figure is considerably reduced when the arc current exceeds 250 amperes. It is thus possible to estimate with reasonable accuracy the maximum effect of arc resistance when either overhead lines or cables are in question. It can also be assumed that in the case of the former the length of the arc will usually be greater than that due to a cable fault where the conductors are closer together and also closer to earth. Thus if the maximum arc voltage for an overhead line is taken to be 3 per cent, that for a cable can be assumed to be not more than 1 per cent of normal voltage.

The vector diagrams, Fig. 14, show the effect which the compensator has on the apparent impedance of a line and a cable as measured by an impedance relay. From these diagrams it will be seen that the 15 per cent overlap in the setting of the definite impedance relays will make allowance for the maximum variation in the arc resistance. In the case of the impedance-time relay the maximum difference in the time when the compensator is in use is only 0·2 sec.

Low-Voltage Release Relays.

It sometimes happens that the maximum short-circuit current when the connected generating capacity is small is actually less than the normal full-load current when the maximum generating capacity is in use. If, therefore, overcurrent or impedance relays are set to operate at the estimated minimum short-circuit current they would probably operate or tend to operate at normal maximum loads, unless the settings were increased during the period at which such loads exist. The following method has been successfully employed to overcome this difficulty and allows of the overcurrent or impedance relays being set low enough to operate on the lowest possible short-circuit current. The arrangement includes a low-voltage relay which will allow the overcurrent or impedance relay to operate only in the event of the voltage of the system falling owing to a short-circuit. The contacts of this low-voltage relay are connected in the secondary winding of the overcurrent or impedance relay (see Fig. 15), and until the contacts of the former are closed there can be no operation of the latter. The relays will therefore only operate when current is flowing and the voltage has dropped to a predetermined value. As such conditions will only exist during a short-circuit, selective operation can be obtained without re-adjustment of the relays.

This method is also very useful as a means of providing busbar protection when several incoming feeders are connected to the same busbar, since a short-circuit on the latter under low-load conditions may not draw sufficient current from the individual feeders to operate the separate overcurrent relays if they are set high enough to prevent operation at normal full load. It will be appreciated that it is not permissible to connect the contacts of the low-voltage release relay in series with the trip contacts of overcurrent or impedance relays, since, although this would prevent the tripping of the circuit breaker, it would not prevent the overcurrent or impedance relays operating and consequently the selective features would be lost.

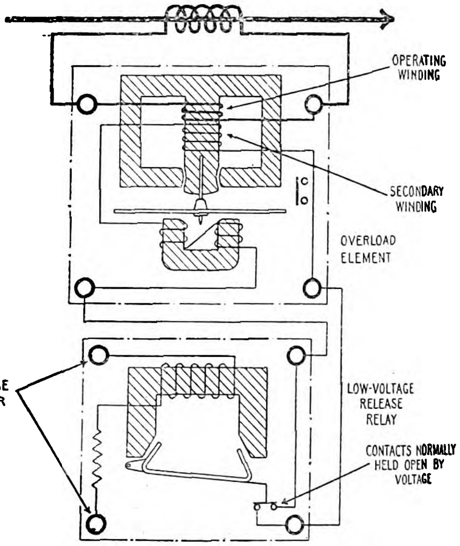

Fig. 15.—Low-voltage release relay with overload relay.

Pilot-Wire Protective Gear.

The types of protective gear already described are not always suitable for the protection of networks feeding dense load areas such as exist in industrial centres, and it is probably for this reason that the balanced type of protective gear has been so largely used in Great Britain. The original balanced protective gear was that due to Messrs. Merz and Price, and until recent years this system has proved satisfactory for feeder protection.

Balanced-Voltage Protective Gear.—This system consists of balancing the secondary voltages of current transformers connected at either end of the feeder, by means of pilot wires and through instantaneous relays. It is usually known as the balanced-voltage system because, as distinct from other balanced schemes, no current flows from the secondary windings of the protective transformers until a fault occurs in the feeder.

As power systems have increased in size and distribution voltages become higher, certain difficulties have arisen which have necessitated modifications to the original scheme. These modifications were designed with the intention of preventing incorrect operation due to variable characteristics of protective transformers or to the other difficulties already referred to in the paper.

It was early realized that ordinary current transformers were unsuitable for the balanced-voltage scheme since, due to the absence of secondary or back ampere-turns, the iron circuit of the transformers would quickly reach magnetic saturation and thus render it very difficult to obtain satisfactory balance, even between transformers of similar design. Balanced-voltage transformers were then designed with an air-gap in the iron circuit which prevented magnetic saturation up to fault currents of the order of 3 000 amperes. It was then found that, due to the fringing flux from this gap, the presence of adjacent magnetic material upset the balance between pairs of transformers and it became necessary to provide several smaller air-gaps equally spaced round the iron circuit. This lack of balance due to disturbance of the fringing flux became more serious with increase in length of the air-gaps necessitated by the larger fault currents. The advent of metal-clad switchgear further aggravated the difficulty owing to the smaller clearances between the transformers and extraneous ironwork.

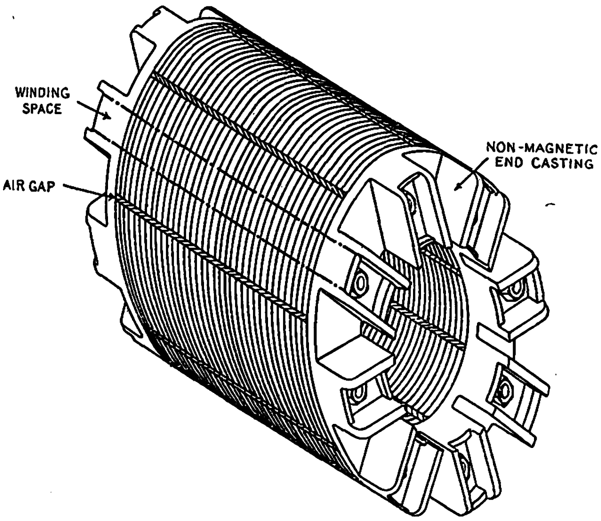

FIG. 16.—Isometric view of balanced-voltage transformer.

A recent research has shown that if the transformers are fully to meet modern requirements the minimum number of air-gaps which can be employed is 8. A protective transformer of recent design is illustrated in Fig. 16. From its mechanical design the transformer possesses great rigidity and the secondary windings are well protected under all conditions, whilst its characteristics are practically unaffected by neighbouring magnetic material or currents of fault magnitude in adjacent conductors. The secondary-voltage characteristic for this transformer is shown in Fig. 17. It should be appreciated that the voltage characteristic of such a transformer cannot be actually a straight line, owing to the shape of the magnetization curve of iron, but it will be seen from this curve that in this transformer the approximation to a straight line is exceedingly close.

In testing the balance of balanced-voltage transformers it is not sufficient to compare the secondary voltages, because considerable out-of-balance currents may be set up by phase differences between the voltages. The only satisfactory method is to connect the primary of a standard transformer in series with that of the transformers being tested and, with the secondary windings connected in opposition, to measure the out-of-balance current by means of a low-impedance milliammeter when a large primary current is flowing. This is more stringent than the most severe working conditions since the circuit normally will contain both pilot-wire resistance and the impedance of the relays. Fig. 18 is a curve plotted between values of primary current and secondary out-of-balance current obtained with two transformers of this type, the relays and pilot wires being replaced by a milliammeter having an impedance of only 3 ohms. The primary currents used in this test exceed 60 times full-load current and, since the presence of the relays and pilot wires will reduce the out-of-balance to less than half, and the relays will not generally be set for less than 60 mA, it will be seen that the factor of safety against operation due to transformer unbalance is ample.

Difficulties with Balanced-voltage Protective Gear.—Mention has already been made of causes other than lack of balance between protective transformers which may give rise to incorrect operation, and these will now be briefly considered.

Instability of balanced-voltage gear due to capacity currents flowing through the capacity of the pilot cables has been successfully avoided by the use of the screened pilot suggested by Mr. Beard. This arrangement prevents wrong tripping due to currents in the pilot capacities at both normal and super-normal frequencies, provided that the voltages in the pilot system are symmetrical with respect to earth. If, however, for any reason the voltage of the pilot sheaths differs substantially from earth potential, very puzzling wrong operation may take place.
